This shows that any reciprocal process $S(\cdot)$ on T with $R > 0$ gives rise to an NNM of the form (6). Now we have to show that a well-posed NNM of the form (6), (7) is necessarily reciprocal. Let us therefore define the difference operator associated to (6) by

$$\Lambda = M_0(t)I - M_-(t)Z^{-1} - M_1(t)Z^1 - M_2(t)Z^2 \quad (8)$$

where Z^{-1} denotes the backward shift on the binary tree $Z^{-1}f(t) = f(\hat{t})$, and Z^i , $i = 1, 2$ denotes the forward shift $Z^i f(t) = f(t_{\gamma_i})$.

The operator Λ maps n -vector functions defined on T into n -vector functions defined on the interior of T . Consider now the L^2 -space of n -vector functions defined over the interior of T , with the inner product $\langle f, g \rangle = \sum_{s \in \text{int}(T)} f(s)' g(s)$. In Appendix A, we show that the following Green's identity holds:

$$\begin{aligned} \langle f, \Lambda S(\cdot) \rangle - \langle \Lambda f, S(\cdot) \rangle \\ = \sum_{i \in I_i} [f(t)' f(t_{\gamma_1})' f(t_{\gamma_2})'] E_i^j \begin{bmatrix} S(t) \\ S(t_{\gamma_1}) \\ S(t_{\gamma_2}) \end{bmatrix} \\ + \sum_{i \in I_j} [f(t)' f(\hat{t})'] E_i^j \begin{bmatrix} S(t) \\ S(t) \end{bmatrix} \end{aligned} \quad (9)$$

where the matrices E_i^j and E_i^j are defined as follows:

$$E_i^j = \begin{bmatrix} 0 & M_1(t) & M_2(t) \\ -M_-(t_{\gamma_1}) & 0 & 0 \\ -M_-(t_{\gamma_2}) & 0 & 0 \end{bmatrix} \quad (10)$$

and

$$E_i^j = \begin{bmatrix} 0 & M_-(t) \\ -M_-(t)' & 0 \end{bmatrix}. \quad (11)$$

The Green's function Γ is defined by

$$\begin{cases} \Lambda \Gamma(t, s) = I \delta(t, s) & t, s \in \text{int}(T) \\ \Gamma(t, s) = 0 & t \text{ or } s \in \{T_i, T_j\}. \end{cases} \quad (12)$$

We show also in Appendix A that $\Gamma(t, s) = \Gamma(s, t)'$ for $t, s \in T$.

Following exactly the work of Levy *et al.* [8], we derive for the N -ary tree that

$$\begin{aligned} S(k) = \sum_{s \in \text{int}(T)} \Gamma(k, s) e(s) + \sum_{i \in I_i} (\Gamma(k, t_{\gamma_1}) M_-(t_{\gamma_1}) \\ + \Gamma(k, t_{\gamma_2}) M_-(t_{\gamma_2})) S(t) + \sum_{i \in I_j} \Gamma(k, \hat{t}) M_-(t)' S(t). \end{aligned} \quad (13)$$

Equation (13) can be used to show that the solution $S(k)$ is orthogonal to $e(s)$ for $k \neq s$

$$\begin{aligned} E[S(k)e(s)'] &= \sum_{i \in \text{int}(T)} \Gamma(k, i) E[e(i)e(s)'] = (\Lambda \Gamma(s, k))' \\ &= I \delta(s, k). \end{aligned} \quad (14)$$

Now we can state and prove the following.

Theorem 2.1: Let $S(\cdot)$ be a zero-mean Gaussian process on a binary tree, having covariance matrix $R > 0$. Then, $S(\cdot)$ is reciprocal if and only if it admits a well-posed NNM of the form (6), (7).

Proof of Theorem 2.1: We have shown in this section that if $S(\cdot)$ is reciprocal, we can write the process in the form (6), (7). Now we must show that the solution $S(k)$ of (6), (7), given by (13), is reciprocal. To do this, let T' be a subtree of T (having the same structure as T), and let l and k be two nodes of T , such that $k \in \text{int}(T')$ and $l \notin T'$.

To prove that $S(\cdot)$ is reciprocal, we have to show that $\hat{S}(k) = S(k) - E[S(k)|S(t), t \in \{T'_i, T'_j\}] \perp S(l)$. The orthogonality principle derived above says that for $s \in \text{int}(T')$ and for $t \in \{T'_i, T'_j\}$, $e(s) \perp S(t)$. Therefore, using the solution of (6) on the subtree T' [similar to (13)], we obtain

$$\begin{aligned} E[S(k)|S(t), t \in \{T'_i, T'_j\}] &= \sum_{i \in I'_i} (\Gamma(k, t_{\gamma_1}; T') M_-(t_{\gamma_1}) \\ &+ \Gamma(k, t_{\gamma_2}; T') M_-(t_{\gamma_2})) S(t) + \sum_{i \in I'_j} \Gamma(i, k; T')' M_-(t)' S(t) \end{aligned} \quad (15)$$

where $\Gamma(k, s; T')$ is the Green's function for the model on the subtree T' . So $\hat{S}(k) = \sum_{s \in \text{int}(T')} \Gamma(k, s; T') e(s)$, which shows that $\hat{S}(k) \perp S(l)$, and therefore that the process is reciprocal. This completes the proof.

III. RECURSIVE DESCRIPTION OF A RECIPROCAL PROCESS

The NNM described in (6), (7), or (13) is nonrecursive. We derive in this section a recursive description.

We construct a moving average representation of the driving noise $e(t)$. For this, we introduce $w(t)$, a white Gaussian noise (WGN) process with intensity $W(t)$, which is uncorrelated with the boundary process b of the reciprocal process. Let us define $e(t)$ by introducing the matrix $A(t)$ in the following way:

$$e(t) = W(t)^{-1} w(t) - A(t_{\gamma_1})' W(t_{\gamma_1})^{-1} u(t_{\gamma_1}) - A(t_{\gamma_2})' W(t_{\gamma_2})^{-1} u(t_{\gamma_2}) \quad (16)$$

for $t \in \text{int}(T)$. Then, the relations (7) for the covariance of $e(t)$ imply that the matrices $A(t)$ and $W(t)$ must satisfy, for $t \in \text{int}(T)$,

$$\begin{aligned} M_0(t) &= W(t)^{-1} + A(t_{\gamma_1})' W(t_{\gamma_1})^{-1} A(t_{\gamma_1}) \\ &+ A(t_{\gamma_2})' W(t_{\gamma_2})^{-1} A(t_{\gamma_2}) \end{aligned} \quad (17)$$

and for $i = 1, 2$, $t, t_{\gamma_i} \in \text{int}(T)$

$$M_i(t) = -E[e(t)e(t_{\gamma_i})'] = A(t_{\gamma_i})' W(t_{\gamma_i})^{-1}. \quad (18)$$

We can now substitute, for $t, t_{\gamma_i} \in \text{int}(T)$, $A(t_{\gamma_i}) = W(t_{\gamma_i}) M_i(t)'$. We define, by choice of an arbitrary symmetric positive definite matrix $W(t_{\gamma_i})$, $A(t_{\gamma_i}) = W(t_{\gamma_i}) M_i(t)'$ for $t_{\gamma_i} \in T_j$. We see that $W(t)$ must satisfy, for $t \in \text{int}(T)$, the backward difference equation

$$W(t)^{-1} = M_0(t) - M_1(t) W(t_{\gamma_1}) M_1(t)' - M_2(t) W(t_{\gamma_2}) M_2(t)'. \quad (19)$$

Since we want the solution $W(t)$ to be a covariance matrix for each $t \in \text{int}(T)$, it must be a nonnegative matrix. We show in Appendix B, that this indeed holds.

The noise representation in (16) satisfies (7) if we use (19). The NNM (6), (7) also implies that, for $t \in \text{int}(T)$,

$$M_-(t) = (A(t)' W(t)^{-1})' = W(t)^{-1} A(t). \quad (20)$$

Consider now the operators

$$\begin{cases} \Omega = I - A(t)Z^{-1} \\ W = W(t)I \\ \Omega^* = I - A(t\gamma_1)^T Z^{-1} - A(t\gamma_2)^T Z^T \end{cases} \quad (21)$$

then we derive, for $t \in \text{int}(T)$

$$\begin{cases} \Omega^* W^{-1} u(t) = \Omega^* W(t)^{-1} u(t) = \epsilon(t) \\ \Omega^* W^{-1} \Omega S(t) = M_0(t)S(t) - M_1(t)S(t\gamma_1) \\ \quad - M_2(t)S(t\gamma_2) - W(t)S(t) \end{cases} \quad (22)$$

and thus the relation $\Lambda S(t) = \epsilon(t)$ gives us $\Omega^* W^{-1}(\Omega S(t) - \epsilon(t)) = 0$. Define now for $t \in T \setminus I$

$$\begin{aligned} Z(t) &= W^{-1}(\Omega S(t) - u(t)) \\ &= W(t)^{-1}(S(t) - A(t)S(t) - u(t)) \end{aligned} \quad (23)$$

Then we know that $\Omega^* Z(t) = 0$ $t \in \text{int}(T)$. This together with (23) results in the following

Proposition 3.1 The set of equations

$$\begin{cases} Z(t) = A(t\gamma_1)^T Z(t\gamma_1) + A(t\gamma_2)^T Z(t\gamma_2) & \text{for } t \in \text{int}(T) \\ S(t) = A(t)S(t) + u(t) + W(t)Z(t) & \text{for } t \in T \setminus I \end{cases} \quad (24)$$

together with the Dirichlet boundary conditions introduced before describe the NNM (6), (7).

Let us assume we have the solution of (24) with the boundary conditions $Z_0(t) = 0$ $t \in I_f$ and $S_0(t) = b(t)$ $t \in I$. We get $Z_t(t) = 0$ for all t of interest and thus $S_0(t)$ is an autoregressive process (on a tree) which can be computed recursively by performing the last part of (24). This process satisfies (6) and the correct initial condition but its end values are generally different from b_f the final node values. If $\Gamma(t, s)$ is the Green's function the solution of (6) (7) for $t \in \text{int}(T)$ is therefore given by

$$S(t) = S_0(t) + \sum_{s \in I_f} \Gamma(t, s) M(s)^T (S(s) - S_0(s)) \quad (25)$$

The correction formula requires the precomputation of $\Gamma(t, s)$ $t \in T$ $s \in I_f$.

Let us now discuss the assumption of the autoregressive property in the final nodes as in (5). This assumption is equivalent to the assumption of an extended tree \bar{T} with zero valued final nodes. Computing for the extended tree \bar{T} the variable $Z(t)$ $t \in \bar{T}_f$ (or $t \in T \setminus I_f$) using (16) (20) and (23) gives us

$$\begin{aligned} Z(t) &= W(t)^{-1}(S(t) - A(t)S(t) - u(t)) \\ &= M_0(t)S(t) - M_1(t)S(t\gamma_1) - \epsilon(t) = 0 \end{aligned} \quad (26)$$

resulting in using (24) $Z(t) = Z_0(t) = 0$ $t \in \bar{T} \setminus \bar{T}_f$. Finally this results in $S(s) = S_0(s)$ for $t \in \bar{T}$. That is if we assume we have the autoregressive property in the final nodes of the original tree, we can rewrite the reciprocal process as an autoregressive process on the tree for all $t \in \bar{T}$. Of course the reverse is true as well leading to the following

Proposition 3.2 A reciprocal process on the tree is an autoregressive process on the entire tree if and only if the reciprocal process has the autoregressive property in the final nodes

IV A SMOOTHING PROBLEM

We shall now apply the previous definitions and insights to the estimation problem. Consider a reciprocal process $S(\cdot)$ defined on T , having zero-valued final nodes, described by the model (6) (7). We are given the observations $Y(t) = H(t)S(t) + \epsilon(t)$ where $\epsilon(\cdot)$ is a WGN process, uncorrelated with $S(\cdot)$ having intensity $\Lambda(\cdot)$. We want to compute the smoothed estimate in all nodes of the tree $\hat{S}(t) = E[S(t)|Y]$, where Y is the vector of all observations. We derive, for $t \in \text{int}(T)$, following the derivation of Levy [6] using iterated conditioning

$$\begin{aligned} M_0(t)S(t) &= M_-(t)S(t) + M_1(t)S(t\gamma_1) \\ &\quad + M_2(t)S(t\gamma_2) + H(t)^T \Lambda(t)^{-1} (Y(t) - H(t)S(t)) \end{aligned} \quad (27)$$

We have a difference equation for the smoothed estimates which we shall solve recursively. Equation (27) implies that we have the following model for the smoothed estimates in the interior of T

$$\Lambda_I S(t) = H(t)^T \Lambda(t)^{-1} Y(t) \quad (28)$$

with

$$\begin{cases} \Lambda_I = M_{0I}(t)I - M_1(t)Z^{-1} - M_2(t)Z^{-1} - M_1(t)Z^{-1} \\ M_{0I}(t) = M_0(t) + H(t)^T \Lambda(t)^{-1} H(t) \end{cases} \quad (29)$$

Then, following the procedure of the previous section the operator Λ_I can be represented as $\Lambda_I = \Omega_I^T W_I^{-1} \Omega_I$ with

$$\begin{cases} \Omega_I = I - A_I(t)Z^{-1} \\ W_I = W_I(t)I \\ \Omega_I^* = I - A_I(t\gamma_1)^T Z^{-1} - A_I(t\gamma_2)^T Z^T \end{cases} \quad (30)$$

where $A_I(t) = W_I(t\gamma_1)M(t)^T$ for $t \in \text{int}(T)$ ($W_I(t)$ is an arbitrary symmetric positive definite matrix for $t \in I_f$) and

$$\begin{aligned} W_I(t)^{-1} &= M_{0I}(t) - M_1(t)W_I(t\gamma_1)^{-1}M_1(t)^T \\ &\quad - M_2(t)W_I(t\gamma_2)^{-1}M_2(t)^T \end{aligned} \quad (31)$$

for $t \in \text{int}(I)$. Define now for $t \in T \setminus I$

$$Z_I(t) = W_I(t)^{-1} \Omega_I S(t) = W_I(t)^{-1} (S(t) - A_I(t)S(t)) \quad (32)$$

Then (28) leads to $\Omega_I^T Z_I(t) = \Lambda(t)^{-1} Y(t)$ for $t \in \text{int}(T)$.

Proposition 4.1 The smoother equations (28) can be rewritten as (33), found at the bottom of the page. These two equations propagate causally in the backward and forward directions (on the tree) respectively, describing the structure of the smoother.

Now let $Z_{0I}(t)$ and $S_0(t)$ be the solution of (33) with boundary conditions $Z_{0I}(s) = 0$ $s \in T_f$ and $S_0(s) = Y(s)$ $s \in T$. The smoothed estimate we obtain does not take into account the boundary conditions in \bar{T} and T_f . Following the solution (13) we can conclude that the correction formula for the boundary conditions then becomes

$$\begin{aligned} S(t) &= S_0(t) + \sum_{s \in I_f} (\Gamma_I(t, s\gamma_1)M(s\gamma_1) \\ &\quad + \Gamma_I(t, s\gamma_2)M(s\gamma_2))(S(s) - Y(s)) \\ &\quad + \sum_{s \in I_f} \Gamma_I(t, s)M(s)^T (S(s) - S_0(s)) \end{aligned} \quad (34)$$

where Γ_I is the Green's function for (28)

$$\begin{cases} Z_I(t) = A_I(t\gamma_1)^T Z_I(t\gamma_1) + A_I(t\gamma_2)^T Z_I(t\gamma_2) + \Lambda(t)^{-1} Y(t) \\ \quad \text{for } t \in \text{int}(T) \\ S(t) = A_I(t)S(t) + W_I(t)Z_I(t) \\ \quad \text{for } t \in T \setminus T_f \end{cases} \quad (33)$$

If we are able to observe $S(s)$ exactly at the boundary nodes, we have

$$\hat{S}(t) = \hat{S}_0(t) + \sum_{s \in T_f} \Gamma_E(t, \hat{s}) M_{-}(s)^T (\hat{S}(s) - \hat{S}_0(s)). \quad (35)$$

In the case of an autoregressive process, or an extended tree \bar{T} with zero-valued final nodes, we have $A_{T_f}(t\gamma_i) = W_{E_f}(t\gamma_i) M_i(t)^T = 0$ for $t\gamma_i \in \bar{T}_f$ (since $M_i(t) = 0$). Therefore, since we have chosen $Z_{0E}(s) = 0$ for $s \in \bar{T}_f$, we get $\hat{S}(s) = \hat{S}_0(s) = 0$ for $s \in \bar{T}_f$. Then, if we are able to observe $S(s)$ exactly at the boundary nodes in T_f , we have $\hat{S}(t) = S_0(t)$, $t \in T$ and we do not need a correction equation as in (34) or (35). The smoothing reduces in this case to a simple double-sweep algorithm.

The Rauch-Tung-Striebel (RTS) algorithm for autoregressive processes on trees, developed by Chou *et al.* [2], is quite similar to the double-sweep algorithm here. The difference with Chou's algorithm is that the true value of $\hat{S}(s)$ for $s \in T_f$ is obtained in their upward sweep (T_f should, however, consist of just one node), and there is no need for a correction equation. We need to observe exactly $S(s)$ for $s \in T_f$, or apply the correction equation (34).

Let us study the smoothing error $\hat{S}(t) = S(t) - \hat{S}(t)$. We derive, using (6) and (28), that $\Lambda_E \hat{S}(t) = \Lambda_E S(t) - \Lambda_F \hat{S}(t) = \hat{e}(t)$, with $\hat{e}(t)$ having a covariance structure similar to $e(t)$, due to the orthogonality of e and v . Consider now the boundary process $\hat{S}(t) = S(t) - \hat{S}(t) = Y(t) - v(t) - \hat{S}(t)$ for $t \in T_f$. Linear estimation theory tells us that $\hat{S}(t)$ is orthogonal to all $Y(s)$, $s \in T$. Therefore, the driving noise $\hat{e}(s) = \Lambda_E \hat{S}(s)$ for $s \in \text{int}(T)$ is orthogonal to all $Y(s)$, $s \in T$. The smoothing error $\hat{S}(t)$, $t \in T_f$, can be written as a linear combination of $Y(s)$, $s \in T$ and $v(t)$, and is therefore orthogonal to $\hat{e}(s)$, $s \in \text{int}(T)$. Thus, we have proved the following.

Proposition 4.2: The smoothing error $\hat{S}(t) = S(t) - \hat{S}(t)$ of a reciprocal process on a tree is itself reciprocal.

Assume now that we have an autoregressive process, described as a reciprocal process on an extended tree, with zero-valued final nodes. Therefore, the error of the smoothing problem on the extended tree (without necessarily observing $S(t)$ in the final and root nodes of the original tree) is again a reciprocal process on an extended tree with zero-valued final nodes. We can conclude the following.

Corollary 4.1: The smoothing error of a first-order autoregressive process on a tree is itself a first-order autoregressive process.

Remark: Luetgen [9] proved this result directly for autoregressive processes on a tree, obtaining explicitly the model parameters. We derived the result as a byproduct of our study of reciprocal processes.

V. CONCLUSION

Motivated by multiresolution decompositions of signals, we have introduced reciprocal processes on truncated N -ary trees; and following the results of Levy, Frezza, and Krener [8], we have described nearest neighbor models and recursive structures for these processes. We found that reciprocal processes with zero-valued final nodes reduce to autoregressive processes on a tree, which motivates, for

another time, the study of these processes in, for example, [1] and [2]. We described the smoother equations for such processes.

Reciprocal processes could model in an efficient way many interesting stochastic phenomena on multiple scales. Their recursive structure makes them suitable for fast signal processing algorithms of processes. The more general study of Markov random field processes on trees (having arbitrary neighborhood structures, including possible neighbors on the same scale in the tree) is now being pursued.

APPENDIX A

In this appendix, we prove the Green's identity used in Section II, and show that the Green's function $\Gamma(t, s)$ is symmetric, i.e., $\Gamma(t, s) = \Gamma(s, t)^T$, for $t, s \in T$.

We prove the Green's identity by means of an example which can be generalized for any reciprocal process on a truncated N -ary tree. Let us consider the very simple binary tree as in Fig. 1, using the indicated numbering of the nodes. We define the matrix $\hat{\Lambda}$ as shown in (A.1), found at the bottom of the page.

Using $M_{-}(t\gamma_i)^T = M_i(t)$, we see that $\hat{\Lambda}$ is a symmetric matrix. We also see that the rows of this matrix relating to the interior nodes of T describe the operator Λ in matrix form. Using the symmetry of $\hat{\Lambda}$, we have for any appropriate dimensional vector f (in this case, 7-dimensional) that the equality $f^T \hat{\Lambda} S = (\hat{\Lambda} f)^T S$ holds. Now we derive, using the definition of the inner product in Section II,

$$f^T \hat{\Lambda} S = \langle f, \Lambda S(\cdot) \rangle + \sum_{t \in T_f} f(t)^T (M_0(t) S(t) - M_1(t) S(t\gamma_1) - M_2(t) S(t\gamma_2)) + \sum_{t \in T_f} f(t)^T (M_0(t) S(t) - M_1(t) S(t\gamma_1)) \quad (A.2)$$

and

$$(\hat{\Lambda} f)^T S = \langle \Lambda f, S(\cdot) \rangle + \sum_{t \in T_f} f(t)^T M_0(t) S(t) - (f(t\gamma_1))^T M_{-}(t\gamma_1) + f(t\gamma_2)^T M_{-}(t\gamma_2) S(t) + \sum_{t \in T_f} f(t)^T M_0(t) S(t) - f(t)^T M_1(t)^T S(t). \quad (A.3)$$

Therefore, since we have $f^T \Lambda S = (\Lambda f)^T S$, we obtain, by using (A.2) and (A.3),

$$\begin{aligned} \langle f, \Lambda S(\cdot) \rangle - \langle \Lambda f, S(\cdot) \rangle &= \sum_{t \in T_f} f(t)^T (M_1(t) S(t\gamma_1) + M_2(t) S(t\gamma_2)) \\ &\quad - \sum_{t \in T_f} (f(t\gamma_1))^T M_{-}(t\gamma_1) + f(t\gamma_2)^T M_{-}(t\gamma_2) S(t) \\ &\quad + \sum_{t \in T_f} f(t)^T M_{-}(t) S(t) - f(t)^T M_1(t)^T S(t) \end{aligned} \quad (A.4)$$

as in (9).

Now we show that the Green's function $\Gamma(t, s)$ is symmetric, i.e., $\Gamma(t, s) = \Gamma(s, t)^T$, for $t, s \in T$. It is easy to see that for t or

$$\hat{\Lambda} = \begin{bmatrix} M_0(0) & -M_1(0) & -M_2(0) & 0 & 0 & 0 & 0 \\ -M_{-}(1) & M_0(1) & 0 & -M_1(1) & -M_2(1) & 0 & 0 \\ -M_{-}(2) & M_0(2) & 0 & 0 & 0 & -M_1(2) & -M_2(2) \\ 0 & -M_{-}(3) & 0 & M_0(3) & 0 & 0 & 0 \\ 0 & -M_{-}(4) & 0 & 0 & M_0(4) & 0 & 0 \\ 0 & 0 & -M_{-}(5) & 0 & 0 & M_0(5) & 0 \\ 0 & 0 & -M_{-}(6) & 0 & 0 & 0 & M_0(6) \end{bmatrix}. \quad (A.1)$$

$\in T_i, T_f$, we have $\Gamma(t, s) = 0 = \Gamma(s, t)^T$. Define now the two square matrices Λ and Γ having rows and columns associated with all nodes of $\text{int}(T)$. Each element of the matrix Λ is taken from the same corresponding row and column of Λ , and therefore Λ is a submatrix of Λ , representing only the nodes of $\text{int}(T)$. Γ is on the row associated with node t and the column associated with node s , as element $\Gamma(t, s)$. It can be easily verified, using $\Lambda \Gamma(t, s) = I \delta(t, s)$, $t, s \in \text{int}(T)$ that $\Lambda \Gamma = I$ and $\Lambda^T = \Lambda$ so that $I = (\Lambda \Gamma)^T = \Gamma^T \Lambda^T = \Gamma^T \Lambda$, and therefore $I = \Gamma^T$ and thus $\Gamma(t, s) = \Gamma(s, t)^T$ for $t, s \in \text{int}(T)$ which was left to show.

APPENDIX B

In this appendix, we show that the noise covariance matrices $\mathbb{W}(t)$, $t \in \text{int}(T)$ introduced in Section III are positive definite. Let us assume that not every noise covariance matrix $\mathbb{W}(t)$, $t \in \text{int}(I)$ is positive definite. We scan each scale of the tree above T_f from bottom to top until we find a node s such that $\mathbb{W}(s)$ is not positive definite. Then we stop and we denote the set of nodes scanned so far (including s but excluding T_f) by I_s . The fact that $\mathbb{W}(t) > 0$ for $t \in T \setminus s$ and the construction of $\mathbb{W}(t)$ through the difference equation (19) guarantees that $\mathbb{W}(t)^{-1}$ exists for all $t \in T$. Denote with ϵ the vector containing all $\epsilon(t)$, $t \in T$. Define by Q_s^{-1} the matrix consisting of zeros except for the matrices $\mathbb{W}(t)^{-1}$ on the diagonal. We have

$$E = F[\epsilon, \epsilon^T] = Y_s^T Q_s^{-1} Y_s, \quad (B 1)$$

where Y_s is a lower triangular matrix defined by (16) having all 1's on its diagonal. The matrix F is the covariance matrix of part of the residual process of the reciprocal process, and since we assumed $R > 0$ we must have $E > 0$ as well; otherwise a linear combination of $S(t)$, $t \in \text{int}(T)$ would be identically zero, contradicting the fact that $R > 0$. Therefore $\forall u, u^T I_s u > 0$. Since we assumed that $\mathbb{W}(s)$ is not positive definite $\exists \epsilon_s$ such that $\epsilon_s^T \mathbb{W}(s)^{-1} \epsilon_s \leq 0$. However, since Y_s is a lower triangular matrix with 1's on its diagonal, we can always find u such that

$$Y_s^T u = [0 \quad 0 \quad \epsilon_s^T \quad 0 \quad 0]^T \quad (B 2)$$

resulting in

$$\begin{aligned} u^T I_s u &= [0 \quad 0 \quad \epsilon_s^T \quad 0 \quad 0] \\ &\quad Q_s^{-1} [0 \quad 0 \quad \epsilon_s^T \quad 0 \quad 0]^T \\ &= \epsilon_s^T \mathbb{W}(s)^{-1} \epsilon_s \leq 0 \end{aligned} \quad (B 3)$$

contradicting $E > 0$. Therefore we must have $\mathbb{W}(t) > 0$ for all $t \in \text{int}(I)$ which is what we wanted to show.

Comments on the Loop Transfer Recovery

Ahmed Rachid

Abstract—This paper deals with observer-based linear control systems. More precisely, it is shown that Tsui's loop transfer recovery procedure can lead to poor results.

I. INTRODUCTION

It is now well understood that the CORC (combined observer/regulator compensator) problem is not a trivial extension of the linear quadratic regulator (LQR) case which has been widely studied since early 1960's. In particular, it has been shown by Doyle [1] that linear quadratic Gaussian (LQG) regulators have no intrinsic robustness properties and can exhibit poor stability margins contrary to the LQR case which ensures the well known $[1/2, \infty]$ gain margin and phase margins of at least 60 degrees at the plant input [2].

An attempt to recover these stability margins for the CORC case is loop transfer recovery (LTR) method which forces the return difference $F_r(s)$ at the break point λ (Fig. 1) to be identical (in the limit) to the return ratio $T_{r,r}(s)$ at the break point λ corresponding to the full state feedback.

Doyle and Stein [3] have proposed an iterative procedure which asymptotically achieves the LTR by adding a fictitious noise at the input plant before designing the observer using Kalman filter formulas. This procedure drives some observer poles toward stable plant zeros and the rest toward infinity.

More recently, an alternative to Doyle and Stein's approach has been given by Tsui [4], [5], [6] and aims to guarantee some stability margins at the breakpoint λ . Unfortunately, the method proposed by Tsui can lead to quite poor results; in the sequel, his technique is discussed and its limitations are highlighted.

II. PROBLEM STATEMENT

Consider the linear continuous MIMO plant

$$\dot{x} = Ax + Bu$$

Manuscript received August 3, 1993.

The author is with Laboratoire des Systemes Automatiques, 7 rue du Moulin Neuf, 80 000 Amiens, France.
IEEE Log Number 9407216.

Fig. 1. CORC scheme.

$$y = Cx \quad (1)$$

under the state feedback

$$u = -K_c x. \quad (2)$$

The full observer equations for the considered system are given by

$$\dot{z} = Fz + Ly + TBu \quad (3)$$

under the constraints

$$TA - FT = LC \quad (4)$$

$$K_c = NT. \quad (5)$$

Equivalently, this observer can be described by

$$\dot{\hat{x}} = A\hat{x} + Bu + K_o(y - C\hat{x}).$$

z and \hat{x} are related by $z = T\hat{x}$ from which one can deduce the following relations

$$K_o = T^{-1}L \quad (6)$$

$$A_o = A - K_o C = T^{-1}FT. \quad (7)$$

Fig. 1 summarizes the CORC scheme: At the breakpoint XX , the transfer function can be expressed as

$$\begin{aligned} T_{xx}(s) &= K_c(sI - A_o)^{-1}(B + K_o G(s)) \\ &= K_c(sI - A)^{-1}B \end{aligned} \quad (8)$$

At the breakpoint X , the transfer function is

$$T_x(s) = K_c(sI - A_o + BK_c)^{-1}K_o G(s) \quad (9)$$

where

$$G(s) = C(sI - A)^{-1}B. \quad (10)$$

Doyle and Stein [3] have proved that if

$$K_o[I + C(sI - A)^{-1}K_o^{-1}] = B[C(sI - A)^{-1}B]^{-1} \quad (11)$$

then

$$T_x(s) = T_{xx}(s).$$

Tsui [4] has proposed the following necessary and sufficient condition allowing LTR when using either Kalman type observer or Lunberger type state or function observers

$$\begin{aligned} T_x(s) &= T_{xx}(s) \text{ if and only if } TB = 0 \text{ or} \\ &N(sI - F)^{-1}TB = 0. \end{aligned}$$

Based on this result, he has proposed a robust observer design procedure which consists in selecting the observer poles so that $\|TB\|$ is minimum. An explicit solution to this optimization problem has also been obtained when the canonical observable form is used for $\{A, B, C\}$.

III. DISCUSSION

First, we notice that Tsui's procedure does not apply to systems with no zeros, i.e., with a constant transfer function numerator; to illustrate this fact, let us consider the following example.

Fig. 2. $T_{xx}(s)$ for the procedure of Tsui.Fig. 3. Full state $T_x(s)$ for Example 2.

Example 1: The considered system is described by

$$G(s) = \frac{3}{(s+1)(s+3)}.$$

The associated observable canonical form (needed in the procedure) is

$$\{A, B, C\} = \left\{ \begin{bmatrix} 0 & -3 \\ 1 & -4 \end{bmatrix}, \begin{bmatrix} 3 \\ 0 \end{bmatrix}, [0 \quad 1] \right\}.$$

Let λ_1 and λ_2 be the observer poles to be selected so that TB is small. Then we have two possible cases:

a) $\lambda_1 \neq \lambda_2$:

$$T = \begin{bmatrix} 1 & \lambda_1 \\ 1 & \lambda_2 \end{bmatrix} \rightarrow TB = \begin{bmatrix} 3 \\ 3 \end{bmatrix}$$

b) $\lambda_1 = \lambda_2$:

$$T = \begin{bmatrix} 1 & \lambda_1 \\ 0 & \lambda_2 \end{bmatrix} \rightarrow TB = \begin{bmatrix} 3 \\ 0 \end{bmatrix}.$$

We see that both cases yield to a TB which is independent of the observer poles, so that there is no way to select them using Tsui's procedure. This simple example shows the first gap in the method proposed by Tsui for LTR.

A second major inconvenience in Tsui's technique is that even when it is possible to select the observer poles, LTR is not approximated in many cases. In this context, the following example shows that one can encounter quite unacceptable results.

Example 2: Consider the simple system

$$\{A, B, C\} = \left\{ \begin{bmatrix} 0 & -1 \\ 1 & 2 \end{bmatrix}, \begin{bmatrix} 0.1 \\ 1 \end{bmatrix}, [0 \quad 1] \right\}.$$

The feedback state controller has been chosen so that $\lambda(A - BK_c) = \{-7, -7\}$ which gives

$$K_c = [-57.78 \quad 17.78].$$

Applying Tsui's procedure, the observer poles λ_1, λ_2 can be chosen as

$$\lambda_1 = -0.1 \quad \text{and} \quad \lambda_2 = -0.11.$$

Fig. 2 shows the corresponding Nyquist of $T_x(s)$ which is to be compared to the Nyquist of the full state feedback transfer function $T_{xx}(s)$ (Fig. 3).

Remark In terms of pole placement Tsui's procedure consists in shifting some of the observer poles at the stable plant zeros and the rest at their neighborhood. This is in contradiction with the Doyle and Stein technique. As a consequence Tsui's technique cannot be applied to nonminimum phase systems contrary to the claims in [6].

Sensitivity Properties of Multirate Feedback Control Systems, Based on Eigenstructure Assignment

R. J. Patton, G. P. Liu, and Y. Patel

Abstract—Some sampled-data systems, e.g., fly-by-wire control schemes, have a necessarily multirate structure, various input and/or outputs sampled at different rates. When considering a multirate system which has parameter uncertainty, it is important to examine ways in which the full freedom of the multivariable design can be utilized to minimize the sensitivity to parameter variations, given the accompanying problems induced by intersample ripple disturbance. This note examines the design capabilities of a class of multirate systems with multiple input and fixed state sampling rates (MIFS), based on eigenstructure assignment. Although the use of eigenstructure assignment for continuous and single rate discrete systems is well understood, the eigenstructure assignment for the design of multirate feedback systems is an open topic of research. Accepting that the problems of intersample ripple are often magnified through multirate control, there are advantages in terms of increased freedom for minimizing sensitivity and optimizing robustness to parameter variations. A special feature of the MIFS class of multirate systems is the ability to introduce extra design freedom in the eigenproblem by a suitable choice of eigenstructure assignment and sample rates. The criteria for the selection of minimum sample rates to produce this extra freedom, and the implication that this has on the eigenstructure assignment problem, are outlined. The improved insensitivity properties are demonstrated using an example comparing the performance of multirate and corresponding single rate designs.

I. INTRODUCTION

For a controllable continuous-time system described by

$$\dot{x}(t) = Ax(t) + Bu(t) \quad (1)$$

Manuscript received March 8, 1991; revised August 23, 1993 and July 7, 1994. This work was supported by the U.K. Engineering and Physical Research Council under Grants GR/H43953.

The authors are with the Department of Electronics, University of York, York YO1 5DD, U.K.

IEEE Log Number 9406998.

where $x \in R^{n \times 1}$ and $u \in R^{m \times 1}$ are the state and control vectors respectively, $A \in R^{n \times n}$, $B \in R^{n \times m}$ and the assignability of a desired self-conjugate set of poles to the equivalent discrete system using multirate feedback control has been well established ([1]-[4] and references therein). For sampled data systems with fast multiple input rates and a slow fixed state rate there are two main problems associated with the application of state feedback control design methods [6]-[7]. The first is the excessive and highly oscillatory nature of state and control effort that is produced. This often makes the implementation of multirate control impractical. The second problem is the increased sensitivity of feedback design to intersample behavior and disturbance effects. The latter is a common drawback of periodic control structures, as highlighted in the work of Francis and Gargios [4]. The problem is particularly prevalent in MIFS control schemes due to fast input control signal updates within a slow fixed state rate. Clearly there is a greater risk of undesirable intersample effects propagating through the system during a slower state period and causing an adverse response before they can be monitored. The two problems are linked: the intersample effects (which cause the system to deviate from its desired behavior) demand a greater control effort to provide the necessary corrective action.

Eigenstructure assignment can be used to alleviate both these problems. The specification of the closed loop system eigenstructure (which comprises the eigenvalues and right eigenvectors) is an important design consideration for the multirate feedback problem. The eigenvectors determine the modal interaction present in the closed loop system transient responses. A multirate feedback design which incorporates a reduction in modal interaction will confine the effects of undesired intersample behavior and disturbances to specific subsystems or individual modes. This minimizes the occurrence of adverse responses due to crossfeed signal which in turn reduces the demanded control effort. Hence a suitable choice of the multirate system eigenvectors will provide an insensitive or well conditioned closed loop performance. Thus the specification of system eigenstructure is seen to address the sensitivity and disturbance issues raised in [4].

The primary motivation for the use of eigenstructure assignment methods to design a multirate system is the ability of the techniques to directly address the problems associated with MIFS feedback control. However a much stronger case for its use is the perfectly decoupled solutions that can be obtained with MIFS sampling. This special characteristic arises from the ability of the MIFS system to generate maximum design freedom for the eigenproblem by an appropriate combination of input sample rates.

II. MIFS MULTIRATE SYSTEM MODEL

The MIFS system of Fig. 1 is classed as an m_1 -input n -state periodic system. The integer m_1 defines the sum of control input updates during a main sample period within which all periodic transitions of the system are described.

To describe the MIFS multirate system where the samplers operate periodically but with different period a complete set of transition equations must be determined for an interval equal to the least common multiple of all sample periods (I in Fig. 1). This interval is referred to as the main interval of sampling. Since the sampling is periodic with I the transition equations will codify the invariant nature of the multirate system.

The MIFS system equations state parameters are represented only at the main interval sample instants, while the control matrix accounts

Fig. 1. MIFS sampled multirate system.

for all input changes within the period T . The system sample periods are defined by the following set of relationships:

$$T_b = \frac{T}{n_0}, \quad T_i = \frac{T}{n_i}, \quad m_\mu = \sum_{i=1}^m n_i \quad (2)$$

for $i = 1, 2, \dots, m$, where T_b is the base sample period, n_0 is the least common multiple of the positive integers n_i , and T_i is the i th input sample period.

These sampling interrelationships describe an MIFS sampled system. The time-invariant behavior of the multirate system states of Fig. 1 is described by

$$x((k+1)T) = e^{AT} x(kT) + \sum_{i=1}^m \sum_{j=0}^{n_i-1} \int_0^{T_i} e^{A(T-jT_i-\tau)} B_i d\tau u_i(kT+jT_i) \quad (3)$$

where u_i is the i th control input, B_i denotes the i th column of the original system control matrix B of (1). Therefore, the sampled data multirate model (3) can be rewritten as

$$x(k+1) = \Phi_M(k)x(k) + \Gamma_M(k)u_M(k) \quad (4)$$

where

$$u_M(k) = \begin{bmatrix} u_{M1}(k) \\ u_{M2}(k) \\ \vdots \\ u_{Mm}(k) \end{bmatrix}, \quad u_{Mi}(k) = \begin{bmatrix} u_i(kT) \\ u_i(kT+T_i) \\ \vdots \\ u_i(kT+(n_i-1)T_i) \end{bmatrix} \quad (5)$$

for $i = 1, 2, \dots, m$, $\Phi_M(k) \in \mathbb{R}^{n \times n}$ and $\Gamma_M(k) \in \mathbb{R}^{n \times m_\mu}$ can be obtained from (3), and $x(k) \in \mathbb{R}^{n \times 1}$ and $u_M(k) \in \mathbb{R}^{m_\mu \times 1}$ are the states and the inputs of the MIFS system, respectively.

Fig. 1 illustrates the system structure with which the MIFS system is formed by keeping one fixed state sampling rate. The diagram relates a state-space system.

III. EIGENSTRUCTURE ASSIGNMENT

For the system of (4), the eigenvalue assignment problem is to design a gain matrix F such that the state feedback control

$$u_M(k) = Fx(k), \quad F \in \mathbb{R}^{m_\mu \times n} \quad (6)$$

produces a closed-loop system matrix $(\Phi_M + \Gamma_M F)$ which has a set of desired self-conjugate eigenvalues $\{\lambda_1, \lambda_2, \dots, \lambda_n\}$. Assume (Φ_M, Γ_M) are completely controllable, a range of feedback gain matrices will provide the solution [8]–[11].

Eigenstructure assignment uses the extra degrees of freedom in the underdetermined solution to specify the closed-loop right eigenvectors, $V = [v_1 \ v_2 \ \dots \ v_n]$, corresponding to the desired self-conjugate set $\{\lambda_i\}$. For an insensitive solution, the eigenvectors are chosen to be as mutually orthogonal as possible or to have a specific

modal structure. A measure of the sensitivity of a solution is the conditioning of the closed-loop system right eigenvectors given by [12], [13]

$$\kappa(V) = \|V\|_2 \|V^{-1}\|_2. \quad (7)$$

The eigenstructure assignment problem is to select a set of the desired eigenvalues $\{\lambda_i\}$ and a set of linearly independent right eigenvector matrix V which minimizes $\kappa(V)$ and, furthermore, satisfies the following relation: $(\Phi_M + \Gamma_M F)v_i = v_i \lambda_i$, for $i = 1, \dots, n$, that is,

$$[\Phi_M - \lambda_i I \quad \Gamma_M] \begin{bmatrix} v_i \\ Fv_i \end{bmatrix} = 0. \quad (8)$$

To find a solution, define

$$S_{\lambda_i} = [\Phi_M - \lambda_i I \quad \Gamma_M] \quad (9)$$

and a compatibly dimensioned matrix

$$R_{\lambda_i} = \begin{pmatrix} N_{\lambda_i} \\ M_{\lambda_i} \end{pmatrix} \quad (10)$$

whose columns form the basis for the nullspace of S_{λ_i} . Thus,

$$[\Phi_M - \lambda_i I \quad \Gamma_M] \begin{pmatrix} N_{\lambda_i} \\ M_{\lambda_i} \end{pmatrix} w_i = 0 \quad (11)$$

for any $m_\mu \times 1$ vector, w_i .

It can be deduced from (8) and (11) that

$$v_i = N_{\lambda_i} w_i \quad (12)$$

and if the $\{v_i\}$ are linearly independent set, a real F can be expressed by

$$F = [M_{\lambda_1} w_1 \quad M_{\lambda_2} w_2 \quad \dots \quad M_{\lambda_n} w_n] V^{-1}. \quad (13)$$

For the single rate eigenproblem of (12), an achievable set of eigenvectors is limited by the nullity of the solution space, n_{λ_i} . In general, $m_\mu = m < n$ indicates an underdetermined problem. In this case, a maximum of m elements of the desired eigenvectors can be achieved exactly, and the achievable set of eigenvectors will only approximate the desired set. For the MIFS multirate system, the dimension of R_{λ_i} can be extended beyond that produced by a fixed single rate system, by virtue of the periodic description used for the MIFS sampling scheme.

IV. FEEDBACK DESIGN OF MIFS SAMPLED SYSTEMS

It is well established that the controllability and observability conditions which must be satisfied by the multirate system for the assignability of an arbitrary set of eigenvalues are determined by the choice of input, output, and state sample rates [1]–[7]. These sample parameters have, however, a much more significant role in the eigenstructure assignment procedure; a suitable choice of sample parameters can be used to produce maximum dimension solution space. The extra degrees of freedom generated in this way can be used to ensure a perfectly conditioned solution [14], [15].

The multirate feedback control problem and sensitivity measures relate to the assignment of n eigenvalues $\{\lambda_1, \lambda_2, \dots, \lambda_n\}$ designed by a transition matrix which represents the closed-loop system at the main interval sample instants. The set $\{\lambda_i\}$ corresponds to an equivalent set $\{\lambda_{m_i}\}$, representing the faster eigenvalues of the closed-loop system sampled at the based rate T_b . The two sets are related by $\lambda_{m_i} = (\lambda_i)^{n_0}$. The sensitivity measures relate to the n eigenvalues of the MIFS system representation and, therefore, only provide an assessment of system performance at the main sample instants.

The criteria for the selection of the MIFS multirate sample rates have a perfectly conditioned feedback solution are based on the calculation of the extended controllability matrix

$$= [\Gamma_1 \quad \Phi\Gamma_1 \quad \Phi^{2-1}\Gamma_1 \quad \dots \quad \Gamma_m \quad \Phi\Gamma_m \quad \Phi^{2-1}\Gamma_m] \quad (14)$$

where Γ_i is the i th column of the single rate system control matrix evaluated at T , and Φ is the corresponding single rate state transition matrix i.e., $\Phi = \Phi_{AT}$. And define

$$\mu = \sum_{i=1}^m \mu_i \quad (15)$$

The columns of B are selected such that starting from Γ_1 further columns are added until all vectors associated with Γ_1 are linearly independent. The process is continued for all control inputs required for the achievement of (A, B) controllability. When the condition

$$\sum_{i=1}^j \mu_i = n$$

$j < m$ is reached then all subsequent input sample rates have unity input multiplicity i.e. $\mu_i = 1$ for $i = j+1 \dots m$.

For a controllable system if $m_i \geq n$ eigenvalues and eigenvectors can be assigned arbitrarily; if $m_i < n$ the $n - m_i$ entries of each eigenvector cannot be assigned arbitrarily [16]. Thus the indices μ_i , $i = 1 \dots m$ determine the dimension of the maximum solution subspace that the i th input is capable of generating with an MIFS samples system [17]. A choice of input sample rate $\{T_i\} = \left\{\frac{T}{\mu_i}\right\}$ i.e. $n - \mu$ will produce full design freedom for the eigenstructure assignment procedure of Section III if $\mu \geq n$. This choice of input rates is referred to as the *ideal sample set*. (Note also that a rearrangement of columns in the original control matrix may produce a different set $\{\mu_i\}$.)

If $\mu > n$ then $R_{\lambda_i} \in \mathbb{R}^{(n-\mu_i) \times \mu_i}$ for the eigenproblem of (10) thus providing full design freedom for the eigenstructure assignment procedure. This effectively allows the precise assignment of any set of finite magnitude desired eigenvectors of the closed loop multirate system. For $\mu = n$ the design vector u is determined uniquely resulting in a simpler formula for the multirate gain matrix

$$K = [V_{\lambda_1}(\lambda_{\lambda_1})^{-1} \dots V_{\lambda_n}(\lambda_{\lambda_n})^{-1}]V^{-1} \quad (16)$$

For $\mu < n$ one method of solving the state feedback eigenproblem is by a least squares minimization of the error between the desired and achieved eigenvectors i.e. the minimization of $\|v_i - \bar{v}_i\|_2$. The least squares projection of the desired eigenvector v_i onto the solution space λ_{λ_i} determines the design vector to be

$$u = (\lambda_{\lambda_i}^T \lambda_{\lambda_i})^{-1} \lambda_{\lambda_i}^T v_i \quad (17)$$

The least squares projection method is termed the 'direct' assignment due to its noniterative assignment of the desired eigenvectors. The direct method is well suited for comparison purposes due to its single pass calculation. This leaves no opportunity for varying levels of attention in the design of the control laws (as for example with optimized assignment methods).

A choice of the 'nonideal' set of sampling rates ($\mu < n$) can also be implemented to design multirate feedback control that provides superior insensitivity performance than that achievable by the corresponding single rate design. This flexibility in the choice of input sample rate design multiplicity allows insensitivity properties of the closed-loop MIFS multirate system to be determined by the designer. An advantage of a 'nonideal' set of sample rates is the improved intersample behavior that can be obtained by effectively relaxing the eigenproblem solvability conditions as demonstrated in Section V.

(a)

Fig. 2 (a) State responses of the closed loop systems formed by the feedback gain matrices K_1 , K_2 (and K_3). — indicates K_1 system, --- indicates K_2 and K_3 systems. (b) Control input responses of the closed loop system with K_2 (multirate). (c) Control input responses of the closed loop system with K_1 (single rate).

For cases where the sample rate selection process gives $\mu > n$, a characteristic of the resulting feedback gain matrix produced is the generation of $\mu - n$ null rows. This is a direct consequence of the overdetermined solution produced by this choice of sample rates. This effectively limits the number of nonzero gain elements of a feedback control matrix of any multirate scheme satisfying the necessary conditions for multirate eigenvalue assignability to $\leq n^2$. The extra design freedom is illustrated in Fig. 2 which shows the additional effective inputs which arise as a consequence of the multisampling.

Eigenstructure assignment techniques are also noted for their ability to generate closed-loop systems which are insensitive to variations or perturbations in the nominal system dynamics [13]. This insensitivity

Fig. 2 (b) Control input responses of the closed-loop system with K_2 (multirate). (c) Control input responses of the closed-loop system with K_1 (single rate).

is achieved by decoupling the modal interactions presented in the closed-loop system. The benefits of closed-loop system insensitivity can be observed very clearly in the time domain.

V. EXAMPLE

A simple example is used to demonstrate the effects of applying the direct eigenstructure assignment procedure and the sample rate selection criteria outlined in Sections III and IV. Multirate gain matrices are designed for ideal and nonideal sample rates for the example considered to produce perfectly conditioned solutions to the multirate eigenstructure assignment problem. The performance of the multirate feedback designs is compared to the corresponding single rate design to demonstrate the improved insensitivity of the multirate designs.

Let the matrices of a system be

$$A = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ -6 & -11 & -6 \end{pmatrix} \quad B = \begin{pmatrix} 1 & 1 \\ 0 & 1 \\ 1 & 1 \end{pmatrix}. \quad (18)$$

TABLE I

$\kappa(V)$ AND $\|K\|_2$ OF K_1 , K_2 , AND K_3 CLOSED-LOOP SYSTEMS

Performance Measure	Feedback Gain Matrix		
	K_1	K_2	K_3
$\kappa(V)$	172.14	1	1
$\ K\ _2$	7.8253	67.156	75.622

The desired closed-loop eigenvalues $\{-0.5, -0.6, -0.7\}$ are assigned using a least squares solution such that the corresponding right eigenvectors are maximally orthogonal (ideally $\{v_i\} = I_n$). The main interval of sampling is selected to be $T = 0.1$. This does not render any of the modes uncontrollable, thus ensuring the assignability of the desired eigenvalues. Formulating matrix β , gives two choices of input multiplicities: $\{\mu_1 = 2, \mu_2 = 1\}$ and $\{\mu_1 = 3, \mu_2 = 1\}$. The multirate feedback design produced by these two choices of sample rates are given below together with the corresponding single rate design.

- 1) The input sampling intervals $T_1 = T$, $T_2 = T$ and the state sampling interval is T (single rate); this gives the single rate gain matrix K_1

$$K_1 = \begin{pmatrix} 2.9832 & 5.9881 & 3.7679 \\ -0.2931 & -1.0622 & -1.1507 \end{pmatrix}$$

$$\|K_1\|_2 = 7.8253.$$

- 2) The input sampling intervals $T_1 = T/2$, $T_2 = T$, the state sampling interval is T (multirate); this gives the "nonideal" multirate feedback gain matrix K_2

$$K_2 = \begin{pmatrix} 22.1843 & -40.2434 & -16.5515 \\ 20.1605 & 37.5406 & 17.6343 \\ 0.525 & 0.3829 & 0.5409 \end{pmatrix}$$

$$\|K_2\|_2 = 67.1560.$$

- 3) The input sampling intervals $T_1 = T/3$, $T_2 = T$, the state sampling interval is T (multirate); this gives the ideal multirate feedback gain matrix K_3

$$K_3 = \begin{pmatrix} 25.3670 & 45.8164 & 18.3884 \\ 0.0 & 0.0 & 0.0 \\ -22.3352 & -41.7645 & -20.0087 \\ -0.5243 & -0.3821 & 0.5389 \end{pmatrix}$$

$$\|K_3\|_2 = 75.6217$$

which has one null row since $\mu - n = 1$.

Table I shows the eigenvector conditioning $\kappa(V)$ and $\|K\|_2$ figures for the above designs. The $\|K\|_2$ figure gives an indication of the magnitude of the control effort demanded by each design.

Fig. 2 shows the responses of the K_1 and K_2 closed-loop systems to initial state perturbation of $x(0) = [0.1, 0.3, 0.15]^T$. The main sample responses of the K_2 and K_3 design are identical. Fig. 2 shows that both multirate systems exhibit the perfect modal decoupling that all designs are attempting to achieve.

Both multirate feedback designs have a very high $\|K\|_2$ compared to the equivalent single rate design. Thus, an increased demand on the control inputs is predicted (as verified by the responses of Fig. 2). The only difference in the control input responses of the two multirate systems (in addition to the different update rates) is a slight increase in the magnitude of u_1 demanded by feedback design K_1 . The u_2 control signal for all designs is, however, smooth and has an acceptable magnitude. Thus, the faster u_1 sampling required for the

Fig. 3. Intersample state behavior of closed-loop systems formed by the multirate gain matrix K_2 .

K_3 closed-loop system appears to offer no advantage over the K_2 system. Both achieve the required decoupled responses at the main sample instants.

Fig. 2 shows the system responses at a rate $1/T$ (which is the correct state sample rate of the MIFS system). The state responses during the interval T are shown in Fig. 3. These responses show that the improved decoupling of the multirate designs is obtained at the cost of large magnitude, switched intersample state behavior (x_2 of both multirate design does not suffer from any intersample switching).

The most important point to note from the tabulated performance measure and the time responses is the achievement of perfect modal decoupling by multirate feedback gains K_2 and K_3 at the main sample instants. In comparison, the modal decoupling achievable by the single rate design K_1 is relatively poor.

The insensitivity of the multirate and single rate closed-loop systems to perturbations in the nominal open loop systems dynamics

TABLE II
THE CLOSED-LOOP NOMINAL AND PERTURBED EIGENVALUES

Nominal Eigenvalues	Perturbed Eigenvalues	
	K_1	K_2 and K_3
0.9512	1.0153	$0.9530 + j0.0070$
0.9324	0.9136	$0.9530 - j0.0070$
0.9418	0.9504	0.9364

is tested. A comparison of the shift in position of the K_1 (single rate), K_2 and K_3 closed-loop system poles caused by this perturbation will establish the sensitivity of each system.

The sensitivities of the closed-loop systems produced by K_1 , K_2 , and K_3 are tested by perturbing the open-loop system transition matrix A . A proportional perturbation in the system dynamics of the form $A = (1 + \delta)A$ is considered. A perturbation $\delta = -0.1$ (which corresponds to a 10% perturbation) just makes the single rate system unstable. The closed-loop eigenvalues produced by each feedback gain matrix in response to this perturbation in the nominal system dynamics are given in Table II (together with the nominal eigenvalues).

Thus, the multirate closed-loop system maintains stable performance, while the single rate system becomes unstable. The multirate system can, in fact, tolerate an extreme proportional perturbation in the open-loop system dynamics. A value of $\delta = -0.75$ (i.e., a 75% perturbation) will cause the above K_2 , K_3 systems to become unstable.

VI. CONCLUSION

Many systems have a sampled-data structure which is necessarily multirate to fit in with the use of different data buses and digital sensors and actuators. The criteria for the selection of input sample rate multiplicities to achieve a perfectly conditioned closed-loop system have been outlined. This note has demonstrated the application of eigenstructure assignment to multirate systems. The criteria for the selection of input sample rate multiplicities to achieve a perfect conditioned closed-loop system have been outlined. An example has demonstrated the achievement under certain conditions of perfectly decoupled solutions at the main sample instants by an MIFS system, whose input sample rates are chosen using the proposed criterion. For the example system, two input rate multiplicities (determined using the general selection criterion) were examined. The nominal responses of both multirate designs have been compared to the corresponding single rate designs. The multirate solutions are seen to provide much more insensitive feedback control than that produced by the equivalent single rate design. The results demonstrate the applicability of the eigenstructure assignment technique for MIFS feedback control design.

A direct eigenstructure assignment method, where the desired eigenvectors are approximated using a least squares projection, has been used to solve the multirate eigenstructure assignment problem. This serves to demonstrate the principles of multirate feedback design using eigenstructure assignment. The direct approach is, by no means, the ideal method of utilizing the design freedom offered by MIFS system models. A more useful approach is to optimize the solution to the MIFS eigenproblem such that intersample switching is alleviated while maintaining a near-perfectly conditioned modal structure. An MIFS eigenstructure assignment technique of this type is presented in [14]. The optimization procedure [15] makes full use of the extra MIFS system design freedom to balance the different closed-loop system qualities.

Optimality Conditions for Truncated Kautz Networks with Two Periodically Repeating Complex Conjugate Poles

Tomás Oliveira e Silva

Abstract—We present optimality conditions for the approximation of an SISO system by a truncated Kautz network with two repeating complex conjugate poles. Both the continuous and the discrete time cases are discussed. We approach the problem in a system approximation framework, and we do not assume that the input signal is white (or an impulse). The results we obtain generalize the results already known for truncated Laguerre networks.

1 INTRODUCTION

The usage of orthonormal series of exponential functions in the representation of signals pioneered by the work of Lee and Wiener in the 1930's [1] is an important topic of research in the areas of automatic control and digital signal processing. For the continuous time (CT) case these orthonormal functions can be obtained quite easily if we express them by their Laplace transforms [1]–[4]

$$G_k(s) = \sqrt{p_k + p_k^*} \frac{\prod_{l=1}^k \frac{1}{s - p_l^*}}{\prod_{l=1}^k \frac{1}{s + p_l}} \quad k \in \mathbb{N} \quad (1)$$

The poles of these functions, which correspond to the exponents of the exponential functions, are arbitrary except that they must have negative real parts, i.e., $\text{Re } p_k < 0$. For the discrete time (DT) case the orthonormal sequences can also be obtained quite easily if we express them by their Z transforms [5]

$$G_k(z) = \sqrt{1 - a_l a_l^*} \frac{\prod_{l=1}^k \frac{1}{1 - a_l^* z^*}}{\prod_{l=1}^k \frac{1}{1 - a_l z}} \quad l \in \mathbb{N} \quad (2)$$

The poles of these functions are arbitrary except that they must be inside the unit circle, $|a_l| < 1$. Of all the possible selections of the poles of these functions, the special case where all the poles are equal (and real), corresponding to the so called Laguerre functions (CT: $p_k = p$) and sequences (DT: $a_l = a$) has attracted the interest of several researchers [6]–[11]. Because in practice we are forced to truncate the Laguerre series expansion of a given or estimated function (sequence) after a finite number of terms, an important problem related to this approach is the choice of a good value for p (or a) [12]–[15]. A directly related problem is the choice of the optimal value of p (or a) for a truncated Laguerre series with a specified number of terms [16]–[18].

Unfortunately, the approximation of a function whose transform has one or more pairs of complex conjugate dominant poles by a truncated Laguerre series requires a large number of terms [9]. A simple way to ameliorate this problem is to use the orthonormal functions given by (1) or (2). To avoid too many degrees of freedom one usually assumes that the poles of the expansion are just two complex conjugate periodically repeating poles, i.e., $p_{k+1} = p$, $p_k = p^*$, $l \in \mathbb{N}$ (and a similar definition for the a_k 's). In this

¹We will denote the real part of a variable by the subscript *re* and its imaginary part by *im*. For Laplace/Z transforms a subscript *re* will denote the transform of the real part of the function/sequence, not the real part of the transform, likewise for *im*. The square root of -1 will be denoted by j .

we can apply an unitary transformation to (1) to obtain [2], [3]

$$G_{2k-1}(s) = \sqrt{p+p^*}(s-|p|) \frac{[(s-p)(s-p^*)]^{k-1}}{[(s+p)(s+p^*)]^k} \quad (3)$$

and

$$G_{2k}(s) = \sqrt{p+p^*}(s+|p|) \frac{[(s-p)(s-p^*)]^{k-1}}{[(s+p)(s+p^*)]^k} \quad (4)$$

For the DT case, (2) can also be replaced by [5]

$$G_{2k-1}(z) = |1+a| \frac{\sqrt{1-aa^*}}{\sqrt{2}} (z^{-1}-1) \frac{[(z^{-1}-a)(z^{-1}-a^*)]^{k-1}}{[(1-az^{-1})(1-a^*z^{-1})]^k} \quad (5)$$

and

$$G_{2k}(z) = |1-a| \frac{\sqrt{1-aa^*}}{\sqrt{2}} (z^{-1}+1) \frac{[(z^{-1}-a)(z^{-1}-a^*)]^{k-1}}{[(1-az^{-1})(1-a^*z^{-1})]^k} \quad (6)$$

We will call these functions (and their inverse transforms) generically by the name of Kautz functions with two periodically repeating complex conjugate poles, or Kautz(cc) for short.

Like the Laguerre functions, the Kautz(cc) functions can approximate arbitrarily well, in the integrated squared error (ISE) sense, any impulse response with finite energy. This property of Laguerre functions was used in the past to model plants with unknown or unmodeled dynamics [6], [7], [19], [20]. Unfortunately, the Laguerre functions are not well suited to approximate functions with strong oscillatory behavior—a task that can be done more efficiently with Kautz(cc) functions. For this reason, some researchers have recently turned their attention to this kind of functions [21], [22].

The problem of deducing the optimality conditions for p (or a) in the approximation, in the ISE sense, of the impulse response of an SISO plant by a truncated Laguerre series was solved in [16] and [17]. Recently, these results have been extended to the more general case where the plant to be identified is excited by a signal with a nonconstant power spectrum and where the plant is approximated by a truncated Laguerre network [18]. We will extend here the results of [18] to the case of a truncated Kautz(cc) network. To this end, we will first deduce the optimality conditions for a truncated Laguerre network with one complex pole. We then proceed to show that the real part of the output of this network is the output of a Kautz(cc) network. Finally, using some results of the Laguerre case, we deduce the optimality conditions for Kautz(cc) networks. We conclude the note with a simple numerical example.

A. CT versus DT Signals and Deterministic versus Stationary Stochastic Signals

It is interesting to note that (5) and (6) are quite similar to (3) and (4). This suggests that the results for DT are similar to those for CT, which in fact is the case. We will therefore discuss in detail only the CT case. The DT case will be dealt with in a couple of remarks.

Another point worth mentioning is the similarity of the results for deterministic and for stationary stochastic signals. In the rest of this note, we will need to evaluate inner products of the form (CT, $s = j\omega$)

$$(FX, GY) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} F(j\omega) G^*(j\omega) X(j\omega) Y^*(j\omega) d\omega$$

where F , G , X , and Y are the Laplace transforms of deterministic signals with finite energy. When $x(t)$ and $y(t)$ are stationary stochastic signals with finite power, we can also evaluate an inner product of this form by replacing in the above expression $X(j\omega)Y^*(j\omega)$ by the generalized Fourier transform of the cross-correlation between $x(t)$ and $y(t)$. Therefore, by a suitable modification of the inner product definition, we can cover the cases of deterministic and stochastic signals simultaneously.

Fig. 1. Network for generating the continuous-time Laguerre functions with one complex pole. (The variable u is the real part of p .) A similar network exists to generate the discrete-time Laguerre sequences.

II. OPTIMALITY CONDITIONS FOR TRUNCATED LAGUERRE NETWORKS WITH ONE COMPLEX POLE

We will basically follow the approach of [18], adapted to our present needs and to the CT case. For convenience, we will assume that $p = u + jv$. The CT Laguerre functions are obtained easily from (1), with the result

$$L_k(s, p) = \sqrt{2u} \frac{(s-p^*)^{k-1}}{(s+p)^k}, \quad k \in \mathbb{N}.$$

These functions can be easily generated by the block diagram of Fig. 1. By applying to this network a general input signal, and by forming a linear combination of its various outputs to approximate a given desired signal, we obtain a Laguerre network.

Let $X(s)$ be the Laplace transform of the input signal of the Laguerre network, and let $D(s)$ be that of the desired signal. Both signals are assumed to have finite energy and to be real. Let n be the number of sections of the Laguerre network, and let $Y_n(s, p)$ be the Laplace transform of the network's output. We then have

$$Y_n(s, p) = \sum_{k=1}^n w_{n,k} L_k(s, p) X(s).$$

Note the dependence of the weights $w_{n,k}$ on the number of sections. This is a consequence of the fact that the L_k 's are not orthonormal when the weighting function, the power spectrum of the input signal, is not the constant function 1. With the notation $A_k(s, p) = L_k(s, p) X(s)$, the error signal is given by

$$E_n(s, p) = \sum_{k=1}^n w_{n,k} A_k(s, p) - D(s)$$

and, by denoting the usual inner product of complex signals by (\cdot, \cdot) , we obtain the ISE of the Laguerre network with n sections as $\xi_n = (E_n, E_n)$. (Due to Parseval's theorem, we have chosen to represent the ISE as an inner product in the transform domain.)

The optimal values for the weights $w_{n,k}$ can be easily found by applying the orthogonality property of Hilbert spaces, the result being the following set of so-called normal equations:

$$(E_n, A_k) = 0, \quad k = 1, \dots, n. \quad (7)$$

Furthermore, we have for the partial derivative of ξ_n with respect to a generic real parameter (a prime denotes here differentiation with respect to that parameter):

$$\xi'_n = \sum_{k=1}^n [w_{n,k} (A'_k, E_n) + w_{n,k}^* (E_n, A'_k)]. \quad (8)$$

To actually compute the partial derivatives with respect to u and v , we will need the following remarkable formulas:

$$\frac{\partial L_k(s, p)}{\partial u} = \frac{(1-k)L_{k-1}(s, p)}{2u} + k \frac{L_{k+1}(s, p)}{2u} \quad (9)$$

$$\frac{\partial L_k(s, p)}{\partial v} = j \frac{(k-1)L_{k-1}(s, p) + (1-2k)L_k(s, p)}{2u} + jk \frac{L_{k+1}(s, p)}{2u}. \quad (10)$$

Because we have $A'_k = L'_k \lambda$, we conclude that²

$$\frac{\partial A_k}{\partial u} = k \frac{A_{k+1}}{2u} + \text{terms in } A_k \text{ and } A_{k-1} \quad (11)$$

and that

$$\frac{\partial A_k}{\partial v} = jk \frac{A_{k+1}}{2u} + \text{terms in } A_k \text{ and } A_{k-1} \quad (12)$$

Applying (11) and (12) to (8) and simplifying the result with (7), we obtain for the stationary points of ξ_n with respect to p (i.e., with respect to u and v) the following system of equations

$$\begin{cases} u_{n+1} (A_{n+1}, E_n) + u_{n+1}^* (E_n, A_{n+1}) = 0 \\ u_{n+1} (A_{n+1}, E_n) - u_{n+1}^* (E_n, A_{n+1}) = 0 \end{cases}$$

It is a simple matter to verify that the only solutions of this system are

$$u_{n+1} = 0 \quad \text{or} \quad (E_n, A_{n+1}) = 0$$

We will now show that the second condition is equivalent to $u_{n+1} = 0$. To this end, we apply the Gram-Schmidt orthonormalization procedure to the set $\{A_k\}$, obtaining the orthonormal set $\{B_k\}$. This can always be done because there are no linear dependencies between the A_k 's.³ We can express the orthonormalization procedure by

$$B_n = T_n A_n$$

where T_n is a lower triangular non-singular matrix. A_n is a column matrix defined by

$$A_n = [A_1 \quad A_2 \quad \dots \quad A_n]^T$$

and B_n is defined in a similar way. To simplify the notation in the rest of this section, we will denote the element of the last row and column of the matrix T_n by r_n . Note that $r_n \neq 0$ and that for $\lambda(s) = 1$ we have $r_n = 1$ for all n . It is also interesting to note that the element of the last row and column of the matrix T_n^{-1} is equal to r_n^{-1} .

Due to the orthonormality of the B_k 's, we have

$$F_{n+1} = E_n + r_{n+1} B_{n+1}$$

where $r_{n+1} = (D, B_{n+1})$ is the $n+1$ th Fourier coefficient associated with the expansion of $D(s)$ with respect to the orthonormal set $\{B_k\}$. Therefore, we have

$$(E_n, A_{n+1}) = (E_{n+1}, A_{n+1}) - r_{n+1} (B_{n+1}, A_{n+1})$$

One of the normal equations for a network with $n+1$ sections gives us immediately $(E_{n+1}, A_{n+1}) = 0$. We also have $(B_{n+1}, A_{n+1}) = r_{n+1}^{-1} \neq 0$. From these facts we conclude that the condition $(E_n, A_{n+1}) = 0$ is equivalent to $r_{n+1} = 0$. We finish the proof by noting that $u_{n+1} = r_{n+1} = 0$.

From the above results, we conclude that the stationary points of the truncated Laguerre network satisfy

$$u_{n+1} u_{n+1}^* = 0 \quad (13)$$

as well as the normal equations (7) for orders n and $n+1$. Equation (13) is exactly the optimality condition obtained in [16] and [17] under much more restrictive assumptions. Because the normal equations define completely the weights $u_{n,k}$ (and the weights $u_{n+1,k}$), the solutions of (13) are the values of p for which $u_{n,n} = 0$ or $u_{n+1,n+1} = 0$. One of these solutions will correspond to the global minimum of ξ_n (other solutions may correspond to local minima or maxima, or even to saddle points).

²The term in A_k in (11) is missing for the CT case but is present for the DT case [cf. (14)].

³In fact, by factoring out the common nonzero term $\lambda(s)$ an operation that can always be done because $\lambda(s)$ is an analytic function in the right-half plane, the resultant set is orthonormal. (Obviously, we are not considering the uninteresting case $\lambda(s) = 0$.)

Remark 1 For the DT case, we have for the Z -transforms of the Laguerre sequences

$$L_k(z, a) = \sqrt{1 - a^2 - a^2} \frac{(z^{-1} - a^*)}{(1 - az^{-1})^k}, \quad k \in \mathbb{N},$$

where $a = u + jv$, and the remarkable formulas

$$\frac{\partial L_k(z, a)}{\partial u} = \frac{(1-k)L_{k-1}(z, a) + j(1-2k)L_k(z, a)}{1 - a^2 - a^2} + k \frac{L_{k+1}(z, a)}{1 - a^2 - a^2} \quad (14)$$

$$\frac{\partial L_k(z, a)}{\partial v} = j \frac{(k-1)L_{k-1}(z, a) + (2k-1)L_k(z, a)}{1 - a^2 - a^2} + jk \frac{L_{k+1}(z, a)}{1 - a^2 - a^2} \quad (15)$$

Note that the last term of (14) is almost equal to that of (9) — the same happening between (15) and (10). For this reason, (11) and (12) are also valid for the DT case (with $2u$ replaced by $1 - a^2 - a^2$). Therefore, the proof for the CT case can be adapted quite easily to the DT case.

III. OPTIMALITY CONDITIONS FOR TRUNCATED SECOND-ORDER KAUTZ NETWORKS WITH TWO COMPLEX CONJUGATE POLES

In this section we will show that the real part of the output of the Laguerre network of the previous section is the output of a Kautz network of second order with two complex conjugate poles and with the same number of sections as the Laguerre network.⁴ We then proceed to compute the optimality conditions for truncated Kautz networks. To simplify the exposition we will discuss here only the CT case. The DT case is similar.

The Laplace transform of the real part of the output of a Laguerre network with a complex pole is given by⁵

$$\begin{aligned} Y_{re}(s, p) &= \frac{\lambda(s)}{2} \sum_{k=1}^n [u_{n,k} L_k(s, p) + u_{n,k}^* L_k(s, p^*)] \\ &= \sqrt{\frac{u}{2}} \lambda(s) \sum_{k=1}^n F_{n,k}(s, p) \end{aligned}$$

where

$$F_{n,k}(s, p) = u_{n,k} \frac{(s - p^*)^{k-1}}{(s + p)^k} + u_{n,k}^* \frac{(s - p)^{k-1}}{(s + p^*)^k}$$

It is clear that this last expression can be put in the form

$$F_{n,k}(s, p) = \sum_{m=1}^k (\phi_{n,k,m} s + \psi_{n,k,m}) \frac{[(s + - + p^*)(s - p)]^{n-1}}{[(s + p)(s + p^*)]^n}$$

where all coefficients involved in this expression are real.⁶ It is then obvious that $Y_{re}(s, p)/\lambda(s)$ can be expressed in a unique way as a linear combination of equations (3) and (4), i.e., $Y_{re}(s, p)$ is the output of a second-order Kautz network. More specifically, we have

$$Y_{re}(s, p) = \sum_{k=1}^n [a_{n,k} G_{-k-1}(s, p) + b_{n,k} G_{2k}(s, p)] \lambda(s)$$

where the $a_{n,k}$'s and the $b_{n,k}$'s can be obtained from the $u_{n,k}$'s (or the $\phi_{n,k,m}$'s and $\psi_{n,k,m}$'s) by an invertible transformation. Because

⁴Note that for p (or a) real (i.e., $v = 0$), the Kautz network collapses into a Laguerre network (with twice the number of sections). We will not discuss this special case here.

⁵Note that the input signal is real.

⁶It can be shown that the conditions $\phi_{n,k,m} = 0$ and $\psi_{n,k,m} = 0$ are equivalent to the condition $u_{n,k} = 0$ when $v \neq 0$.

and $b_{r,n}$ are related to $\phi_{r,n}$ and $\psi_{r,n}$ by a invertible linear transformation when $\epsilon \neq 0$, we conclude that

$$\begin{cases} a_{r,n} = 0 \\ b_{r,n} = 0 \end{cases} \Leftrightarrow \begin{cases} \phi_{r,n} = 0 \\ \psi_{r,n} = 0 \end{cases} \Rightarrow u_{r,n} = 0 \quad (16)$$

We now turn our attention to the problem of deducing the optimality conditions for truncated second order Kautz networks. The starting point is the equation

$$J = Y_{rr} - D = \sum_{k=1}^n [u_{r,k} A_{r,k} - u_{rr,k} A_{rr,k}] - D$$

where we have explicitly separated the real from the imaginary parts of all complex variables and functions. The ISE to be minimized is now $\xi_r = (F_r, F_{rr})$. The subscript r in ξ is just to distinguish the Kautz case from the Laguerre case. Note that we have

$$A_{r,k}(s, p) = \frac{A_k(s, p) + A_k(s, p^*)}{2}$$

and

$$A_{rr,k}(s, p) = \frac{A_k(s, p) - A_k(s, p^*)}{2j}$$

From these equations and from (9) and (10) it is possible to show that

$$\frac{\partial A_{r,k}}{\partial u} = \frac{A_{r,k+1}}{2u} + \text{other terms} \quad (17)$$

$$\frac{\partial A_{rr,k}}{\partial u} = k \frac{A_{rr,k+1}}{2u} + \text{other terms} \quad (18)$$

$$\frac{\partial A_{r,k}}{\partial t} = -I \frac{A_{r,k+1}}{2u} + \text{other terms} \quad (19)$$

$$\frac{\partial A_{rr,k}}{\partial t} = k \frac{A_{rr,k+1}}{2u} + \text{other terms} \quad (20)$$

where the "other terms" are terms in $A_{r,j}, A_{rr,k}, A_{r,k+1}$ and $A_{rr,k+1}$ (some may be missing).

In the present case the weights $u_{r,j}$ have to satisfy the following set of normal equations

$$\begin{cases} (F_r, A_{r,k}) = 0 \\ (F_{rr}, A_{rr,k}) = 0 \end{cases} \quad k = 1, \dots, n \quad (21)$$

Note that these normal equations are *different* from those in (7). In fact in the Kautz case we have $2n$ equations with $2n$ *real* unknowns while in the Laguerre case we have n equations in n *complex* unknowns. Therefore the set of weights for the optimal Laguerre case when transformed to the Kautz case usually do not produce an optimal solution.

The partial derivatives of ξ_r with respect to a real parameter u are now given by

$$\begin{aligned} \xi_r &= 2(F_r, F_{rr}) \\ &= 2 \sum_{k=1}^n [u_{r,k} (F_r, A_{r,k}) - u_{rr,k} (F_{rr}, A_{rr,k})] \end{aligned}$$

Using (17) to (20) in this expression and simplifying the result with (1) we obtain the following stationary conditions for ξ_r ,

$$\begin{cases} u_{r,k} (F_r, A_{r,k+1}) - u_{rr,k} (F_{rr}, A_{rr,k+1}) = 0 \\ u_{r,k} (F_{rr}, A_{rr,k+1}) + u_{rr,k} (F_r, A_{r,k+1}) = 0 \end{cases}$$

The only solutions of this system of equations are

$$u_{r,k} = 0 \quad \text{or} \quad \begin{cases} (F_r, A_{r,k+1}) = 0 \\ (F_{rr}, A_{rr,k+1}) = 0 \end{cases}$$

As in the Laguerre case we will now show that the second condition is equivalent to $u_{r,k+1} = 0$. We start by orthonormalizing

the set $\{A_{r,k}, A_{rr,k}\}$ obtaining the set $\{B_{r,k}, B_{rr,k}\}$. This can be expressed by

$$B_{r,k} = T_{r,k}^{-1} A_{r,k}$$

where again we have used the subscript r to denote the Kautz case.⁷ Again $T_{r,k}$ is a lower triangular nonsingular matrix which in this case can be partitioned in 2×2 blocks. We will denote by R the 2×2 block whose elements are the elements of the last two rows and columns of $T_{r,n}$. Note that R is itself a lower triangular nonsingular matrix. The 2×2 block similarly positioned in the matrix $T_{r,n}^{-1}$ is equal to R^{-1} .

Using the orthonormal set we have⁸

$$F_{r,n+1} = F_r + \epsilon_{r,n+1} B_{r,n+1} + \epsilon_{rr,n+1} B_{rr,n+1}$$

Using this expression and after some manipulations similar to the Laguerre case we obtain⁹

$$\begin{bmatrix} (F_r, A_{r,n+1}) \\ (F_{rr}, A_{rr,n+1}) \end{bmatrix} = -R^{-1} \begin{bmatrix} \epsilon_{r,n+1} \\ \epsilon_{rr,n+1} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

Because $|R| \neq 0$ the only solution of this system is $\epsilon_{r,n+1} = 0$ which implies $u_{r,n+1} = 0$. As in the Laguerre case we conclude that the stationary points for the Kautz case satisfy

$$u_{r,n+1} = u_{rr,n+1} = 0$$

as well as the normal equations (21) for orders n and $n+1$. According to (16) these conditions can be translated to weights of the Kautz network as

$$\begin{cases} a_{r,n+1} = 0 \\ b_{r,n+1} = 0 \end{cases} \quad \text{or} \quad \begin{cases} a_{r,n+1} + b_{r,n+1} = 0 \\ b_{r,n+1} - a_{r,n+1} = 0 \end{cases} \quad (22)$$

as long as $\epsilon \neq 0$.

Remark 2. The corresponding proof for the DT case is in every respect similar to that of the CT case. In particular we have (for $\epsilon \neq 0$)

$$Y_r(z, a) = \sum_{k=1}^n [a_{r,k} G_{r,k}(z, a) + b_{r,k} G_{rr,k}(z, a)] V(z)$$

where $a_{r,k} = b_{r,k} = 0$ if and only if $u_{r,k} = 0$. Equations (17)–(20) remain valid in the DT case with $2u$ replaced by $1 - u - \epsilon$.

IV. EXAMPLE

To illustrate the results of the previous section we will approximate the rational system

$$H(z) = \sum_{k=1}^n 1 - \frac{1}{k} z^{-k} \quad (23)$$

by a truncated Kautz network using as input the signal

$$V(z) = \frac{1}{1 + 0.8z^{-1}} \quad (24)$$

The values of all parameters of this system are presented in Table I.

The normalized ISL surface of the approximation of the output of (23) by the output of a Kautz network with four sections ($n = 4$) is

⁷The vector $A_{r,n}$ is now defined as

$$A_{r,n} = [A_{r,n}, A_{rr,n}, A_{r,n}, A_{rr,n}]^T$$

⁸For convenience we will represent the two real Fourier coefficients as the real and imaginary parts of a complex number.

⁹Note that

$$R^{-1} = \begin{bmatrix} (B_{r,n+1}, A_{r,n+1}) & (B_{rr,n+1}, A_{r,n+1}) \\ (B_{r,n+1}, A_{rr,n+1}) & (B_{rr,n+1}, A_{rr,n+1}) \end{bmatrix}$$

Fig. 2 Contour plot of the normalized ISE of the approximation of the output of (23) by the output of a Kautz network with four sections as a function of the pole position (only first quadrant shown). The input of both systems was (24). Superimposed in this figure are the curves $a_{1,4} = 0$ and $b_{1,4} = 0$. For each value of p , the weights are computed from the normal equations.

Fig. 3 Same as Fig. 2 but with the curves $a_{5,5} = 0$ and $b_{5,5} = 0$ instead of $a_{1,4} = 0$ and $b_{1,4} = 0$. Note that the global minimum is located at a point ($p \approx 0.619 + j0.580$) where the two curves cross.

displayed in Figs. 2 and 3 using contour lines separated by 1 dB¹⁰. The input of both systems was (24). We have superimposed the curves $a_{1,4} = 0$ and $b_{1,4} = 0$ in Fig. 2, and the curves $a_{5,5} = 0$ and $b_{5,5} = 0$ in Fig. 3. Note that, in this example, the global minimum is located at a point where $u_{5,5} = 0$ ($p \approx 0.619 + j0.580$). However, our conditions do not exclude the possibility that $u_{n,n} = 0$ (and not $u_{n+1,n+1} = 0$) may hold at a global minimum. This is known to be possible in Laguerre networks.

¹⁰For each value of p , we have computed the weights from (21). For this reason, in these figures the normalized ISE is only a function of p .

V CONCLUSIONS

We have deduced the optimality conditions for truncated Kautz networks with two complex conjugate periodically repeating poles. It is shown that these conditions are a simple generalization of those of the Laguerre case. The system approximation case discussed here is more general than the function approximation case usually considered in the literature. Surprisingly, the optimality conditions are the same in the two cases.

Another proof of these results, which is not based on a Laguerre network with a complex pole and is therefore easier to generalize, is presented in [23] (only for the special case of an impulsive input).

Stable Adaptive Control of a Class of First-Order Nonlinearly Parameterized Plants

Jovan D. Bošković

Abstract—Stable adaptive control algorithms are designed for a class of first-order nonlinearly parameterized plants containing nonlinearities similar to those arising in fermentation process models. When the plant nonlinearity is conveniently parameterized and when the controller parameters are adjusted adaptively, the output error is shown to converge to zero. Stability of the overall system is proved using the Lyapunov function with a suitably chosen cubic term.

1 INTRODUCTION

The past several years have witnessed substantial progress in the field of adaptive feedback linearizing control. While most of the existing results are derived in the context of linear parameterizations, in [6] the control problem is also solved for a class of nonlinearly parameterized plants, both in nonadaptive and adaptive cases. In this note we suggest a method for solving the adaptive control problem for a class of nonlinearly parameterized models similar to those arising in fermentation processes. Unlike the adaptive method from [6] which is based on high gain adaptation, in this note we suggest the method based on certainty equivalence principle and a novel form of Lyapunov functions.

The class of plants considered in this paper contains a nonlinearity which is of the form of a ratio of polynomials in x with three unknown parameters, the two of which do not enter linearly. Such a model captures all the important features of a large class of models of fermentation processes. It is shown that, for a constant desired response of the plant, the appropriate plant parameterization, in conjunction with the corresponding adaptive algorithms and a suitably chosen Lyapunov function, enables us to prove, without neglecting any terms in the derivative of the Lyapunov function, that the output error of the plant converges to zero, i.e., that $\lim_{t \rightarrow \infty} x(t) = 0$. The results presented in this note are based on the results from [3] and are aimed to be an important step towards designing stable adaptive algorithms for a class of uncertain nonlinear plants arising in continuous flow and fed batch fermentation processes.

The paper is organized as follows. In Section II the motivation is given and the tracking problem is stated for a special class of nonlinear plants. In Section III two plant parameterizations are presented and the corresponding error models are derived. Section IV contains the stability analysis for both cases of plant parameterizations, while the conclusions are given in Section V.

II MOTIVATION AND PROBLEM STATEMENT

To illustrate the difficulties encountered when attempting to control a nonlinear fermentation process, we will consider a class of fermentation process models in which the growth of microorganisms and substrate consumption are described by the Monod's growth model. In this case, using the notation adopted in biochemical engineering, the process model can be described by

$$\dot{\lambda} = \lambda \left[\frac{\mu_m S}{K_s + S} - D \right] \quad (1)$$

$$\dot{S} = -\frac{1}{Y} \frac{\mu_m S \lambda}{K_s + S} + (S_f - S)D \quad (2)$$

where λ and S denote respectively microorganisms and substrate concentrations and D denotes the dilution rate, $D = 1/\tau$, where τ denotes the substrate feed and V denotes the volume of the fermentation broth ($V = \text{const}$ for continuous flow processes and $V = F\tau$ for fed-batch processes). In the above equations, μ_m denotes the maximum value of the specific growth rate, K_s denotes the Monod's coefficient, Y denotes the yield coefficient, and S_f denotes the concentration of the substrate in the feed.

In the above equations the functional form of the growth model may be known, while the coefficients μ_m , K_s and Y may vary in an unknown fashion within known bounds. If we wanted to regulate $S(t)$ around some desired value S^* , we would use a control law of the form

$$D(t) = \frac{1}{S_f - S(t)} \left\{ \frac{1}{Y} \frac{\mu_m(t) S(t) \lambda(t)}{K_s(t) + S(t)} - \lambda[S(t) - S^*] \right\}$$

where $\lambda > 0$. In the case we wanted to regulate $\lambda(t)$ around λ^* , the control law would take the form

$$D(t) = \frac{1}{\lambda(t)} \left\{ \frac{\mu_m(t) S(t) \lambda(t)}{K_s(t) + S(t)} + \lambda[\lambda(t) - \lambda^*] \right\}$$

The question naturally arises as to how should the parameter estimates be adjusted in each case to provide that the output assumes values close to the desired one over an interval of interest. Due to the fact that some of the unknown parameters enter the static equation nonlinearly, the way in which the estimates should be adjusted so that the control objective is achieved is not immediately obvious. Thus a question arises whether the process nonlinearities can be more conveniently parameterized in a fashion which would simplify the analysis and the design of adaptive algorithms. In this context we will address two problems:

- (1) how to conveniently parameterize the nonlinearities from (1)
- (2) which would simplify the design of adaptive laws, and
- (2) how to prove the stability of the overall system.

To solve these problems we adopt a prototype plant whose nonlinearity captures main features of the nonlinearities from (1). The prototype plant is chosen in the form

$$\dot{x} = \frac{\rho f_1(x)}{k + k_1 x} + q(t)u - x(t) \quad (3)$$

where $x(t)$ represents a physical quantity in total coordinates, such that it cannot assume values less than zero. The input and the output of the plant are respectively denoted by $u(t)$ and $y(t)$ and $u \in \mathcal{S}$, where \mathcal{S} is a suitably chosen set. Also we assume that $t \in \mathbb{R}^+$ and that $|q(t)| > 0 \forall t \in (0, +\infty)$. It is further assumed that the value of ρ can be either +1 or -1. We now introduce the parameter vector $p = [f_1, k, k_1]^T$, and the set \mathcal{S}_p such that $p \in \mathcal{S}_p = \{p \mid p = [f_1, k, k_1]^T, 0 < (f_1)_{\min} \leq f_1 \leq (f_1)_{\max}, +\infty < k_1 \leq k < +\infty, j = 1, 2, 3\}$. It is also assumed that only $(k_1)_{\min}$ and $(k_1)_{\max}$ ($j = 1, 2, 3$) are known as well as that $t \in \mathcal{S} = \{t \mid 0 \leq t \leq t_f, t_f \in (0, +\infty)\}$.

Comment. The state and parameters of the plant (3) can assume only nonnegative values, which substantially restricts the class of plants under consideration. On the other hand, nonlinear models of fermentation processes, as well as a large number of nonlinear models arising in process industry, are given in total coordinates. In such a case the total values of the process states (e.g., pressures, levels, temperatures, flows, concentrations and other variables) assume strictly nonnegative values. Such models are also characterized by nonnegative values of parameters. These facts may justify the analysis of the restricted class of plants (3).

Manuscript received October 26, 1993; revised July 20, 1994.

We next consider the control objective for the plant (3). We will assume that the desired response of the plant is defined by

$$\dot{x}^*(t) = -\lambda_d x^*(t) + b_m r, x^*(0) = r \quad (4)$$

where $\lambda = b_m \in (0, +\infty)$, $0 \leq r \leq r_{\max} < +\infty$, and r is constant.

We further introduce the output error $e(\cdot) = x(\cdot) - r$. Since $e(0) = e_0 = x_0 - r$, we have that $e_0 \in \mathcal{S}_{e_0} = \{e_0 : -r_{\max} \leq e_0 \leq r_1 + r_{\max}\}$. Now we are ready to state the control objective for the plant (3).

Objective Design a control law for the plant (3) such that, for $p \in \mathcal{S}_p$ and for $e_0 \in \mathcal{S}_{e_0}$, all signals in the system are bounded, and $\lim_{t \rightarrow \infty} e(t) = 0$.

To solve this problem, we will first consider different possible parameterizations of the plant nonlinearity.

III. PLANT PARAMETRIZATIONS AND ERROR MODELS

A Left Parameterization

When $\rho = 1$, we use the left parameterization of the plant (3) [3]. Such a parameterization is of the form

$$\dot{x} = \frac{\alpha_1 x^2}{\alpha_2 + x} + g(x)u \quad (5)$$

where $\alpha_1 = k_1/k_3$ and $\alpha_2 = k_2/k_3$. We further introduce $\alpha = [\alpha_1 \ \alpha_2]^T$, and $\alpha \in \mathcal{S}_\alpha = \{\alpha : \alpha = [\alpha_1 \ \alpha_2]^T, 0 < (\alpha_j)_{\min} \leq \alpha_j \leq (\alpha_j)_{\max}, j = 1, 2\}$, where $(\alpha_j)_{\min} = (k_j)_{\min}/(k_3)_{\max}$, $(j = 1, 2)$, and $(\alpha_j)_{\max} = (k_j)_{\max}/(k_3)_{\min}$, $(j = 1, 2)$. In this case the control law is chosen in the form

$$u(t) = \frac{1}{g(x(t))} \left[-\frac{\theta_1(t)x^2(t)}{\theta_2(t) + x(t)} - \lambda x(t) + b_m r \right] \quad (6)$$

where θ_1 and θ_2 denote the adjustable controller parameters. To avoid division by zero in the above expression (and to assure the stability of the overall system, as will be shown in Section IV), the adaptive algorithms should be designed to ensure that

$$\theta(t) \in \mathcal{S}_\theta = \{\theta : \theta = [\theta_1 \ \theta_2]^T, 0 < (\alpha_j)_{\min} - \epsilon_j \leq \theta_j \leq (\alpha_j)_{\max} + \epsilon_j, j = 1, 2, \forall t \in \mathbb{R}^+\} \quad (7)$$

where $\epsilon_j = \min\{(\alpha_j)_{\min}, 0.5[(\alpha_j)_{\max} - (\alpha_j)_{\min}]\}$, $j = 1, 2$ [1], [3]. After substituting expression (6) into (3) and subtracting (4), we obtain

$$\begin{aligned} \dot{e}(t) = & -\lambda e(t) - \frac{\phi_1(t)x^2(t)}{\theta_2(t) + x(t)} \\ & + \frac{\alpha_1 \phi_2(t)x^2(t)}{[\alpha_2 + r(t)][\theta_2(t) + x(t)]} \end{aligned} \quad (8)$$

where $\phi_j(\cdot) = \theta_j(\cdot) - \alpha_j$, $(j = 1, 2)$, denote the controller parameter errors.

In this case the adaptive algorithms are suggested in the form

$$\begin{aligned} \dot{\phi}_j(t) = \dot{\theta}_j(t) = & (-1)^{j+1} \frac{\gamma_j e(t)x^2(t)}{[\theta_2(t) + x(t)]^j} \\ & \cdot \left\{ 1 - \text{sign}[e(t)x(t)] \cdot \frac{(\alpha_j)_{\max} - 2\theta_j(t) + (\alpha_j)_{\min}}{(\alpha_j)_{\max} + 2\epsilon_j - (\alpha_j)_{\min}} \right. \\ & \cdot \left. \frac{1}{k_{\theta_j}[(\alpha_j)_{\max} - \theta_j(t) - \epsilon_j][\theta_j(t) + (\alpha_j)_{\min} - \epsilon_j] + 1} \right\} \\ j = 1, 2 \end{aligned} \quad (9)$$

where $\gamma_j > 0$, $(j = 1, 2)$ denote the adaptive gains, and where $k_{\theta_j} \gg 1$, $(j = 1, 2)$. The system (8), (9) represents the error model for the case of the left parameterization.

The adaptive algorithms of the form (9) represent "smooth" adaptive algorithms with projection [2, 1]. Such algorithms assure that (7) holds. Also, it can be shown [2, 1] that (for $r = \text{const.}$) the following holds

$$\begin{aligned} \phi_j \dot{\phi}_j \leq & (-1)^{j+1} [\theta_j - \alpha_j] \frac{\gamma_j e x^2}{[\theta_2 + x]^j}, \\ \forall (\theta, \alpha, x) \in & (\mathcal{S}_\theta \times \mathcal{S}_\alpha \times \mathbb{R}^+), j = 1, 2. \end{aligned} \quad (10)$$

B Right Parameterization

In the case when $\rho = -1$, we will use the right parameterization of the plant (3) [3], which takes the form

$$\dot{x} = -\frac{\alpha_1 x^2}{1 + \alpha_2 x} + g(t, r)u \quad (11)$$

where $\alpha_1 = k_1/k_2$ and $\alpha_2 = k_3/k_2$. In this case $\alpha = [\alpha_1 \ \alpha_2]^T$, and $\alpha \in \mathcal{S}_\alpha = \{\alpha : \alpha = [\alpha_1 \ \alpha_2]^T, 0 < (\alpha_j)_{\min} \leq \alpha_j \leq (\alpha_j)_{\max}, j = 1, 2\}$, where $(\alpha_j)_{\min} = (k_{2j-1})_{\min}/(k_2)_{\max}$, $(j = 1, 2)$, and $(\alpha_j)_{\max} = (k_{2j-1})_{\max}/(k_2)_{\min}$, $(j = 1, 2)$. Also, in this case the control law is chosen as

$$u(t) = \frac{1}{g(r(t))} \left[\frac{\theta_1(t)x^2(t)}{1 + \theta_2(t)x(t)} - \lambda x(t) + b_m r \right]. \quad (12)$$

As in the previous case, we want to assure that (7) holds, for the quantities as defined above.

After substituting expression (12) into (3) and subtracting (4) we obtain

$$\begin{aligned} \dot{e}(t) = & -\lambda e(t) + \frac{\phi_1(t)x^2(t)}{1 + \theta_2(t)x(t)} \\ & - \frac{\alpha_1 \phi_2(t)x^2(t)}{[1 + \alpha_2 x(t)][1 + \theta_2(t)x(t)]} \end{aligned} \quad (13)$$

where, as in the previous case, $\phi_j(\cdot) = \theta_j(\cdot) - \alpha_j$, $(j = 1, 2)$, denote the controller parameter errors.

In this case the adaptive algorithms are suggested in the form

$$\begin{aligned} \dot{\phi}_j(t) = \dot{\theta}_j(t) = & (-1)^j \frac{\gamma_j e(t)x^2(t)}{[1 + \theta_2(t)x(t)]^j} \\ & \cdot \left\{ 1 - \text{sign}[e(t)x(t)] \cdot \frac{(\alpha_j)_{\max} - 2\theta_j(t) + (\alpha_j)_{\min}}{(\alpha_j)_{\max} + 2\epsilon_j - (\alpha_j)_{\min}} \right. \\ & \cdot \left. \frac{1}{k_{\theta_j}[(\alpha_j)_{\max} - \theta_j(t) - \epsilon_j][\theta_j(t) + (\alpha_j)_{\min} - \epsilon_j] + 1} \right\}, \\ j = 1, 2 \end{aligned} \quad (14)$$

where $k_{\theta_j} \gg 1$, $(j = 1, 2)$. Equations (13), (14) constitute the error model in the case of the right parameterization.

As in the previous case it can be also be shown that the following holds

$$\begin{aligned} \phi_j \dot{\phi}_j \leq & (-1)^j [\theta_j - \alpha_j] \frac{\gamma_j e x^{j+1}}{[1 + \theta_2 x]^j}, \\ \forall (\theta, \alpha, x) \in & (\mathcal{S}_\theta \times \mathcal{S}_\alpha \times \mathbb{R}^+), j = 1, 2. \end{aligned} \quad (15)$$

IV. STABILITY ANALYSIS

From the linear relationship $\phi_j = \theta_j - \alpha_j$, $(j = 1, 2)$, and from the definitions of the sets \mathcal{S}_α and \mathcal{S}_θ , it follows that

$$\begin{aligned} \phi(t) \in \bar{\mathcal{S}}_\phi = & \left\{ \phi : \phi = [\phi_1 \ \phi_2]^T, |\phi_j| \leq (\alpha_j)_{\max} \right. \\ & \left. - (\alpha_j)_{\min} + \epsilon_j, j = 1, 2, \forall t \in \mathbb{R}^+ \right\}. \end{aligned} \quad (16)$$

We also define sets \mathcal{S}_e and \mathcal{S}_ϕ which respectively represent open connected neighborhoods of points $e = 0$ and $\phi = 0$, with $\mathcal{S}_\phi \supset \bar{\mathcal{S}}_\phi$.

As it is well known [5], on the set $\mathcal{S} \times \mathcal{S}_\omega$ there always exists a function $V(\epsilon, \omega)$ satisfying $V \in C^{(1)}(\mathcal{S}_\epsilon \times \mathcal{S}_\omega)$, and the conditions

$$0 < b_{11}\epsilon^2 + b_{12}\|\omega\|^2 \leq V(\epsilon, \omega) \leq b_{21}\epsilon^2 + b_{22}\|\omega\|^2 \quad \forall (\epsilon, \omega) \in \mathcal{S}_\epsilon \times \mathcal{S}_\omega \quad (17)$$

where $b_{ij} \in (0, +\infty)$, $(i = 1, 2, j = 1, 2)$. The conditions (17) imply that $V(\cdot)$ is positive definite and decrescent on $\mathcal{S} \times \mathcal{S}$, as well as that it is a radially unbounded function.

Now we are ready to state the tracking conditions for the plant (3).

Theorem If the following conditions are simultaneously satisfied i) the conditions (16) and (17) hold, and ii) along the motions of the corresponding error model the following holds

$$\dot{V}(\epsilon, \omega) \leq -\lambda \epsilon^2 \leq 0 \quad \forall (\epsilon, \omega) \in (\mathcal{S} \times \mathcal{S}) \quad \forall t \geq 0 \quad (18)$$

then $\lim_{t \rightarrow \infty} \epsilon(t) = 0$.

Proof The proof follows directly from [7].

The next step is to test the stability conditions in the two cases of plant parameterizations. Since in both cases of plant parameterizations it can be readily shown that a quadratic tentative Lyapunov function is not well suited for the stability analysis of the plant (3) in this paper we will present special tentative Lyapunov functions with cubic terms originally suggested in [3].

A Left Parameterization

In this case the tentative Lyapunov function is of the form

$$V(\epsilon, \omega) = \frac{1}{2} \left(\epsilon^2 + \frac{\omega_1^2}{1} + \alpha_1 \omega^2 \right) + \frac{1}{3} \left(\frac{\alpha_1}{1 + \alpha_1} \right) \omega^3 \quad (19)$$

The first question that arises is whether $V(\epsilon, \omega)$ as defined above satisfies conditions (17). Expression (19) can be rewritten as

$$V(\epsilon, \omega) = \frac{1}{2} \left(\epsilon^2 + \frac{\omega_1^2}{1} + \frac{\alpha_1(\alpha_1 + 3\epsilon + 2\theta)}{3(\alpha_1 + 1)} \omega^3 \right) \quad (20)$$

and since the adaptive algorithms (9) assure that (7) holds, it can be readily shown that (17) holds as well. Also, since (7) holds, this implies that (16) holds as well, so that the condition i) of the Theorem is satisfied. Further, since

$$\dot{V}(\epsilon, \omega) = \epsilon\dot{\epsilon} + \frac{\omega_1\dot{\omega}_1}{1} + \alpha_1 \left(\frac{\theta_2 + \epsilon}{\alpha_1 + 1} \right) \omega\dot{\omega}$$

and with (10) in mind, the first derivative of the function $V(\epsilon, \omega)$ along the motions of (8)–(9) yields

$$\begin{aligned} \dot{V}(\epsilon, \omega) &\leq -\lambda \epsilon^2 - \frac{\epsilon\omega_1\dot{\omega}_1}{\theta + 1} + \frac{\alpha_1\epsilon\omega\dot{\omega}}{(\alpha_1 + 1)(\theta + 1)} \\ &\quad + \frac{\epsilon\omega_1\dot{\omega}_1}{\theta + 1} - \frac{\alpha_1\epsilon\omega_2\dot{\omega}}{(\theta + 1)} - \frac{\theta + 1}{\alpha_2 + 1} \\ &\leq -\lambda \epsilon^2 - \frac{\alpha_1\epsilon\omega_2\dot{\omega}}{(\alpha_1 + 1)(\theta + 1)^2(\alpha_1 + 1)} \\ &\leq -\lambda \epsilon^2 \leq 0 \quad \forall (\epsilon, \omega) \in (\mathcal{S} \times \mathcal{S}) \quad \forall t \geq 0 \end{aligned}$$

which implies that condition ii) of the theorem is satisfied. It can be concluded that when $\rho = 1$ when the control law (6) is used and when its parameters are adjusted according to (9) the output error converges to zero.

B Right Parameterization

In this case the tentative Lyapunov function is chosen in the form

$$V(\epsilon, \omega) = \frac{1}{2} \left(\epsilon^2 + \frac{\omega_1^2}{1} + \alpha_1 \frac{\omega_2^2}{\gamma} \right) + \frac{1}{3\gamma^2} \left(\frac{\alpha_1\gamma}{1 + \alpha_1\gamma} \right) \omega^3 \quad (21)$$

The above expression can be rewritten as

$$V(\epsilon, \omega) = \frac{1}{2} \left(\epsilon^2 + \frac{\omega_1^2}{\gamma} + \frac{\alpha_1(3 + \alpha_1\gamma + 2\theta\gamma)}{3\gamma(1 + \alpha_1\gamma)} \omega^3 \right) \quad (22)$$

and since (7) holds, it follows that (17) holds as well. Also, (7) implies that (16) holds, so that condition i) of the theorem is satisfied. We also have that

$$\dot{V}(\epsilon, \omega) = \epsilon\dot{\epsilon} + \frac{\omega_1\dot{\omega}_1}{\gamma} + \frac{\alpha_1}{\gamma} \left(\frac{1 + \theta\gamma}{1 + \alpha_1\gamma} \right) \omega\dot{\omega}$$

We now evaluate the first derivative of $V(\epsilon, \omega)$ along the motions of the system (13)–(14). Keeping in mind (15) we obtain

$$\begin{aligned} \dot{V}(\epsilon, \omega) &\leq -\lambda \epsilon^2 + \frac{\epsilon\omega_1\dot{\omega}_1}{1 + \theta\gamma} - \frac{\alpha_1\epsilon\omega\dot{\omega}}{(1 + \alpha_1\gamma)(1 + \theta\gamma)} \\ &\quad - \frac{\epsilon\omega_1\dot{\omega}_1}{1 + \theta\gamma} + \frac{\alpha_1\epsilon\omega\dot{\omega}}{(1 + \theta\gamma)} - \frac{1 + \theta\gamma}{1 + \alpha_1\gamma} \\ &\leq -\lambda \epsilon^2 - \frac{\alpha_1\epsilon\omega\dot{\omega}}{(1 + \alpha_1\gamma)(1 + \theta\gamma)^2(1 + \alpha_1\gamma)} \\ &\leq -\lambda \epsilon^2 \leq 0 \quad \forall (\epsilon, \omega) \in (\mathcal{S} \times \mathcal{S}) \quad \forall t \geq 0 \end{aligned}$$

It follows that for $\rho = -1$ when the control law (12) is used and when its parameters are adjusted according to (14) the output error converges to zero.

Comment In both cases of plant parameterizations it can be readily shown that the closed loop system is robust to parameter time variations and bounded external disturbances. The proof of robustness is based on the fact that the adaptive algorithms assure that the controller parameter errors are bounded for all time.

Comment One of the questions that arise is whether it is possible to use left parameterization in the case when $\rho = -1$. In such a case the plant is of the form

$$\dot{x} = -\frac{\alpha_1 x}{\alpha_1 + 1} + q(t)u$$

and the control input is chosen as

$$u(t) = \frac{1}{q(t - \tau(t))} \left[\frac{\theta_1(t)\dot{x}(t)}{\theta(t) + \tau(t)} - \lambda x(t) + b - \dot{x} \right]$$

which leads to the following error model

$$\dot{\epsilon}(t) = -\lambda \epsilon(t) + \frac{\omega_1(t)\dot{\omega}_1(t)}{\theta(t) + \tau(t)} - \frac{\alpha_1\omega_2(t)\dot{\omega}_2(t)}{[\alpha_1 + \tau(t)][\theta(t) + \tau(t)]}$$

In this case the adaptive algorithms are of the form

$$\begin{aligned} \omega_j(t) &= \theta_j(t) = (-1)^j \frac{\dot{x}(t)\dot{x}^*(t)}{[\theta(t) + \tau(t)]^j} \\ &\quad \left\{ 1 - \text{sign}[\epsilon(t)] \frac{(\alpha_1)_j \gamma - 2\theta_j(t) + (\alpha_1)_j \gamma}{(\alpha_1)_j \gamma + 2\epsilon_j - (\alpha_1)_j} \right. \\ &\quad \left. \frac{1}{k_{\theta_j}[(\alpha_1)_j \gamma - \theta_j(t) - \epsilon_j][\theta_j(t) + (\alpha_1)_j \gamma + 1]} \right\} \\ &\quad j = 1, 2 \end{aligned}$$

for which the following holds

$$\begin{aligned} \omega_j\dot{\omega}_j &\leq (-1)^j [\theta_j - \alpha_1] \frac{\dot{x}^2}{[\theta_2 + \tau]^j} \\ \forall (\theta, \alpha_1) &\in (\mathcal{S}_\theta \times \mathcal{S}_\alpha \times \mathbb{R}^+) \quad j = 1, 2 \end{aligned}$$

If we choose the tentative Lyapunov function of the form (19), its derivative being

$$\dot{V}(\epsilon, \omega) = \epsilon\dot{\epsilon} + \frac{\omega_1\dot{\omega}_1}{\gamma} + \frac{\alpha_1}{\gamma} \left(\frac{\theta_2 + \epsilon}{\alpha_1 + 1} \right) \omega\dot{\omega}$$

we obtain

$$\begin{aligned} \dot{V}(r, \phi) &\leq -\lambda e^2 + \frac{e\phi_1 x^2}{\theta_2 + x} - \frac{\alpha_1 e\phi_2 x^2}{(\alpha_2 + x)(\theta_2 + x)} \\ &\quad - \frac{e\phi_1 x^2}{\theta_2 + x} + \frac{\alpha_1 e\phi_2 x^2}{(\theta_2 + x)^2} \cdot \frac{\theta_2 + r}{\alpha_2 + r} \\ &\leq -\lambda e^2 + \frac{\alpha_1 e^2 \phi_2^2 x^2}{(\alpha_2 + x)(\theta_2 + x)^2(\alpha_2 + r)}. \end{aligned}$$

It is seen that the proof of stability goes through if

$$\lambda > \frac{4\phi_{\max}^2(\alpha_1)_{\max}}{27(\alpha_2 + r)}$$

where $\phi_{\max} = (\alpha_2)_{\max} + e_2 - (\alpha_2)_{\min}$, which may be a restrictive requirement. On the other hand, when the right parameterization is applied, the system is stable for any $\lambda > 0$.

V. CONCLUSION

In this paper the stability conditions are proved for a class of first-order plants, which contain nonlinearities similar to those arising in fermentation process growth models. Such nonlinearities are nonnegative functions of the state of the system as well as of the possibly unknown process parameters.

It was shown that different signs in front of the plant nonlinearity lead to different plant parameterizations. Such parameterizations are crucial in the choice of the control laws and adaptive algorithms for controller parameter adjustment. These parameterizations also serve as a guideline for the design of appropriate Lyapunov functions used to prove the stability conditions. The Lyapunov functions $V(\cdot)$ used in the stability analysis contain suitably chosen cubic terms which assure positive definiteness of $V(\cdot)$ as well as that the stability conditions are satisfied. Steps involved in the choice of the plant parameterization, the control laws, adaptive algorithms and the Lyapunov function, form a basis of a method for designing robust adaptive control algorithms for a class of fermentation processes. Further development of such a method is currently in progress [4].

Multiproduct Production/Inventory Control Under Random Demands

Jin Qiu and Richard Loulou

Abstract—In this note we study the optimal production/inventory control policy for a single machine multiproduct production system. The machine produces to fill the end-product inventory stock and the demand is satisfied from the inventory when available; unsatisfied demand is backlogged until the product becomes available as the result of production. For each product, the demand follows a Poisson process and the unit processing time is known. When the machine switches production from one product to another, it incurs a set-up time and a set-up cost. The relevant costs include the set-up cost, a cost per unit time while the machine is running, and linear costs for inventory and backlogging.

This problem is modeled as a semi-Markov decision process using the criterion of minimizing expected total cost with discounting over an infinite horizon. Procedures for computing near-optimal policies and their error bounds are developed. The error bound given by our procedure is shown to be much tighter than the one given by the "Norm-based" approach. Computational test results are presented to show the structure of the near-optimal policy and how its accuracy is affected by the system characteristics such as capacity utilization and set-up time.

I. INTRODUCTION

There has been a growing interest in design of multiproduct production/inventory control policies for capacitated manufacturing systems. A good control policy leads to low inventory and backlogging costs. Policies studied frequently in the literature of operations management include base stock policies (Karmarkar [8], Graves [7]), lot-sizing policy (Karmarkar *et al.* [9], Zipkin [17]), and linear control rules (Graves [5], Denardo, and Tang [2]). These policies are heuristic in nature since they are restricted to a predetermined policy structure (e.g., constant production lot size in lot-sizing policies).

In this note we explore the optimal production/inventory control policy for a single machine multiproduct production system. The machine produces to fill the end-product inventory stock, and the demand is satisfied from the inventory when available; unsatisfied demand is backlogged until the product becomes available as the result of production. There is limited stock space for each product. When the machine switches production from one product to another, it incurs a set-up time and a set-up cost, both of which are deterministic. For each product, the demand follows a Poisson process and the unit processing time is known. The relevant costs include the set-up cost, a cost per unit time while the machine is running, and linear costs for inventory and backlogging. The research objective is to find the production/inventory control policy that minimizes the expected total discounted cost over an infinite horizon.

Optimal control policies have been studied for decades for various single product production systems (see Sobel [12], Gavish and Graves [4], Srinivasan and Lee [13]). Chauny *et al.* [1] study the control problem for a single machine center multiproduct FMS (Flexible Manufacturing System) where no end-product inventory is allowed. They formulate the problem as a discrete semi-Markov decision process, which is solved by the Successive Approximation method in conjunction with interpolation techniques. Seidmann and Schweitzer [11] study the interaction of the flexible machine center and dedicated assembly lines that immediately follow. The linear cost charged

IEEE Log Number 9407000.

the time during which the assembly lines are idle is used as a surrogate measure of the throughput loss. This measure may, however, be difficult to justify when the goal of the production system is to produce to match the demand at the lowest cost rather than producing at the maximum rate. Graves [6] proposes a state-dependent heuristic solution procedure for the discrete-time, single machine multiproduct cycling problem. The simulation results show that the heuristic policies perform better than (s, S) or lot-sizing policies in most cases.

In this research, we allow both end-product inventory and backorders and develop a near-optimal production/inventory control policy for the production control problem. In Section II, we formulate the problem as a discrete semi-Markov decision process. In Section III, we develop a solution procedure which leads to a near-optimal policy and a procedure for generating its error bound. Computational test results are also presented to show the structure of the near-optimal policy and how its accuracy is affected by the system characteristics such as capacity utilization and set-up time. In Section IV, we conclude with a discussion on the future extension of this research.

II. DEVELOPMENT OF THE MODEL

Notations:

n	index for product, $1 \leq n \leq N$.
λ_n	demand rate of product n .
$d_n(t)$	cumulative demand of product n during time interval $[0, t]$; its distribution is Poisson with mean $\lambda_n t$.
τ_n	unit processing time of product n .
T_{ij}, W_{ij}	set-up time and cost when the machine switches production from product i to product j .
	$T_{n,n}, W_{n,n} = 0 \quad \forall n$.
c	production cost rate (\$/unit time).
g_n	inventory holding cost rate of product n (\$/unit time/unit).
g_{bn}	backlogging cost rate of product n (\$/unit time/unit).
$I(x_n)$	inventory/backlogging cost = $\begin{cases} g_n x_n & \text{if } x_n \geq 0 \\ -g_{bn} x_n & \text{if } x_n < 0. \end{cases}$
Q_n	limit on the end-product inventory of product n .
α	continuous discount rate, $\alpha > 0$.
$\text{Prob}(y = y_0)$	probability that y is equal to y_0 .
$E[y]$	expectation of random variable y .
$\exp(y)$	exponential function e^y .

The production/inventory control problem is formulated as a semi-Markov decision process (SMDP) (Denardo [3]) with the following characteristics.

State Space: The state of the system is comprised of the inventory state and machine set-up status. The inventory state space is defined as $X = \{x \in Z^N: x_n \leq Q_n, 1 \leq n \leq N\}$ with x_n representing the inventory (backlog if $x_n < 0$) level for product n . Let index k denote the machine status such that $k = n$ means that the machine is set up for product n . The state space of the system is thus defined as $S = \{s \in Z^{N+1}: s = (x, k)\}$.

Action Space: We assume that the production process is reviewed at those points in time when either the machine is idle and some demand arrives or when an item has just been processed and the machine becomes free. In other words, we assume that preemption of set-up or processing is not allowed. At any review point, one of $N+1$ actions is taken: let the machine stay idle ($a = 0$) and keep the latest set-up, or produce one of the N products ($a = n, 1 \leq n \leq N$).

The action space is thus defined as $A = \{a: a = 0, 1, \dots, N\}$. A stationary policy π consists of the set of actions taken depending on the observed state s .

Immediate Costs: Given any state of the system $s = (x, k)$, if action a ($a > 0$) is taken, the next decision point is the epoch at which one item of product a has just been processed. The discounted production cost during the time period $T_{ka} + \tau_a$ (note that $W_{ka} = T_{ka} = 0$ if $k = a$), $PC(k, a)$, includes set-up and variable costs and is given by

$$\begin{aligned} PC(k, a) &= W_{ka} + \int_{T_{ka}}^{T_{ka} + \tau_a} \exp(-\alpha \cdot t) \cdot c \cdot dt \\ &= W_{ka} + c \cdot \exp(-\alpha \cdot T_{ka}) \cdot \frac{1 - \exp(-\alpha \cdot \tau_a)}{\alpha}. \end{aligned}$$

The expected discounted inventory cost for product n during the same time period $T_{ka} + \tau_a$, $R_n(x_n, k, a)$, is given by

$$R_n(x_n, k, a) = \begin{cases} u_n(k, a) - b_n(k, a) \cdot x_n & \text{if } x_n \leq 0 \\ (g_n + g_{bn}) \cdot \sum_{i=0}^{x_n} (x_n - i) \cdot F_n(i, k, a) \\ \quad + u_n(k, a) - b_n(k, a) \cdot x_n & \text{if } x_n > 0 \end{cases}$$

where

$$u_n(k, a) = g_{bn} \cdot \lambda_n \cdot \left(\frac{1 - \exp(-\alpha \cdot (T_{ka} + \tau_a))}{\alpha^2} - \frac{(T_{ka} + \tau_a) \exp(-\alpha \cdot (T_{ka} + \tau_a))}{\alpha} \right)$$

$$b_n(k, a) = g_{bn} \cdot \frac{1 - \exp(-\alpha \cdot (T_{ka} + \tau_a))}{\alpha}. \quad (1)$$

See Appendix A for details of $F_n(i, k, a)$ and $R_n(x_n, k, a)$.

If the decision is to let the machine stay idle ($a = 0$) at state $s = (x, k)$, the next decision point is the epoch at which the next demand arrives. The expected discounted inventory cost for any product n until the next demand arrival is given by

$$\begin{aligned} R_n(x_n, k, a = 0) &= E_\theta \left[\int_0^\theta \exp(-\alpha \cdot t) \cdot I(x_n) \cdot dt \right] \\ &= E_\theta \left[\frac{1 - \exp(-\alpha \theta)}{\alpha} \right] \cdot I(x_n) \end{aligned}$$

where θ is the random variable representing the time between demand arrivals. The probability distribution of θ is exponential with parameter $\Lambda = \sum_{n=1}^N \lambda_n$. It follows that

$$R_n(x_n, k, a = 0) = \frac{I(x_n)}{\Lambda + \alpha} = \begin{cases} \frac{g_n}{\Lambda + \alpha} \cdot x_n & \text{if } x_n \geq 0 \\ -\frac{g_{bn}}{\Lambda + \alpha} \cdot x_n & \text{if } x_n < 0. \end{cases} \quad (2)$$

Therefore, the immediate cost for any action at state s , $C(s, a)$, can be expressed as

$$C(s, a) = PC(k, a) + \sum_{n=1}^N R_n(x_n, k, a) \quad (3)$$

where $PC(k, a = 0)$ is understood to be zero.

The dynamic programming recursion for minimizing the expected total discounted cost over an infinite horizon is as follows

$$\begin{aligned} V(s) &= \min \left\{ \left[C(s, a = 0) + \rho(k, a = 0) \right. \right. \\ &\quad \left. \left. + \sum_{n=1}^N \frac{\lambda_n}{\Lambda} \cdot V(x - e_n, k) \right]; \right. \\ &\quad \min_{a > 0} \left[C(s, a) + \rho(k, a) \cdot \sum_{j_1=0}^{\infty} P_1(j_1 | k, a) \cdots \right. \\ &\quad \left. \left. \cdot \sum_{j_N=0}^{\infty} P_N(j_N | k, a) \cdot V(x + e_a - j, a) \right] \right\} \quad (4) \end{aligned}$$

where

$$\rho(k, a) = \begin{cases} E_\theta[\exp(-a \cdot \theta)] = \frac{\lambda}{\lambda + a} & \text{if } a = 0 \\ \exp(-a \cdot (T_{k,a} + \tau_a)) & \text{if } a > 0 \end{cases}$$

$$e_a = \text{unit vector along } a^{\text{th}} \text{ coordinate}, \quad 1 \leq a \leq N$$

$$P_n(j_n | k, a > 0) = \text{Prob}(d_n(T_{k,a} + \tau_a) = j_n), \quad 1 \leq n \leq N$$

$$j = \text{vector}[j_n, 1 \leq n \leq N].$$

The first set of square brackets in (4) contains the cost for letting the machine stay idle until the next demand arrival. The second set of brackets contains the cost for producing one item of product a .

III. SOLUTION METHOD

Note that the model in (4) is defined on an infinite inventory state space which leads to unbounded costs. The general unbounded stochastic dynamic programming problems have been studied by many authors (see Whitt [15], Wessels [14], Lippman [10]). The major results have been summarized and extended by Van Nunen and Wessels [16]. In the context of our model in (4), the key results can be described as follows. Let μ be a positive function on S satisfying Assumption 2.3 in Van Nunen and Wessels [16]. (It could be shown that $\mu(s) = (\prod_{n=1}^N |x_n|)^{-1}$ or $\mu(s) = (\sum_{n=1}^N |x_n|)^{-1}$ satisfy the above assumption for our problem.) Denote by \bar{U} the class of real-valued functions on S with the property $\|v\| = \sup_{s \in S} |v(s)| \cdot \mu(s) < \infty$. Define on \bar{U} operators H for policy π and U^* , respectively, by

$$H_\pi v(s) = C(s, \pi(s)) + G(s, \pi(s), v)$$

where

$$G(s, \pi(s), v) = \begin{cases} \rho(k, a=0) \cdot \sum_{n=1}^N \frac{\lambda_n}{\lambda} \cdot v(x - e_n, k) & \text{if } \pi(s) = 0 \\ \rho(k, \pi(s)) \cdot \sum_{j_1=0}^{\infty} P_1(j_1 | k, \pi(s)) \cdots & \\ \sum_{j_N=0}^{\infty} P_N(j_N | k, \pi(s)) & \\ \cdot v(x + e_{\pi(s)} - j, \pi(s)) & \text{if } \pi(s) > 0 \end{cases} \quad (5)$$

and

$$U^* v(s) = \min \left\{ \left[C(s, a=0) + \rho(k, a=0) \cdot \sum_{n=1}^N \frac{\lambda_n}{\lambda} \cdot v(x - e_n, k) \right]; \right. \\ \left. \min_{a > 0} \left[C(s, a) + \rho(k, a) \cdot \sum_{j_1=0}^{\infty} P_1(j_1 | k, a) \cdots \right. \right. \\ \left. \left. \cdot \sum_{j_N=0}^{\infty} P_N(j_N | k, a) \cdot v(x + e_a - j, a) \right] \right\}. \quad (6)$$

Wessels [14] has shown that successive applications of U^* (respectively, H_π) converge in norm to V^* , the value function following the optimal policy (respectively, to V_π , the value function following policy π).

Due to the infinite inventory state space, however, the Successive Approximations scheme cannot be applied directly to our model. In Subsection A, a near-optimal policy is obtained by solving a problem defined on a truncated inventory state space. The challenge of our problem lies with the development of an error bound for using the near-optimal policy. A general approach proposed by Lippman [10] and Van Nunen and Wessels [16] for unbounded stochastic programming problems results in an extremely large error bound when applied to our policy. In Subsection B, we derive an alternative approach that yields a much tighter error bound on the same policy.

We also discuss the reasons for the improvement. In Subsection C we show the computational test results of the error bounds and the structure of our policies based on problems involving two products.

A. Approximation via a Finite-State Model

We first define a function that maps the infinite inventory state space onto a finite one. A policy is obtained by applying the Successive Approximations algorithm to a model defined on the finite inventory state space. This policy is then extended to construct a near-optimal policy for the original model.

Construct a finite inventory state space $\bar{X} = \{\bar{x} \in Z^N: L_n \leq \bar{x}_n \leq B_n, 1 \leq n \leq N\}$ through a mapping $p: X \mapsto \bar{X}$ defined by

$$\begin{cases} p(x_n) = x_n & \text{if } x_n \geq L_n \\ p(x_n) = L_n & \text{if } x_n < L_n \end{cases} \quad (7)$$

where $L = [L_n, 1 \leq n \leq N]$ can be interpreted as a truncation state in the original inventory state X . We restrict L_n to be less than zero for all n in order to allow for both positive and negative (backorders) inventories in \bar{X} . Define $\bar{S} = \{\bar{s} \in Z^{N+1}, \bar{s} = (\bar{x}, k)\}$. Clearly \bar{S} is a subset of S . Let \bar{U} be the class of bounded functions $\bar{U}(\cdot): \bar{S} \mapsto \mathcal{R}$, and $\bar{\pi}$ be a policy on \bar{S} . On \bar{U} we define operators $\bar{H}_{\bar{\pi}}$ for any policy $\bar{\pi}$, and \bar{U}^* , respectively, by

$$\bar{H}_{\bar{\pi}} \bar{v}(\bar{s}) = H_{\bar{\pi}} v_p(\bar{s}) \quad (8)$$

and

$$\bar{U}^* \bar{v}(\bar{s}) = U^* v_p(\bar{s}) \quad (9)$$

where $v_p(s)$ is a function in \bar{U} defined as $v_p(s) = \bar{v}(p(s), k)$ and π is a policy on S defined as $\pi(s) = \bar{\pi}(p(s), k)$.

Starting with an arbitrary function \bar{v}_0 in \bar{U} , iterations based on (9) are performed m times. Denote by $\bar{v}^{(m)}$ and $\bar{\pi}^{(m)}$, respectively, the value function and the policy determined by the last iteration. Based on the value function $\bar{v}^{(m)}$, two additional operations are performed as follows: $\bar{v}^{(m+1)} = \bar{H}_{\bar{\pi}^{(m)}} \bar{v}^{(m)}$ and $\bar{\pi}^{(m+1)} = \bar{U}^* \bar{v}^{(m)}$. Let $\delta^* = \max_{\bar{s} \in \bar{S}} |\bar{v}^{(m+1)}(\bar{s}) - \bar{v}^{(m)}(\bar{s})|$ and $\delta_* = \max_{\bar{s} \in \bar{S}} |\bar{v}^{(m)}(\bar{s}) - \bar{v}^{(m-1)}(\bar{s})|$. According to the contraction mapping theory (Denardo [3]), both δ^* and δ_* converge to zero as the number of iterations m goes to infinity.

In the next subsection, we derive a bound on the error, $V(s) - V_\pi(s)$, due to using policy π ($\pi(s) = \bar{\pi}(p(s), k)$), for the original production/inventory control problem defined in (4). We will also discuss how the error bound is affected by δ^* and δ_* .

B. Error Bound on the Near-Optimal Policy

Define a row vector $B(s) = [b_1(k, \pi(s)), \dots, b_N(k, \pi(s))]$, where $b_n(k, a > 0)$ is the immediate expected backlogging ($x_n < 0$) cost per unit defined in (1) and $b_n(k, a = 0) = g_{bn}/(\lambda + a)$ as indicated in (2).

Let $y^+ = \max\{y, 0\}$ and $(L - x)^+$ represent the column vector $[(L_n - x_n)^+, 1 \leq n \leq N]$. Define a sequence of value functions $u^{(i)}$ on S as follows:

$$u^{(1)}(s) = B(s) \cdot (L - x)^+ \quad (10)$$

$$u^{(i+1)}(s) = G(s, \pi(s), u^{(i)}), \quad i \geq 1 \quad (11)$$

where $G(s, \pi(s), v)$ in (11) is defined in (5).

Theorem 1. Let $\rho = \max_{k,a} \{\rho(k, a)\}$ and define a function $v_p^{(i)}(s)$ in \bar{U} as $v_p^{(i)}(s) = \bar{v}^{(i)}(p(s), k)$, then

$$V_\pi(s) \leq v_p^{(i)}(s) + \frac{\delta^*}{1 - \rho} + \sum_{i=1}^i u^{(i)}(s). \quad (12)$$

Proof Since $\pi(s) = \bar{\pi}(p(i) | k)$ by the definition of policy π immediate inventory cost $R_i(i, k | \pi(s))$ and the immediate cost $C(s | \pi(s))$ (both defined in Section II) can be rewritten as

$$l(i, k | \pi(s)) = R_n(p(i, k | \pi(s))) + b(k | \pi(s)) (L - i)^+$$

$$C(s | \pi(s)) = PC(k | \pi(s)) + \sum_1^N R(i, k | \pi(s)) \\ = C(p(i) | k | \pi(s)) + u^{(1)}(s)$$

$$H_{\pi} i_j'(s) = C(s | \pi(s)) + G(s | \tau(s) | i_j) \\ = i_j^{-1}(p(i) | k) + u^{(1)}(s) \\ \leq i_j(s) + \delta^* + u^{(1)}(s)$$

$$H_{\pi} i_j'(s) \leq H_{\pi}(i_j + \delta^* + u^{(1)}) \\ = C(s | \pi(s)) + G(s | \tau(s) | i_j + \delta^* + u^{(1)}) \\ \leq i_j(s) + (1 + \rho) \delta^* + u^{(1)}(s) + u^{(1)}(s)$$

Since $H_{\pi} i_j \rightarrow V_{\pi}$ we obtain

$$V_{\pi}(s) \leq i_j(s) + \frac{\delta^*}{1 - \rho} + \sum_1^N u^{(1)}(s) \quad \square$$

Theorem 2

$$V(s) = E^{\infty} i_j(s) \geq i_j(s) - \frac{\delta_*}{1 - \rho} \quad (13)$$

Theorem 2 is proved in a way similar to Theorem 1. Theorems 1 and 2 lead to the following result

$$i_j(s) - \frac{\delta_*}{1 - \rho} \leq V(s) \leq V_{\pi}(s) \leq i_j(s) + \frac{\delta^*}{1 - \rho} + \sum_1^N u^{(1)}(s)$$

Computing an Upper Bound on $\sum_1^N u^{(1)}(s)$ The exact value of $\sum_1^N u^{(1)}(s)$ is difficult to compute since $u^{(1)}(s)$ itself may involve infinite arithmetic operations (when $\pi(s) \sim 0$). In what follows we provide a procedure for finding its upper bound.

First a crude upper bound on $u^{(1)}(s)$ $\bar{u}^{(1)}(s)$ can be easily derived and is given as follows

$$\bar{u}^{(1)}(s) = \rho^{-1} B^* [(L - i)^+ + (i - 1) - V^*] \quad \forall s \in S, i \geq 1$$

where the row vector $B^* = [\max_k \{b(k | a)\} \quad 1 \leq n \leq N]$ and the column vector $V^* = [\max \{V / \Lambda \mid \max_k \{F[d(\tau + I_k)]\} \quad 1 \leq n \leq N\}]$. Note that $F[d(\tau + I_k)] = V(\tau + I_k)$. Given an integer M we obtain

$$\sum_1^N u^{(1)}(s) \leq \sum_1^M u^{(1)}(s) + \sum_{M+1}^N \bar{u}^{(1)}(s) \\ = \sum_1^M u^{(1)}(s) + \rho^M B^* \\ \left[\frac{(L - i)^+}{1 - \rho} + \frac{M(1 - \rho) + \rho}{(1 - \rho)^2} - V^* \right]$$

Clearly when M is large the right-hand side of the above inequality is close to $\sum_1^N u^{(1)}(s)$

Second define a sequence of value functions $u^{(n)}(s)$ as follows

$$\bar{u}^{(1)}(s) = u^{(1)}(s) \quad \forall s \in S$$

$$u^{(n)}(s) = \bar{u}^{(n)}(s) \quad \text{if } i < I \quad \text{for some } n \leq i - 1$$

$$u^{(n+1)}(s) = G(s | \pi(s) | u^{(n)}) \quad \text{if } i \geq I \quad \text{for all } n \leq i - 1$$

It can be shown by induction that $u^{(i)}(s) \leq u^{(i-1)}(s)$. Appendix B shows that $u^{(i)}(s)$ can be computed within finite arithmetic. Let

$$\delta(s) = \sum_1^M u^{(i)}(s) + \rho^M B^* \\ \left[\frac{(L - i)^+}{1 - \rho} + \frac{M(1 - \rho) + \rho}{(1 - \rho)^2} - V^* \right]$$

The bound on the error due to using near optimal policy $\tau | \pi(s) - V(s)$ is thus given by

$$\epsilon(s) = \frac{\delta_* + \delta}{1 - \rho} + \delta(s) \quad (14)$$

Remark 1 The error bound in (14) has three components: δ_* , δ^* and δ where δ_* and δ^* measure the error due to the Successive Approximations on the truncated model. Given any truncated inventory state space δ_* and δ^* can be made arbitrarily small by performing a large number of iterations based on (9). $\delta(s)$ on the other hand measures the error due to truncation and it can only be made small by reducing L . The last point can be demonstrated by the numerical results reported in the next subsection. Consequently the quality of the near optimal solution is mainly determined by the selection of the truncation state L .

Remark 2 A general approach for deriving an error bound for unbounded stochastic dynamic programming problems can be found in Lippman [10] and Van Nunen and Wessels [16]. The key element to the general approach is the norm $\|H_{\pi} i_j - i_j\|$ defined as $\max_{s \in S} \{|H_{\pi} i_j(s) - i_j'(s)| \mid \mu(s)\}$. We have tried two forms of μ : $\mu(s) = (\prod_{i=1}^N |i|)^{-1}$ and $\mu(s) = (\sum_{i=1}^N |i|)^{-1}$ but both yield extremely large error bounds (100-1000% of the lower bound in all instances tested). More critically there is no indication that the error bound would approach zero when the truncation state I decreases to $-\infty$. In contrast the results based on our approach show (in the next subsection) that the error for using policy π is bounded by a rather small value when the initial inventory state is reasonably far above the truncation state. The improvement in our view comes from the fact that our approach explicitly uses the Poisson probability distribution (for computing $u^{(1)}$ in δ) which guarantees that the probability of reaching the inventory state below the current one decreases exponentially. As a result the impact of the value function in inventory states below the truncation state which is not captured by the Successive Approximations procedure on the truncated state space is not significant.

C. Experimental Results Based on Two Product Problems

We now consider a manufacturing system that produces two homogeneous products. Four experiments (shown in Table I) are conducted to examine the impact of set-up time and capacity utilization denoted by τ ($\tau = 2 - \lambda \tau$, for our experiments), on the error bound of the near-optimal policies.

For each problem a near-optimal policy is computed based on the iteration procedure (9) with the following stopping criterion

$$\max_{s \in S} \left\{ \frac{\delta_* + \delta}{1 - \rho} \right\} \leq 0.001$$

TABLE I
FOUR EXPERIMENTS

Parameters	Experiments			
	Problem 1	Problem 2	Problem 3	Problem 4
$T_{12} = T_{21} = T$	$T = 1.0$	1.0	2.0	2.0
$\lambda_1 = \lambda_2 = \lambda$	0.25	0.40	0.25	0.40
$\tau_1 = \tau_2 = \tau$	1.0	1.0	1.0	1.0
$r = 2\lambda\tau$	0.50	0.80	0.50	0.80
$c_1 = c_2$	\$3000	\$3000	\$3000	\$3000
$W_1 = W_2$	\$50	\$50	\$50	\$50
$g_1 = g_2$	\$100	\$100	\$100	\$100
$g_{b1} = g_{b2}$	\$500	\$500	\$500	\$500
$Q_1 = Q_2$	50	50	50	50
$L_1 = L_2$	-50	-50	-50	-50
α	0.025	0.025	0.025	0.025

The quantity on the left-hand side of the above inequality represents the relative error bound due to the imperfect convergence of the Successive Approximations procedure for generating the near-optimal policy.

We then compute the maximum of the relative error due to truncation, defined as $\delta(s)/\bar{v}'''(s)$, over five different inventory state regions. The results are presented in Table II. The following two observations are of particular interest.

1) In each experiment, the error due to truncation tends to increase as the initial inventory state moves closer to the truncation state L , and becomes extremely large when the initial inventory level for both products is below -35 [with $L = (-50, -50)$]. This means that the near-optimal policy can be a good approximation of the true optimal one only when the initial inventory state is reasonably far above the truncation state L . Therefore, for a given initial inventory state, the near-optimal policy can be improved by reducing L . This obviously means increased computing time required for generating the near-optimal policy since the iterations based on (9) have to be performed over a larger inventory state space.

2) Given the same region of initial inventory states, the error due to truncation tends to increase as the capacity utilization and/or set-up time increase. Intuitively, this is because the probability of the inventory state moving beyond the truncation state in the future transitions increases as the machine becomes busier. This suggests that the truncation state L required for generating good near-optimal policies is determined by the machine capacity utilization and/or set-up time; the higher the machine capacity utilization and/or set-up time, the lower the truncation state has to be (which means more computing time required as a result of observation 1).

Fig. 1 depicts the structure of the near-optimal policy for the problem with $r = 0.5$ and $T = 1.0$. The two coordinates represent the inventory positions for products 1 and 2, respectively. The solid (dashed) lines delimit the actions to be taken when the machine is set up for product 1 (product 2). These lines (also called *switching curves*), create four regions, and in any one region the action is well defined. Thus, in region I (respectively, region III), one should produce product 1 (product 2, respectively), irrespective of the current machine status. In region II, do not produce anything, but keep current machine set-up. In region IV, continue to produce current product (whether 1 or 2). The shape of the policy clearly indicates the monotonicity property: given the machine status and inventory level

Fig. 1. The near-optimal policy

for one product, there is a unique threshold level for the other product to switch the decision, either to stop production or start producing the other one. It also shows that the near-optimal policy is not of the classical (s, Q) or (s, S) types, since the points at which production switches depend on *both* inventory levels and the quantities produced depend on the quantities of the realized demands for *both* products during the production run.

IV. CONCLUSIONS

In this note, we have developed a procedure that generates near-optimal policies for the single machine multiproduct production/inventory control problem by solving a problem defined on a truncated inventory state space. The experiment test results have shown that the error for using a near-optimal policy is bounded by a small value if the initial inventory state is reasonably far above the truncation state. We have also found that policies based on predetermined structures such as lot-sizing and (s, S) policies can be very different from the optimal policy and therefore perform poorly in practice. For a problem that involves many products, however, our procedure cannot be both efficient and accurate due to the "curse of dimensionality." For a ten-product problem, for instance, even if we preserve only five inventory states for each product in the truncated space, the total number of inventory states becomes $5^{10} \times 10 = 9.76 \times 10^7$.

We are in the process of developing a decomposition/aggregation solution procedure for problems with many products. For an N -product problem, the procedure decomposes the problem into N subproblems, each involving a single product and a composite product that represents the remaining $N - 1$ products. Based on the solutions of the two-product subproblems using the method developed in this note, the procedure constructs a separate policy for each individual product such that policies for different products do not conflict at any state of the system. Preliminary results have shown that this procedure leads to very good policies.

TABLE II
RELATIVE ERROR BOUNDS OF THE NEAR-OPTIMAL POLICIES DUE TO TRUNCATION

Parameters		Inventory State Regions				
		$x_1 \geq -15$	$x_1 \geq -20$	$x_1 \geq -25$	$x_1 \geq -35$	$x_1 \geq -50$
		$x_2 \geq -15$	$x_2 \geq -20$	$x_2 \geq -25$	$x_2 \geq -35$	$x_2 \geq -50$
$r = 0.5$	$T = 1.0$	1.56×10^{-13}	3.37×10^{-9}	9.76×10^{-6}	8.89×10^{-2}	1.61
	$T = 2.0$	4.56×10^{-13}	9.46×10^{-9}	2.61×10^{-5}	0.21	3.57
$r = 0.8$	$T = 1.0$	4.17×10^{-5}	4.07×10^{-3}	9.64×10^{-3}	0.74	2.71

APPENDIX A

THE INVENTORY COST DURING UNIT PROCESSING TIME

If $x_n < 0$,

$$\begin{aligned} R_n(x_n, k, a) &= \int_0^{T_{ka} + \tau_a} \exp(-\alpha \cdot t) \cdot g_{bn} \cdot E[d_n(t) - x_n] \cdot dt \\ &= \int_0^{T_{ka} + \tau_a} \exp(-\alpha \cdot t) \cdot g_{bn} \cdot (\lambda_n \cdot t - x_n) \cdot dt \\ &= a_n(k, a) - b_n(k, a) \cdot x_n. \end{aligned}$$

If $x_n \geq 0$,

$$\begin{aligned} R(x_n, k, a) &= \int_0^{T_{ka} + \tau_a} \exp(-\alpha \cdot t) \cdot \{g_n \cdot E[(x_n - d_n(t))^+] \\ &\quad + g_{bn} \cdot E[(x_n - d_n(t))^-]\} \cdot dt \\ &= \int_0^{T_{ka} + \tau_a} \exp(-\alpha \cdot t) \\ &\quad \cdot \left[g_n \cdot \sum_{i=0}^{x_n} (x_n - i) \cdot \text{Prob}(d_n(t) = i) \right. \\ &\quad \left. + g_{bn} \cdot \sum_{i=x_n+1}^{\infty} (i - x_n) \cdot \text{Prob}(d_n(t) = i) \right] \cdot dt \\ &= \int_0^{T_{ka} + \tau_a} \exp(-\alpha \cdot t) \\ &\quad \cdot \left[(g_n + g_{bn}) \cdot \sum_{i=0}^{x_n} (x_n - i) \frac{(\lambda_n \cdot t)^i \exp(-\lambda_n \cdot t)}{i!} \right. \\ &\quad \left. + \int_0^{T_{ka} + \tau_a} \exp(-\alpha \cdot t) \cdot g_{bn} \cdot (\lambda_n \cdot t - x_n) \cdot dt \right] \cdot dt. \end{aligned}$$

The second term is exactly $a_n(k, a) - b_n(k, a) \cdot x_n$. The first term becomes

$$\begin{aligned} (g_n + g_{bn}) \cdot \sum_{i=0}^{x_n} (x_n - i) \cdot \int_0^{T_{ka} + \tau_a} \exp(-(\lambda_n + \alpha) \cdot t) \\ \cdot \frac{(\lambda_n \cdot t)^i}{i!} \cdot dt = (g_n + g_{bn}) \cdot \sum_{i=0}^{x_n} (x_n - i) \cdot F_n(i, k, a) \end{aligned}$$

where $F_n(i, k, a)$ can be computed using the recursive relationship

$$\begin{aligned} F_n(i, k, a) &= \int_0^{T_{ka} + \tau_a} \exp(-(\lambda_n + \alpha) \cdot t) \cdot \frac{(\lambda_n \cdot t)^i}{i!} \cdot dt \\ &= \frac{(\lambda_n \cdot (T_{ka} + \tau_a))^i \cdot \exp(-(\lambda_n + \alpha) \cdot (T_{ka} + \tau_a))}{-(\lambda_n + \alpha) \cdot i!} \\ &\quad + \frac{\lambda_n}{\lambda_n + \alpha} \cdot F_n(i-1, k, a) \end{aligned}$$

with $F_n(0, k, a) = \int_0^{T_{ka} + \tau_a} \exp(-(\lambda_n + \alpha) \cdot t) \cdot dt = [1 - \exp(-(\lambda_n + \alpha) \cdot (T_{ka} + \tau_a))]/(\lambda_n + \alpha)$.

APPENDIX B

COMPUTATION OF THE FUNCTIONS $\hat{u}^{(i)}$

The function $\hat{u}^{(i)}(s)$ is easy to compute at state s where $\pi(s) = 0$. The following is the procedure for computing $\hat{u}^{(i)}(s)$ at state s where $\pi(s) > 0$:

$$\begin{aligned} \hat{u}^{(i+1)}(s) &= G(s, \pi(s), \hat{u}^{(i)}) \\ &= \rho(k, \pi(s)) \cdot \sum_{j_1=0}^{x_1 + e_{\pi(s), 1} - L_1} P_1(j_1 | k, \pi(s)) \cdots \\ &\quad \cdot \sum_{j_N=0}^{x_N + e_{\pi(s), N} - L_N} P_N(j_N | k, \pi(s)) \\ &\quad \cdot \hat{u}^{(i)}(x + e_{\pi(s)} - j, \pi(s)) + \rho(k, \pi(s)) \cdot \rho^{i-1} \cdot B^* \\ &\quad \cdot \left\{ (i-1) \cdot \left[1 - \prod_{n=1}^N \sum_{j=0}^{x_n + e_{\pi(s), n} - L_n} P_n(j | k, \pi(s)) \right] \right. \\ &\quad \left. \cdot A^* + D(s) \right\} \end{aligned}$$

where the column vector $D(s)$ is given by

$$\begin{aligned} D(s) &= \left[\lambda_n \cdot (\tau_{\pi(s)} + T_{k, \pi(s)}) \right. \\ &\quad \left. - \sum_{j=0}^{x_n + e_{\pi(s), n} - L_n} P_n(j | k, \pi(s)) \cdot j, 1 \leq n \leq N \right] \end{aligned}$$

and $e_{\pi(s), n}$ represents the n^{th} entry in vector $e_{\pi(s)}$, $1 \leq n \leq N$.

The Partial Model Matching or Partial Disturbance Rejection Problem: Geometric and Structural Solutions

Michel Malabre and Juan Carlos Martinez Garcia

Abstract—The Partial Model Matching Problem (or equivalently, the Partial Disturbance Rejection Problem) is revisited here. It has been initially introduced in [2] and amounts to matching the first k Markov parameters of the plant with those of the model. This obviously finds all its interest when no solution exists to the Exact Problem. We give both geometric and structural solutions to these problems. The geometric solution is in terms of the steps of the well known supremal output nulling controlled invariant subspace algorithm. The structural conditions amount to comparing some list of integers, namely some orders of zeros at infinity.

I. NOTATION AND BASIC CONCEPTS

Throughout the paper we shall essentially follow the notational conventions of [11]. Script capital $(\mathcal{X}, \mathcal{Y}, \dots)$ denote finite-dimensional vector spaces over the field of real numbers \mathbb{R} , and $\dim(\mathcal{X}), \dim(\mathcal{Y}), \dots$ denote their dimensions. The notation $\mathcal{X} \simeq \mathcal{Y}$ means $\dim(\mathcal{X}) = \dim(\mathcal{Y})$. If $\mathcal{V} \subset \mathcal{X}$, then \mathcal{X}/\mathcal{V} denotes the quotient space \mathcal{X} modulo \mathcal{V} .

Italic capitals (A, B, \dots) denote interchangeably linear maps and their matrix representations in particular bases. The image of a map B is written as $\text{Im}B$ and its kernel as $\text{Ker}B$. The identity map on a n -dimensional space is denoted by I_n .

It is assumed here that the reader is familiarized with the concepts of (A, B) and (C, A) -invariance [11].

IEEE Log Number 9407218.

We shall consider linear time-invariant systems described by

$$\begin{cases} \dot{x}(t) = Ax(t) + Bu(t), & t \geq 0 \\ y(t) = Cx(t), & t \geq 0 \end{cases} \quad (1)$$

with $A: \mathcal{X} \rightarrow \mathcal{X}$, $B: \mathcal{U} \rightarrow \mathcal{X}$, $C: \mathcal{X} \rightarrow \mathcal{Y}$ ($\dim(\mathcal{X}) = n$, $\dim(\mathcal{U}) = m$, $\dim(\mathcal{Y}) = p$). This system will be noted by (A, B, C) .

Let us denote:

- $\mathcal{B} = \text{Im}B$.
- $\mathcal{K} = \text{Ker}C$.
- $\mathcal{J}(A, B; \mathcal{K})$ the family of (A, B) -invariant subspaces contained in \mathcal{K} , also called output nulling controlled invariant subspaces.
- $\mathcal{C}(C, A; \mathcal{B})$ the family of (C, A) -invariant subspaces containing \mathcal{B} .
- \mathcal{V}^* the supremal element of $\mathcal{J}(A, B; \mathcal{K})$. \mathcal{V}^* is equal to the limit of the Invariant Subspace Algorithm (ISA) for (A, B, C)

$$\begin{cases} \mathcal{V}^0 := \mathcal{X} \\ \mathcal{V}^i := \mathcal{K} \cap A^{-1}(\mathcal{B} + \mathcal{V}^{i-1}), & i \geq 1. \end{cases} \quad (2)$$

- \mathcal{S}^* the infimal element of $\mathcal{C}(C, A; \mathcal{B})$. \mathcal{S}^* is equal to the limit of the Conditioned Invariant Subspace Algorithm (CISA)

$$\begin{cases} \mathcal{S}^0 := 0 \\ \mathcal{S}^i := \mathcal{B} + A(\mathcal{K} \cap \mathcal{S}^{i-1}), & i \geq 1. \end{cases} \quad (3)$$

- $\mathcal{F}(\mathcal{V}^*)$ the family of static state feedback maps such that $(A + BF)\mathcal{V}^* \subset \mathcal{V}^*$.

Infinite Zero Structure

Given any system (A, B, C) described by (1) or equivalently by its strictly proper $(p \times m)$ transfer function matrix

$$T(s) := C(sI_n - A)^{-1}B \quad (4)$$

its structure at infinity, since such systems have no poles at infinity, is described by the multiplicity orders of its zeros at infinity. From an algebraic point of view, this structure can be derived from the so-called Smith-McMillan Form at infinity of $T(s)$, say Λ_∞ , which is a canonical form under right and left biproper transformations (see for instance [10]). Indeed, there exist biproper matrices, $D_1(s)$ and $D_2(s)$, such that

$$D_1(s)T(s)D_2(s) = \Lambda_\infty = \begin{bmatrix} \Delta_\infty & 0 \\ 0 & 0 \end{bmatrix}$$

where $\Delta_\infty = \text{diag}\{s^{-n_1}, s^{-n_2}, \dots, s^{-n_r}\}$, $r := \text{rank}(T(s))$.

The nonincreasing list of integers $\{n_i\}$ is the list of the orders of the zeros at infinity of the system. From a geometric point of view, various equivalent definitions have been given for this structure. The original one, due to [1], is

$$n_i = \text{card}\{p_i \geq i\} \quad \forall i \in \{1, \dots, r\} \quad (5)$$

where card stands for cardinal (number of elements in the set) and with

$$p_i := \dim \left(\frac{\mathcal{V}^* + \mathcal{S}^{i-1}}{\mathcal{V}^* + \mathcal{S}^{i-1}} \right), \quad \forall i \geq 1. \quad (6)$$

Other geometric characterizations have been given in [5]. Indeed

$$\begin{aligned} p_i &= \dim \left(\frac{\mathcal{V}^* + \mathcal{S}^{i-1}}{\mathcal{V}^* + \mathcal{S}^{i-1}} \right) \\ &= \dim \left(\frac{\mathcal{B} \cap \mathcal{V}^{i-1}}{\mathcal{B} \cap \mathcal{V}^*} \right) \\ &= \dim \left(\frac{\mathcal{S}^* \cap \mathcal{V}^{i-1}}{\mathcal{S}^* \cap \mathcal{V}^*} \right), \quad \forall i \geq 1. \end{aligned} \quad (7)$$

The following lemma will help us in the sequel.

Lemma 1: Let $\mathcal{V}^i, i \geq 0$, denote the subspace obtained in the i th step of (ISA). There exists a (non unique) state feedback F_0 in $\mathcal{F}(\mathcal{V}^*)$ satisfying

$$\mathcal{V}^{i+1} = \mathcal{K} \cap A_{F_0}^{-1} \mathcal{V}^i, \forall i \geq 0 \quad (8)$$

where $A_{F_0} := (A + BF_0)$.

Remark 1: Due to the correspondence (5) between list $\{n_j\}$ and $\{p_i\}$, it is quite obvious that the list

$$\{p_1 - p_i\}, \forall i \in \{1, 2, \dots, n_1\} \quad (9)$$

is the list of the orders of the zeros at infinity of (A, B, C) which are strictly smaller than i .

II. PROBLEMS STATEMENT

The k th-Order Partial Model Matching Problem (PMMP(k)):

Given a linear time-invariant system described by (1) and with associated transfer function matrix described by (4), and given a linear time-invariant prespecified model described by

$$\begin{cases} \dot{x}_m(t) = A_m x_m(t) + B_m u_m(t), & t \geq 0 \\ y_m(t) = C_m x_m(t), & t \geq 0, \end{cases} \quad (10)$$

with the state $x_m \in \mathcal{X}_m \simeq \mathcal{R}^{n_m}$, the input $u_m \in \mathcal{U}_m \simeq \mathcal{R}^{m_m}$ and the output $y_m \in \mathcal{Y} \simeq \mathcal{R}^p$, and with associated transfer function matrix

$$T_m(s) = C_m(sI_{n_m} - A_m)^{-1} B_m \quad (11)$$

we can formulate the k th order Partial Model Matching Problem (initially appeared in [2]), as follows:

Definition 1: Let $k \in \mathcal{N}$ be given. The k th order Partial Model Matching Problem has a solution if and only if there exists a proper rational matrix $C(s)$ such that

$$T(s)C(s) - T_m(s) = s^{-(k+1)}P(s) \quad (12)$$

for some proper $P(s)$. The proper transfer function matrix $C(s)$ can be interpreted as a dynamic precompensator cascaded with the given plant. In other terms, we want to match the first k Markov parameters of the compensated plant with those of the model.

We give Definition 1 for strictly proper plant and model. This assumption is not restrictive: the main interest, for the exposition, is that the associated geometry is much simpler. Extension to the proper case is quite easy.

Note that, because of the assumption of strict properness, (12) is trivially satisfied for $k = 0$. We shall indeed consider in the sequel that $k \geq 1$.

In a similar way, we shall consider the following.

The k th-Order Partial Disturbance Rejection Problem (PDRP(k))

PDRP(k) is defined as follows:

Definition 2: Given a perturbed linear, time-invariant, system

$$\begin{cases} \dot{x}(t) = Ax(t) + Bu(t) + Ed(t), & t \geq 0 \\ y(t) = Cx(t), & t \geq 0 \end{cases} \quad (13)$$

that we shall denote by $(A, [B \ E], C)$, with the state $x \in \mathcal{X} \simeq \mathcal{R}^n$, the input $u \in \mathcal{U} \simeq \mathcal{R}^m$, the output $y \in \mathcal{Y} \simeq \mathcal{R}^p$ and the disturbance $d \in \mathcal{D} \simeq \mathcal{R}^q$ (of course some smoothness properties of $d(\cdot)$, like measurability, shall be implicitly assumed here), and an integer $k \geq 1$, find necessary and sufficient conditions for the existence of a state feedback map $F: \mathcal{X} \rightarrow \mathcal{U}$ such that

$$\begin{cases} CE = 0 \\ C(A + BF)E = 0 \\ \vdots \\ C(A + BF)^{k-1}E = 0. \end{cases} \quad (14)$$

When the control law includes some measurements of the disturbance, we have a modified version of PDRP(k), namely the following.

The k th-Order Partial Modified Disturbance Rejection Problem (PMDRP(k))

Definition 3: Given the perturbed linear, time-invariant, system described by (13) and an integer $k \geq 1$, find necessary and sufficient conditions for the existence of a static state feedback law $u(t) = Fx(t) + Gd(t)$, with $F: \mathcal{X} \rightarrow \mathcal{U}$ and $G: \mathcal{D} \rightarrow \mathcal{U}$, such that

$$\begin{cases} C(E + BG) = 0 \\ C(A + BF)(E + BG) = 0 \\ \vdots \\ C(A + BF)^{k-1}(E + BG) = 0. \end{cases} \quad (15)$$

We shall provide in the next sections geometric and structural solutions to these problems. We shall first consider here PDRP(k).

III. GEOMETRIC SOLVABILITY CONDITIONS

Let us now consider the geometric solvability conditions of both problems introduced in Definition 2 and Definition 3.

Theorem 1: Let $k \geq 1$ be given, there exists a static state feedback map F which solves the k th order Partial Disturbance Rejection Problem if and only if

$$\mathcal{E} \subset \mathcal{V}^k \quad (16)$$

where \mathcal{E} denotes $\text{Im}E$ and \mathcal{V}^k denotes the subspace obtained at the k th step of (ISA) for (A, B, C) .

Proof of Theorem 1: Let \mathcal{K} denotes the kernel of C . If F exists, which satisfies (14), obviously

$$\begin{aligned} \mathcal{E} &\subset \mathcal{K} \\ (A + BF)\mathcal{E} &\subset \mathcal{K} \\ &\vdots \\ (A + BF)^{k-1}\mathcal{E} &\subset \mathcal{K} \end{aligned}$$

thus

$$\mathcal{E} \subset \mathcal{K} \cap A_F^{-1}\mathcal{K} \cap A_F^{-2}\mathcal{K} \cdots \cap A_F^{-(k-1)}\mathcal{K} \quad (17)$$

where $A_F := (A + BF)$. Now, it follows from (17) and (2) that

$$\begin{aligned} \mathcal{K} \cap A_F^{-1}\mathcal{K} &\subset \mathcal{V}^2 := \mathcal{K} \cap A^{-1}(B + \mathcal{K}) \\ &= \mathcal{K} \cap A_F^{-1}(B + \mathcal{K}), \\ \mathcal{K} \cap A_F^{-1}\mathcal{K} \cap A_F^{-2}\mathcal{K} &= \mathcal{K} \cap A_F^{-1}(\mathcal{K} \cap A_F^{-1}\mathcal{K}) \\ &\subset \mathcal{K} \cap A_F^{-1}\mathcal{V}^2 \\ &\subset \mathcal{K} \cap A_F^{-1}(\mathcal{V}^2 + \mathcal{B}) \\ &= \mathcal{K} \cap A^{-1}(B + \mathcal{V}^2) = \mathcal{V}^3, \\ &\vdots \\ \mathcal{K} \cap A_F^{-1}\mathcal{K} \cap A_F^{-2}\mathcal{K} \cdots \cap A_F^{-(k-1)}\mathcal{K} &\subset \mathcal{K} \cap A_F^{-1}(\mathcal{V}^{k-1} + \mathcal{B}) \\ &= \mathcal{K} \cap A^{-1}(B + \mathcal{V}^{k-1}) = \mathcal{V}^k \end{aligned}$$

then $\mathcal{E} \subset \mathcal{V}^k$.

Conversely, from Lemma 1, there exists at least one map F_0 such that

$$\mathcal{V}^{i+1} = \mathcal{K} \cap A_{F_0}^{-1}\mathcal{V}^i, \forall i \geq 0$$

where $A_{F_0} := (A + BF_0)$. Hence

$$\begin{aligned} \mathcal{E} \subset \mathcal{V}^k &\iff \mathcal{E} \subset \mathcal{K} \cap A_{F_0}^{-1} \mathcal{V}^{k-1}, \\ &\iff \begin{cases} \mathcal{E} \subset \mathcal{K} \\ A_{F_0} \mathcal{E} \subset \mathcal{V}^{k-1} = \mathcal{K} \cap A_{F_0}^{-1} \mathcal{V}^{k-2}, \\ \mathcal{E} \subset \mathcal{K} \\ A_{F_0} \mathcal{E} \subset \mathcal{K} \\ A_{F_0}^2 \mathcal{E} \subset \mathcal{V}^{k-2}, \\ \vdots \\ \mathcal{E} \subset \mathcal{K} \\ A_{F_0} \mathcal{E} \subset \mathcal{K} \\ \vdots \\ A_{F_0}^{k-1} \mathcal{E} \subset \mathcal{K} \end{cases} \\ &\iff \begin{cases} \mathcal{E} \subset \mathcal{K} \\ A_{F_0} \mathcal{E} \subset \mathcal{K} \\ \vdots \\ A_{F_0}^{k-1} \mathcal{E} \subset \mathcal{K} \end{cases} \end{aligned}$$

which is equivalent to (14) with $F = F_0$. \square

The following theorem can be proved in a similar quite easy way.

Theorem 2: There exists a static state feedback law $u(t) = Fx(t) + Gd(t)$, which solves the k th order Partial Modified Disturbance Rejection Problem if and only if

$$\mathcal{E} \subset \mathcal{V}^k + \mathcal{B} \quad (18)$$

where \mathcal{E} denotes $\text{Im} E$, \mathcal{B} denotes $\text{Im} B$ and \mathcal{V}^k denotes the subspace obtained at the k th step of (ISA) for (A, B, C) .

We shall now give some structural solutions in terms of structures at infinity.

IV. STRUCTURAL SOLVABILITY CONDITIONS

The following equivalent solvability condition will be expressed in terms of some equalities between integers, namely some orders of the zeros at infinity of (A, B, C) and $(A, [B \ E], C)$. Its main advantage comes from the fact that this structural information can be obtained through various ways, for instance from the Smith-McMillan Form at infinity, and thus is less dependent on a particular approach than Theorem 2.

Structural Solvability Condition for PMDRP(k)

Theorem 3: The k th order Partial Modified Disturbance Rejection Problem is solvable if and only if the orders of the zeros at infinity of both systems (A, B, C) and $(A, [B \ E], C)$, which are smaller than or equal to k , are the same.

To prove this theorem, we shall use the i th step of (ISA) for the combined system $(A, [B \ E], C)$, i.e.,

$$\begin{cases} \mathcal{V}_c^0 := \mathcal{X} \\ \mathcal{V}_c^i := \mathcal{K} \cap A^{-1}(\mathcal{B} + \mathcal{E} + \mathcal{V}_c^{i-1}), \quad i \geq 1 \end{cases}$$

which limit is \mathcal{V}_c^* , the supremal $(A, [B \ E])$ -invariant subspace contained in \mathcal{K} .

First note that (18) is obviously equivalent to

$$\mathcal{B} + \mathcal{E} + \mathcal{V}^i = \mathcal{B} + \mathcal{V}^i, \quad \forall i \in \{0, 1, \dots, k\}. \quad (19)$$

Let us introduce the integers

$$p_{ci} := \dim \left(\frac{(\mathcal{B} + \mathcal{E}) \cap \mathcal{V}_c^{i-1}}{(\mathcal{B} + \mathcal{E}) \cap \mathcal{V}_c^*} \right), \quad \forall i \geq 1$$

which characterize the orders of the zeros at infinity of $(A, [B \ E], C)$ (recall (7)), and remember that the list $\{p_{ci} - p_i\}$ characterizes the orders of the zeros at infinity of $(A, [B \ E], C)$ which are strictly smaller than i (remember Remark 1).

We shall prove that (19) is equivalent to

$$p_i - p_i = p_{ci} - p_{ci}, \quad \forall i \in \{1, 2, \dots, k+1\}. \quad (20)$$

Proof of Theorem 3: Note that if (19) is true, then

$$\mathcal{V}_c^i = \mathcal{V}^i, \quad \forall i \in \{0, 1, \dots, k+1\}. \quad (21)$$

Indeed, this is easily shown by induction:

Clearly, $\mathcal{V}_c^0 = \mathcal{V}^0$ and if $\mathcal{V}_c^{i-1} = \mathcal{V}^{i-1}$, then

$$\begin{aligned} \mathcal{V}_c^i &:= \mathcal{K} \cap A^{-1}(\mathcal{B} + \mathcal{E} + \mathcal{V}_c^{i-1}) \\ &= \mathcal{K} \cap A^{-1}(\mathcal{B} + \mathcal{E} + \mathcal{V}^{i-1}), \text{ since (21) holds for } i-1 \\ &= \mathcal{K} \cap A^{-1}(\mathcal{B} + \mathcal{V}^{i-1}), \text{ since (19) holds for } i-1 \\ &:= \mathcal{V}^i \end{aligned}$$

and thus $\mathcal{V}_c^i = \mathcal{V}^i$, $\forall i \in \{1, 2, \dots, k+1\}$.

From (9), (19) and (21), we have that

$$\begin{aligned} p_1 - p_i &= \dim \left(\frac{\mathcal{B}}{\mathcal{B} \cap \mathcal{V}^{i-1}} \right) = \dim \left(\frac{\mathcal{B} + \mathcal{V}^{i-1}}{\mathcal{V}^{i-1}} \right) \\ &= \dim \left(\frac{\mathcal{B} + \mathcal{E} + \mathcal{V}^{i-1}}{\mathcal{V}^{i-1}} \right) \\ &= \dim \left(\frac{\mathcal{B} + \mathcal{E} + \mathcal{V}_c^{i-1}}{\mathcal{V}_c^{i-1}} \right) \\ &= p_{ci} - p_{ci}, \quad \forall i \in \{1, 2, \dots, k+1\}. \end{aligned}$$

We shall now prove by induction the reverse part.

Indeed, (19) and (21) obviously hold for $i = 0$. Assume that (19) and (21) hold for $i - 1$, then

$$\begin{aligned} \mathcal{V}_c^i &:= \mathcal{K} \cap A^{-1}(\mathcal{B} + \mathcal{E} + \mathcal{V}_c^{i-1}) \\ &= \mathcal{K} \cap A^{-1}(\mathcal{B} + \mathcal{E} + \mathcal{V}^{i-1}), \text{ since (21) holds for } i-1 \\ &= \mathcal{K} \cap A^{-1}(\mathcal{B} + \mathcal{V}^{i-1}), \text{ since (19) holds for } i-1 \\ &:= \mathcal{V}^i \end{aligned}$$

and thus $\mathcal{V}_c^i = \mathcal{V}^i$, $\forall i \in \{0, 1, \dots, k+1\}$.

On the other hand, from (20) we have that

$$p_1 - p_{i+1} = p_{ci} - p_{ci+1}, \quad \forall i \in \{0, 1, \dots, k\}$$

then

$$\dim \left(\frac{\mathcal{B} + \mathcal{V}^i}{\mathcal{V}^i} \right) = \dim \left(\frac{\mathcal{B} + \mathcal{E} + \mathcal{V}_c^i}{\mathcal{V}_c^i} \right), \quad \forall i \in \{0, 1, \dots, k\}.$$

Since we have shown that $\mathcal{V}_c^i = \mathcal{V}^i$, $\forall i \in \{0, 1, \dots, k+1\}$, it follows that

$$\dim(\mathcal{B} + \mathcal{V}^i) = \dim(\mathcal{B} + \mathcal{E} + \mathcal{V}^i), \quad \forall i \in \{0, 1, \dots, k\}$$

which is equivalent to (19) and ends the proof. \square

The following corollary illustrates the obvious fact that exact rejection is just a particular case of partial rejection and brings back to some familiar structural results (see for instance [5] for the equivalent case (see Theorem 4.2) of model matching).

Corollary 1: The Exact Modified Disturbance Rejection Problem is solvable if and only if the k th order Partial Modified Disturbance Rejection Problem is solvable for the order $k = n_1$, where n_1 denotes the supremal order of the zeros at infinity of (A, B, C) .

Proof of Corollary 1: Obvious from Theorem 3, since Exact Rejection means Partial Rejection for any k and since the integers p_i are equal to zero for $i > n_1$. \square

We shall now deduce the corresponding structural result for PDRP(k).

For that purpose, consider the following "extended" perturbed system

$$\tilde{A} = \begin{bmatrix} A & I_n \\ 0 & 0 \end{bmatrix}, \quad \tilde{B} = \begin{bmatrix} 0 \\ B \end{bmatrix}, \quad \tilde{C} = [C \ 0], \quad \tilde{E} = \begin{bmatrix} E \\ 0 \end{bmatrix}. \quad (22)$$

The following lemma establishes some direct links between PMDRP(k) and PDRP(k).

Lemma 2 The k th order Partial Disturbance Rejection Problem for the system

$$\begin{cases} \dot{x}(t) = Ax(t) + Bu(t) + Ed(t) & t \geq 0 \\ y(t) = Cx(t) & t \geq 0 \end{cases}$$

is equivalent to the k th order Partial Modified Disturbance Rejection Problem for the extended system

$$\begin{cases} \dot{\tilde{x}}(t) = \tilde{A}\tilde{x}(t) + \tilde{B}u(t) + \tilde{F}d(t) & t \geq 0 \\ \tilde{y}(t) = C\tilde{x}(t) & t \geq 0 \end{cases}$$

Proof of Lemma 2 Denote $\mathcal{V} = \mathcal{V}^k$ and let \mathcal{V} denote the step of (ISA) for (A, B, C) . The result is then an obvious consequence of the following relation

$$(\mathcal{V} + \mathcal{B}) \cap \mathcal{V} = \mathcal{V}$$

which proof is quite direct \square

Remark now that

$$C(sI - A)^{-1}B = s^{-1}C(sI - A)^{-1}B \quad (23)$$

and

$$C(sI - A)^{-1}F = C(sI - A)^{-1}F \quad (24)$$

This directly leads to the following

Structural Solvability Condition for PDRP(k)

Theorem 4 The k th order Partial Disturbance Rejection Problem is solvable if and only if the orders of the zeros at infinity of both systems (A, B, C) and $(A, [B, E], C)$ which are smaller than or equal to k are the same or equivalently if both transfer function matrices

$$T(s) = s^{-1}C(sI - A)^{-1}B$$

and

$$T(s) = [s^{-1}C(sI - A)^{-1}B \quad C(sI - A)^{-1}F]$$

have the same smallest orders of their zeros at infinity up to value k

To obtain the structural solution of the Partial Model Matching Problem we shall simply use the equivalence existing between this problem and the Partial Disturbance Rejection Problem

From Disturbance Rejection to Model Matching

The natural equivalence existing between Disturbance Rejection and Model Matching was shown in [3]. We shall here propose some alternative inspired from the nice equivalence existing between state feedback laws using dynamic extensions and general proper dynamic precompensators (see [4]) and from the fact that the use of a dynamic extension offers no extra possibility for Partial Disturbance Rejection. Let us define the following

Dynamic k th Order Partial Disturbance Rejection Problem

Do there exist some integer n_d and some dynamic extension (see [11])

$$x_d(t) = B_d u_d(t)$$

with $x_d \in \mathcal{V}_d$, $u_d \in \mathcal{U}_d$, $\dim(\mathcal{V}_d) = \dim(\mathcal{U}_d) = n_d$ such that the k th order Partial Rejection has a solution $u(t) = Fx_d(t)$ for the extended system

$$\begin{cases} \dot{x}(t) = Ax(t) + Bx_d(t) + Fd(t) & t \geq 0 \\ y(t) = Cx(t) & t \geq 0 \end{cases} \quad (25)$$

where

$$x_d(t) = \begin{bmatrix} x_d(t) \\ x_d(t) \end{bmatrix} \in \mathcal{V}_d = \mathcal{V}_d \quad \mathcal{V}_d$$

$$u_d(t) = \begin{bmatrix} u_d(t) \\ u_d(t) \end{bmatrix} \in \mathcal{U}_d = \mathcal{U}_d \quad \mathcal{U}_d$$

$$A = \begin{bmatrix} A & 0 \\ 0 & 0 \end{bmatrix} \quad B = \begin{bmatrix} B & 0 \\ 0 & B \end{bmatrix} \quad C = [C \quad 0] \text{ and } I = \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix}$$

Proposition 1 The k th order Dynamic Partial Disturbance Rejection Problem is solvable if and only if the (static) k th order Partial Disturbance Rejection Problem is solvable

Proof of Proposition 1 The proof is quite direct when using geometric arguments since it rests upon the following relationships

$$\mathcal{V}_d = \mathcal{V} \quad \mathcal{V}_d$$

where \mathcal{V} is the k th step of (ISA) for (A, B, C)

Then since $\mathcal{E} = \text{Im} F \subset \mathcal{V}$ it is quite obvious that

$$\mathcal{E} \subset \mathcal{V}^k \iff \mathcal{E} \subset \mathcal{V}_d^k$$

which ends the proof \square

This equivalence obviously remains true if the disturbance is available for the control law i.e. for solutions of the type

$$u(t) = Ix_d(t) + Gd(t) \quad (26)$$

Now it has been shown in [4] that the class of compensations like (26) applied to (25) is fully equivalent to the class of proper dynamic precompensators like

$$u(s) = C(s)d(s)$$

applied to the initial system

$$\begin{cases} \dot{x}(t) = Ax(t) + Bu(t) & t > 0 \\ y(t) = Cx(t) & t \geq 0 \end{cases} \quad (27)$$

This equivalence immediately shows the following corollary

Corollary The k th order Modified Partial Disturbance Rejection Problem is solvable if and only if there exists a proper solution say $C(s)$ to the following equation

$$T(s)C(s) + T_d(s) = s^{-(k+1)}P(s) \quad (28)$$

where $P(s)$ is a proper rational transfer matrix and

$$T(s) = C(sI - A)^{-1}B \quad (29)$$

and

$$T_d(s) = C(sI - A)^{-1}F \quad (30)$$

Note that (28) is a particular case of the k th order Partial Model Matching Problem where $T(s)$ stands for the plant and $-I_d(s)$ for the model

We can then rephrase Corollary 2 as

Proposition 2 The k th order Modified Partial Disturbance Rejection Problem for (27) is equivalent to the k th order Partial Model Matching Problem with (29) as the plant and (30) as the model

As an immediate consequence of Lemma 2 we also have

Corollary 3 The k th order Partial Disturbance Rejection Problem is solvable if and only if there exists a strictly proper solution to (28)

Proof of Corollary 3: Use Lemma 2, i.e., just replace $T(s)$ by $s^{-1}T(s)$. This is equivalent to replacing $C(s)$ by $s^{-1}C(s)$, hence the result. \square

To show that the equivalence between Partial Disturbance Rejection and Partial Model Matching is complete, we shall quickly describe the reverse path.

Let us again consider the plant

$$\begin{cases} \dot{x}(t) = Ax(t) + Bu(t), & t \geq 0 \\ y(t) = Cx(t), & t \geq 0 \end{cases}$$

and the model

$$\begin{cases} \dot{x}_m(t) = A_m x_m(t) + B_m u_m(t), & t \geq 0 \\ y_m(t) = C_m x_m(t), & t \geq 0 \end{cases}$$

with their associated transfer matrices

$$T(s) := C(sI_n - A)^{-1}B$$

and

$$T_m(s) := C_m(sI_{n_m} - A_m)^{-1}B_m$$

respectively.

Let us introduce the following combination of the plant and of the model, and let us call it the combined system

$$\begin{cases} \dot{x}_c(t) = A_c x_c(t) + B_c u + E_c u_m(t), & t \geq 0 \\ y_c(t) = y(t) - y_m(t) = C_c x_c(t), & t \geq 0 \end{cases} \quad (31)$$

with

$$x_c(t) = \begin{bmatrix} x(t) \\ x_m(t) \end{bmatrix} \in \mathcal{X}_c \mathcal{X}_m$$

and

$$A_c = \begin{bmatrix} A & 0 \\ 0 & A_m \end{bmatrix}, B_c = \begin{bmatrix} B \\ 0 \end{bmatrix}, C_c = [C \quad -C_m] \text{ and } E_c = \begin{bmatrix} 0 \\ B_m \end{bmatrix}.$$

It directly follows from the previous discussion that looking for a proper dynamic compensator $u(s) = C(s)u_m(s)$, that solves the k th order Partial Model Matching Problem is equivalent to considering $u_m(s)$ as a (measured) disturbance in (31) and solving the corresponding k th order Modified Partial Disturbance Rejection Problem.

This complete equivalence allows us to directly deduce the following.

Geometric and Structural Solvability Conditions for PMMP(k)

Theorem 5. The k th order Partial Model Matching Problem has a proper solution $C(s)$ if and only if

$$\text{Im} \begin{bmatrix} 0 \\ B_m \end{bmatrix} \subset \text{Im} \begin{bmatrix} B \\ 0 \end{bmatrix} + \mathcal{V}_c^k$$

where \mathcal{V}_c^k is the k th step of (ISA) for the combined system.

An equivalent structural condition is the following.

The Partial Model Matching Problem has a proper solution $C(s)$

if and only if both transfer matrices $T(s)$ and $[T(s) : -T_m(s)]$ have the same orders of their zeros at infinity which are smaller than or equal to k .

V. CONCLUSION

We have considered here the solution to the Partial Model Matching Problem or, equivalently, the Partial Disturbance Rejection Problem. Lemma 2, Proposition 1, and Proposition 2 precisely describe the basic equivalences between these problems. Our geometric solution (Theorems 2 and 5) uses "classical" geometric tools, which are less involved than Generalized Dynamic Covers, as in [2]. The equivalent structural solution (Theorems 3 and 5) is expressed in terms of the orders of the zeros at infinity which are smaller than or equal to the desired order of the partial problem.

As argued in [2] this partial version of the problems is a very good intermediate to the exact one (see Corollary 1). It has to be noted that the same idea has been used in the context of systems with delays [8].

Further study have been devoted to some algebraic complementary study (with polynomial tools) and to stability requirements (which are compulsory for possible applications) [9]:

- It has been shown that there exists a stable solution to the Partial Model Matching Problem if and only if partial model matching is possible. Unlike in the exact case, there is no further constraint limitation imposed by unstable zeros for the problem to be solvable with stability.
- As is well known (see for instance [7]), exact disturbance rejection with stability has a static state feedback solution if and only if there exists a dynamic state feedback solution. As concerns the partial case, the situation is quite different. Indeed, it can be shown that there exists a dynamic stable solution to the Partial Disturbance Rejection Problem if and only if Partial Disturbance Rejection is actually solvable. However the characterization of static solutions (if any) is still open.
- The combination of partial disturbance rejection and optimal disturbance attenuation (i.e., minimization in H_∞ -terms of the effect of the disturbance on the output of the system while maintaining stability of the compensated plant) has been successfully achieved on some illustrative examples.

Absolute Stability Criteria for Multiple Slope-Restricted Monotonic Nonlinearities

Wassim M. Haddad and Vikram Kapila

Abstract—Absolute stability criteria such as the classical Popov criterion guarantee stability for a class of sector-bounded nonlinearities. Although the sector restriction bounds the admissible class of the nonlinearities, the local slope of the nonlinearity may be arbitrarily large. In this paper we derive absolute stability criteria for multiple slope-restricted time-invariant monotonic nonlinearities. Like the Popov criterion, in the single-input/single-output case our results provide a simple graphical interpretation involving a straight line in a modified Popov plane.

I. INTRODUCTION

Absolute stability theory guarantees stability of feedback systems whose forward path contains a dynamic linear time invariant system and whose feedback path contains a memoryless (possibly time varying) nonlinearity. These stability criteria are generally stated in terms of the linear system and apply to every element of a specified class of nonlinearities. Hence absolute stability theory provides sufficient conditions for robust stability with a given class of uncertain elements [5]–[17].

The literature on absolute stability is extensive. A convenient way to distinguish these results is to focus on the allowable class of feedback nonlinearities. Specifically the small gain, positivity, and circle theorems guarantee stability for arbitrarily time varying nonlinearities, whereas the Popov criterion does not. This is not surprising since the Lyapunov function upon which the small gain, positivity, and circle theorems are based is a fixed quadratic Lyapunov function which permits arbitrary time variation of the nonlinearity [5]. Alternatively the Popov criterion is based on a Lur'e–Postnikov Lyapunov function which explicitly depends on the nonlinearity thereby restricting its allowable time variation.

Further refinements of absolute stability criteria developed in [2], [12], [14], [19] restrict consideration to sector bounded time invariant nonlinearities that are monotonic or odd monotonic and are predicted on extended Lur'e–Postnikov Lyapunov functions [9], [14]. To further restrict the allowable class of feedback nonlinearities the authors in [4], [17], [22]–[24] develop absolute stability criteria by constraining the local slope of the nonlinearity. These classical absolute stability results extend the Popov criterion for sector bounded time invariant nonlinear functions to monotonic and odd monotonic nonlinearities by constructing stability multipliers that effectively place less restrictive conditions on the linear part of the system. However, as a result of the more involved multiplier construction the resulting frequency domain conditions do not provide a simple graphical test as in the case of the Popov criterion.

In recent research [10], [16], [18] a new absolute stability criterion for locally slope restricted nonlinearities involving a simple modification to the Popov multiplier was developed. Specifically it is shown in [18] that replacing the Popov multiplier $Z(s) = 1 + \lambda s$ by the new multiplier $1 + \lambda s^{-1}$ and requiring the frequency domain condition $\mu^{-1} + (1 + \lambda s^{-1})G(s)$ be positive real where

$G(s)$ represents the transfer function of the linear dynamic system and μ is a bound on the local slope of the feedback nonlinearity provides a sufficient condition for the absolute stability for systems with a monotonic time invariant nonlinear element in the feedback path. As noted in [10], [16], however, the statement as well as the proof of the results reported in [18] were far from convincing. It should further be noted that the authors in [10] consider extensions to several differentiable nonlinearities in the feedback loop using an involved method based on integral indices along with stability inequalities that arise from the frequency domain condition. To provide connections between the proposed absolute stability condition and robust controller analysis using the parameterized Lyapunov function framework developed in [5], in this paper we extend the results of [18] to multiple slope restricted monotonic nonlinearities as well as construct explicit Lyapunov functions along with providing the underlying Yakubovich–Kalman–Popov conditions needed to present a concise statement of these results. Specifically an extended notion of a kinetic Lyapunov function [3] is used to show asymptotic stability of the nonlinear feedback system given by

$$\dot{x}(t) = Ax(t) - B\phi(y) \quad y(t) = Cx(t)$$

where $\phi(\cdot)$ is a time invariant sector bounded memoryless nonlinearity. That is, instead of finding the condition for the state variables $x(t)$ to approach the zero equilibrium point, sufficient conditions for $x(t)$ and the output $y(t)$ to approach zero are found. Obviously if the system is observable and $x(t)$ and $y(t)$ approach zero, the system arrives at one of its equilibrium points, and the two results are equivalent if the equilibrium point is unique. Finally, in the single input/single output (SISO) case, we show that the resulting frequency domain condition has a simple graphical interpretation involving a straight line in a modified Popov plane.

II. MATHEMATICAL PRELIMINARIES

In this section we establish definitions, notation, and several key lemmas. Let \mathbb{R} and \mathbb{C} denote the real and complex numbers. Let $(\cdot)^T$ and $(\cdot)^*$ denote transpose and complex conjugate transpose. Let I_n or I denote the $n \times n$ identity matrix and let 0 denote the $n \times n$ zero matrix. Furthermore, $M \geq 0$ ($M > 0$) denotes the fact that the Hermitian matrix M is nonnegative (positive) definite. Let $n(s)$ and $d(s)$ be polynomials in s with real coefficients. A function $q(s)$ of the form $q(s) = n(s)/d(s)$ is called a rational function. The function $q(s)$ is called proper (respectively strictly proper) if $\deg n(s) \leq \deg d(s)$ (respectively $\deg n(s) < \deg d(s)$) where \deg denotes the degree of the polynomial. In this paper a real rational matrix function is a matrix whose elements are rational functions with real coefficients. Furthermore, a transfer function $G(s)$ is called proper (respectively strictly proper) if every element of $G(s)$ is proper (respectively strictly proper). Finally, an asymptotically stable transfer function is a transfer function each of whose poles is in the open left half plane. The space of asymptotically stable transfer functions is denoted by \mathcal{RH}_∞ , i.e., the real rational subset of \mathcal{H}_∞ . Let

$$G(s) \sim \begin{bmatrix} A & B \\ C & D \end{bmatrix}$$

denote a state space realization of a transfer function $G(s)$ that is $G(s) = C(sI - A)^{-1}B + D$. The notation $\overset{\sim}{\sim}$ is used to denote a minimal realization. In addition, the parahermitian conjugate $G^*(s)$

IEEE Log Number 9407219.

of $G(s)$ has the realization

$$G(s) \sim \begin{bmatrix} -A^T & C^T \\ -B^T & D^T \end{bmatrix}.$$

Furthermore, the Hermitian part of G is given by $\text{He } G = \frac{1}{2}(G + G^*)$.

A square transfer function $G(s)$ is called positive real [1, p. 216] if 1) all poles of $G(s)$ lie in the closed left-half plane, and 2) $\text{He } G(s)$ is nonnegative definite for $\text{Re } s > 0$. A square transfer function $G(s)$ is called strictly positive real [21] if 1) $G(s)$ is asymptotically stable and 2) $\text{He } G(j\omega)$ is positive definite for all real ω . Recall that a minimal realization of a positive real transfer function is stable in the sense of Lyapunov, while a minimal realization of a strictly positive real transfer function is asymptotically stable.

For notational convenience we will omit all matrix dimensions throughout the paper and assume that all quantities have compatible dimensions. Furthermore, in this paper, $G(s)$ will denote an $m \times m$ transfer function with input $u \in \mathbb{R}^m$, output $y \in \mathbb{R}^m$, and internal state $x \in \mathbb{R}^n$. Next, we state the strict positive real lemma used to characterize strict positive realness in the state-space setting.

Lemma 2.1 (Strict Positive Real Lemma [20]):

$$G(s) \stackrel{\text{min}}{\sim} \begin{bmatrix} A & B \\ C & D \end{bmatrix}$$

is strictly positive real if and only if there exist matrices P , L , and W with P positive definite such that

$$0 = A^T P + P A + L^T L, \quad (2.1)$$

$$0 = B^T P - C^T + W^T L, \quad (2.2)$$

$$0 = D + D^T - W^T W, \quad (2.3)$$

are satisfied, the pair (A, L) is observable, and $\text{rank } \hat{G}(j\omega) = m$, $\omega \in \mathbb{R}$, where

$$\hat{G}(s) \stackrel{\text{min}}{\sim} \begin{bmatrix} A & B \\ L & W \end{bmatrix}.$$

Finally, we state a key lemma involving controllability of an augmented pair.

Lemma 2.2 [10]: Given a triple (A, B, C) , if (A, B) is controllable and $\det A \neq 0$, then

$$\left(\begin{bmatrix} A & 0 \\ C & 0 \end{bmatrix}, \begin{bmatrix} B \\ 0 \end{bmatrix} \right)$$

is controllable if and only if $\det C A^{-1} B \neq 0$.

III. ABSOLUTE STABILITY CRITERION FOR MULTIPLE SLOPE-RESTRICTED NONLINEARITIES

In this section we consider the absolute stability problem for a class Φ of locally slope restricted monotonic time-invariant nonlinearities $\phi: \mathbb{R}^m \rightarrow \mathbb{R}^m$. Specifically, given

$$G(s) \stackrel{\text{min}}{\sim} \begin{bmatrix} A & B \\ C & 0 \end{bmatrix}$$

we derive conditions that guarantee global asymptotic stability of the negative feedback interconnection of $G(s)$ and ϕ for all $\phi \in \Phi$. Note that the negative feedback interconnection of $G(s)$ and $\phi(\cdot)$ has the state-space representation

$$\dot{x}(t) = A x(t) - B \phi(y), \quad (3.1)$$

$$y(t) = C x(t), \quad (3.2)$$

To state our main result, the following definitions are needed. Let $\mu \in \mathbb{R}^{m \times m}$ be a positive definite diagonal matrix. Next, define the set Φ of allowable nonlinearities ϕ by

$$\Phi \triangleq \{ \phi: \mathbb{R}^m \rightarrow \mathbb{R}^m : \phi(y) = [\phi_1(y_1), \dots, \phi_m(y_m)]^T, \\ \phi(\cdot) \text{ is differentiable,} \\ 0 < \phi'_i(y_i) < \mu_{ii}, \quad i = 1, \dots, m, y \in \mathbb{R}^m \}. \quad (3.3)$$

Note that the nonlinear functions considered, $\phi \in \Phi$, have decoupled components but unlike the multivariable extensions of the Popov criterion [5], [11] we assume a local slope constraint on the nonlinearities. In the scalar case, $m = 1$, ϕ satisfies the usual local slope condition $0 < \phi'(y) < \mu$, $y \in \mathbb{R}$.

For the statement of the main result define

$$A_a \triangleq \begin{bmatrix} A & 0_{n \times m} \\ C & 0_m \end{bmatrix}, \quad B_a \triangleq \begin{bmatrix} B \\ 0_m \end{bmatrix}, \\ C_a \triangleq [0_{m \times n} \ I_m], \quad S \triangleq [C^T \ 0_m].$$

Theorem 3.1. Let

$$G(s) \stackrel{\text{min}}{\sim} \begin{bmatrix} A & B \\ C & 0 \end{bmatrix}$$

be asymptotically stable, let $N \triangleq \text{diag } [N_1, N_2, \dots, N_m]$ be nonnegative-definite, assume $\det C A^{-1} B \neq 0$, and define

$$Z(s) \triangleq I + N s^{-1}. \quad (3.4)$$

Then

$$\mathcal{G}(s) \triangleq \mu^{-1} + Z(s)G(s) \quad (3.5)$$

is strictly positive real if and only if there exist matrices P , L , and W with P positive definite satisfying

$$0 = A_a^T P + P A_a + L^T L, \quad (3.6)$$

$$0 = B_a^T P - N C_a - S + W^T L, \quad (3.7)$$

$$0 = 2\mu^{-1} - W^T W. \quad (3.8)$$

In this case

$$V(\dot{x}, y) = \begin{bmatrix} \dot{x}(t) \\ y(t) \end{bmatrix}^T P \begin{bmatrix} \dot{x}(t) \\ y(t) \end{bmatrix} \\ + 2 \sum_{i=1}^m \int_0^{y_i} N_i \phi'_i(\sigma) \sigma d\sigma \quad (3.9)$$

where $y(t) = C x(t)$, is a Lyapunov function that guarantees that the negative feedback interconnection of $G(s)$ and $\phi(\cdot)$ is globally asymptotically stable for all $\phi \in \Phi$.

Proof: First, define $z(t) \triangleq \dot{x}(t)$ so that

$$\dot{z}(t) = A z(t) - B \phi'(y) \dot{y}, \quad (3.10)$$

$$\dot{y}(t) = C z(t) \quad (3.11)$$

and

$$\dot{x}_a(t) = A_a x_a(t) - B_a f(y) \quad (3.12)$$

where

$$x_a(t) \triangleq \begin{bmatrix} \dot{x}(t) \\ y(t) \end{bmatrix}, \quad f(y) \triangleq \phi'(y) \dot{y}(t).$$

Furthermore, note that in this case $y(t) = C_a x_a(t)$ and $\dot{y}(t) = S x_a(t)$. Now, since (A, B, C) is minimal, (A, B) is controllable. Hence, it follows from Lemma 2.2 that if $\det C A^{-1} B \neq 0$ then (A_a, B_a) is also controllable.

Next, we show that (3.6)–(3.8) imply that $\mathcal{G}(s)$ is strictly positive real. To do this, add and subtract $j\omega P$ to and from (3.6) to obtain

$$0 = (-j\omega I - A_n)^T P + P(j\omega I - A_n) - L^T L. \quad (3.13)$$

Now, forming $B_n^T (-j\omega I - A_n)^{-T}$ (3.13) $(j\omega I - A_n)^{-1} B_n$ and using (3.7) we obtain

$$\begin{aligned} & [NC_n + S - W^T L](j\omega I - A_n)^{-1} B_n \\ & + B_n^T (-j\omega I - A_n)^{-T} [NC_n + S - W^T L]^T \\ & = B_n^T (-j\omega I - A_n)^{-T} L^T L (j\omega I - A_n)^{-1} B_n. \end{aligned} \quad (3.14)$$

Adding and subtracting $W^T W$ to and from (3.14), using (3.8), and grouping terms yields

$$\begin{aligned} & [NC_n + S](j\omega I - A_n)^{-1} B_n \\ & + B_n^T (-j\omega I - A_n)^{-T} [NC_n + S]^T + 2\mu^{-1} \\ & = [W + L(j\omega I - A_n)^{-1} B_n]^* \\ & \cdot [W + L(j\omega I - A_n)^{-1} B_n]. \end{aligned} \quad (3.15)$$

Next, using the identities

$$\begin{aligned} (j\omega I - A_n)^{-1} &= \begin{bmatrix} (j\omega I - A) & 0 \\ -C & j\omega I \end{bmatrix}^{-1} \\ &= \begin{bmatrix} (j\omega I - A)^{-1} & 0 \\ (j\omega)^{-1} C(j\omega I - A)^{-1} & (j\omega)^{-1} I \end{bmatrix} \end{aligned}$$

$$S(j\omega I - A_n)^{-1} B_n = G(j\omega),$$

$$C_n(j\omega I - A_n)^{-1} B_n = \frac{G(j\omega)}{j\omega}.$$

it follows from (3.15) and the rank condition in ii) of Lemma 2.1 that $\text{Re } \mathcal{G}(j\omega) > 0$. Hence $\mathcal{G}(s)$ is strictly positive real.

Conversely, assuming that $\mathcal{G}(s)$ is strictly positive real, spectral factorization theory guarantees the existence of a spectral factor $\Lambda(s)$ such that $\mathcal{G}(s) + \mathcal{G}^*(s) = \Lambda^*(s)\Lambda(s)$, where $\Lambda^{\pm 1}(s) \in RH_\infty$. The existence of P , L , and W with P positive definite satisfying (3.6)–(3.8) now follows from standard algebraic state-space realization manipulations.

Alternatively, the result follows from a direct consequence of Lemma 2.1 by noting that $\mathcal{G}(s)$ has a minimal realization given by

$$\mathcal{G}(s) \stackrel{\text{min}}{\sim} \left[\begin{array}{c|c} A_n & B_n \\ \hline NC_n + S & \mu^{-1} \end{array} \right].$$

Next, for $\phi \in \Phi$ consider the Lyapunov function candidate (3.9). First note that using integration by parts the integral term in (3.9) is equivalent to

$$\sum_{i=1}^m \int_0^{y_i} N_i \phi_i(\sigma) \sigma d\sigma = \sum_{i=1}^m \left\{ N_i \phi_i(y_i) y_i - \int_0^{y_i} N_i \phi_i(\sigma) d\sigma \right\}.$$

Now, since $\phi'(y) > 0$, for all $\phi \in \Phi$, it follows that $\sum_{i=1}^m \{N_i \phi_i(y_i) y_i - \int_0^{y_i} N_i \phi_i(\sigma) d\sigma\} > 0$. Furthermore, since V is positive definite, it follows that $\dot{V}(x_n)$ is positive definite. The corresponding Lyapunov derivative is given by

$$\begin{aligned} \dot{V}(x_n) &= x_n^T [A_n^T P + P A_n] x_n \\ &\quad - f^T(y) [B_n^T P - N C_n] x_n \\ &\quad - x_n^T [B_n^T P - N C_n]^T f(y). \end{aligned} \quad (3.16)$$

Next, it follows from (3.3) that $\phi'(y)(I - \mu^{-1} \phi'(y)) > 0$, for all $\phi \in \Phi$. Hence, $2 \dot{y}^T \phi'(y)(I - \mu^{-1} \phi'(y)) \dot{y} \geq 0$. Now, adding

and subtracting $2 \dot{y}^T \phi'(y)(I - \mu^{-1} \phi'(y)) \dot{y}$ to and from (3.16) and grouping terms yields

$$\begin{aligned} \dot{V}(x_n) &= x_n^T [A_n^T P + P A_n] x_n \\ &\quad - f^T(y) [B_n^T P - N C_n - S] x_n \\ &\quad - x_n^T [B_n^T P - N C_n - S]^T f(y) \\ &\quad - 2 f^T(y) \mu^{-1} f(y) - 2 \dot{y}^T \phi'(y) \\ &\quad \cdot (I - \mu^{-1} \phi'(y)) \dot{y} \end{aligned} \quad (3.17)$$

or, using (3.6)–(3.8), yields

$$\begin{aligned} \dot{V}(x_n) &= -[L x_n - W f(y)]^T [L x_n - W f(y)] \\ &\quad - 2 \dot{y}^T \phi'(y) (I - \mu^{-1} \phi'(y)) \dot{y}. \end{aligned} \quad (3.18)$$

Since $2 \dot{y}^T \phi'(y) (I - \mu^{-1} \phi'(y)) \dot{y} \geq 0$, it follows that $\dot{V}(x_n) \leq 0$, which proves stability in the sense of Lyapunov.

To show global asymptotic stability we need to show that $\dot{V}(x_n) = 0$ implies that $x = 0$. Note that $\dot{V}(x_n) = 0$ implies that $\dot{y}(t) = 0$, $t \geq 0$, and hence $f(y) = 0$ and $L x_n(t) = 0$. Furthermore, in this case $\dot{x}_n(t) = A_n x_n(t) - B_n f(y) = A_n x_n(t)$. Thus, using $\dot{x}_n(t) = A_n x_n(t)$, $L x_n(t) = 0$, and the observability of (A_n, L) , it follows from the PBH test that $x_n(t) = 0$, $t \geq 0$, which further implies, since (A, C) is observable, that $x(t) = 0$, $t \geq 0$. Thus, the only solution satisfying $\dot{V}(x, y) = 0$ is the $x(t) = 0$, $t \geq 0$, solution and hence it follows from the LaSalle's theorem [20] that global asymptotic stability holds. \square

Theorem 3.1 presents a generalization of Theorem 1 of [18] to the case of multivariable plants containing an arbitrary number of memoryless time-invariant slope-restricted monotonic nonlinearities.

The form of $\mathcal{G}(s)$ given by (3.5) is standard in the classical absolute stability theory [14] in which $Z(s)$ is a stability multiplier that distinguishes the class of the allowable feedback nonlinearities. As mentioned in the Introduction specific cases include memoryless time-invariant nonlinearities [15], monotonic and odd monotonic nonlinearities [9], [12]–[14], and locally slope restricted nonlinearities [4], [22]–[24]. A key difference between the results in Theorem 3.1 and the classical theory on monotonic and odd monotonic nonlinearities [9], [12]–[14] is that the multiplier $Z(s)$ in (3.4) involves a simple twist on the Popov multiplier in contrast to the more involved positive real multipliers involving partial fraction expansions of driving point impedances of resistor-inductor (\mathcal{RL}) and resistor-capacitor (\mathcal{RC}) combinations which exhibit interlacing pole-zero patterns on the negative real axis [9], [12], [13] and non-positive real plant-dependent multipliers [4], [7], [23].

In the SISO case, the frequency domain condition in Theorem 3.1 has an interesting geometric interpretation. Specifically, setting $G(j\omega) = x + jy$, $\text{Re } \mathcal{G}(j\omega) > 0$ is equivalent to

$$\frac{1}{\mu} + x + \frac{N}{\omega} y > 0. \quad (3.19)$$

Condition (3.19) is a frequency domain stability criterion with a graphical interpretation in a modified Popov plane, involving $\text{Re } G$ and $\omega^{-1} \text{Im } G$, in terms of a straight line with a real axis-intercept $-1/\mu$ and slope $-1/N$.

Since the condition presented in Theorem 3.1 is only sufficient for absolute stability a natural question that arises is for what class of systems will this criterion give less conservative predictions over the classical Popov criterion. In order to address this question first recall that the effect that the Popov multiplier $1 + Ns$ has on the Nyquist plot is to rotate each point on the Nyquist plot in the counter clockwise direction. Hence, if the Nyquist plot of the plant transfer function $G(s)$ enters the second quadrant then it is clear that there does not exist an N such that $(1 + Ns)G(s)$ is positive real. Thus, in

Fig. 1. Positive real analysis

Fig. 2. Popov analysis.

this case, the Popov criterion does not provide any improvement over the positive real test (see the example in Section IV). Alternatively, since the effect of the proposed multiplier $1 + Ns^{-1}$ is to rotate each point on the Nyquist plot in the clockwise direction, the criterion in Theorem 3.1 will always give less conservative predictions over the Popov criterion when the Nyquist plot of $G(s)$ resides in the first and second quadrants. For example, since the Nyquist plot of the class of third-order transfer functions given by

$$G(s) = \frac{s^2}{a_0 s^3 + a_1 s^2 + a_2 s + a_3}$$

where $a_0 > 0$, $a_1 > 0$, $a_2 > 0$, $a_3 > 0$, and $a_2 a_1 > a_0 a_3$ will always enter the second quadrant, the proposed criterion would give less conservative predictions over the Popov criterion. Of course, using similar arguments as above, if the Nyquist plot of $G(s)$ resides in the third and fourth quadrants then the proposed criterion would not give any improvement over the positivity criterion while the Popov criterion would give less conservative predictions. Hence, the utility of the proposed criterion is when the Popov criterion fails. Finally, it should be noted that the more general class of multipliers consisting of the \mathcal{RL} and the \mathcal{RC} class [9], [12], [13] place less restrictive conditions on $G(s)$ and hence allow the Nyquist plot to reside in all four quadrants. As a result of the more involved multiplier construction, however, the resulting frequency domain conditions provide a complex graphical interpretation involving frequency-dependent off-axis circles in the Nyquist plane [9]. Alternatively, if the classical off-axis circle criterion is used where a single bounding circle in the Nyquist plane is employed [14] as opposed to a family of frequency dependent circles then conservatism will be introduced in the stability predictions.

Remark 3.1 Note that the class Φ of nonlinearities becomes larger as μ increases. In fact, as μ increases the strict positive real condition (3.5) becomes more difficult to satisfy, as expected. Furthermore,

Fig. 3. Modified Popov analysis

even though the frequency domain condition in Theorem 3.1 does not involve an explicit sector constraint on the nonlinearities $\phi(y)$, the requirement that $\phi \in \Phi$ implies that $0 < \phi_i(y_i)y_i < \mu y_i^2$, $y_i \in \mathbb{R}$, $i = 1, \dots, m$.

Next, we partially relax the assumption $\det CA^{-1}B \neq 0$ and provide an alternative Lyapunov function construction for the absolute stability criterion given in Theorem 3.1. The following result does not require a system augmentation of the form (3.12), however, in this case we assume that every element of the stable transfer function $G(s)$ has at least one zero at the origin, i.e., $G(0) = 0$.

Theorem 3.2 Let

$$G(s) \approx \begin{bmatrix} A & B \\ C & 0 \end{bmatrix}$$

be asymptotically stable, let $N \triangleq \text{diag}[N_1, N_2, \dots, N_m]$ be nonnegative-definite, assume that $G(0) = 0$, and define

$$Z(s) \triangleq I + Ns^{-1}. \quad (3.20)$$

Then

$$\tilde{G}(s) \triangleq \mu^{-1} + Z(s)G(s) \quad (3.21)$$

is strictly positive real, if and only if there exists matrices P , L , and W with P positive definite satisfying

$$0 = A^T P + P A + L^T L, \quad (3.22)$$

$$0 = B^T P - N C A^{-1} - C^T + W^T L, \quad (3.23)$$

$$0 = 2\mu^{-1} - W^T W. \quad (3.24)$$

In this case

$$V(\dot{x}) = \dot{x}^T P \dot{x} + 2 \sum_{i=1}^m \int_0^{y_i} N_i \phi_i(\sigma) \sigma d\sigma \quad (3.25)$$

where $y(t) = Cx(t)$, is a Lyapunov function that guarantees that the negative feedback interconnection of $G(s)$ and ϕ is globally asymptotically stable for all $\phi \in \Phi$.

Proof The proof is similar to the proof of Theorem 3.1. \square

Remark 3.2 Note that since $G(s)$ is asymptotically stable A^{-1} exists. Furthermore, in order to construct the proof of Theorem 3.2, it is helpful to note that since every element of the stable transfer function $G(s)$ has at least one zero at the origin, $CA^{-1}B = 0$ and $CA^{-1}(sI - A)^{-1}B = \frac{G(s)}{s}$.

IV. ILLUSTRATIVE NUMERICAL EXAMPLE

For illustrative purposes we consider the stable linear system with transfer function

$$G(s) = \frac{s^2 - 0.2s - 0.1}{s^3 + 2s^2 + s + 1}. \quad (4.1)$$

the closed-loop system (3.1) with linear uncertainty $\phi(y) = Fy$ is asymptotically stable for $0 \leq F \leq 4.6$. The Nyquist plot for the linear system is shown in Fig. 1. Hence, it follows from the positivity theorem that the linear system is asymptotically stable for all time invariant monotone nonlinearities in the sector $[0, 1/24]$. Fig. 2 shows the corresponding Popov plot which, in this case, gives a Popov sector $[0, 1/24]$. Hence, since the Nyquist plot of $G(s)$ enters the second quadrant the Popov criterion does not provide any improvement over the positive real test. Finally, using Theorem 3.1 we construct a modified Popov plot shown in Fig. 3. Using the modified Popov exclusionary half plane graphical test given by (3.19) the absolute stability sector is now found to be $[0, 4.6]$ which is a significant improvement over the positivity and Popov sectors for time invariant monotone feedback nonlinearities.

CONCLUSION

In this paper we extended the SISO absolute stability criterion for locally slope restricted monotonic nonlinearities developed in [18] to multivariable systems containing an arbitrary number of monotonic slope bounded nonlinearities. Specifically, explicit Lyapunov functions along with extended Yakubovich-Kalman-Popov conditions are given. These results can be used to synthesize robust feedback controllers in the spirit of [6], [8], [9].

Simultaneous Disturbance Rejection and Regular Row by Row Decoupling With Stability: A Geometric Approach

Juan Carlos Martinez Garcia and Michel Malabre

Abstract—The simultaneous disturbance rejection problem and regular row by row decoupling problem with stability is solved here through a geometric approach. It is shown in this paper that the combined problem has a solution if and only if each problem, separately, has a solution.

1 INTRODUCTION

As far as its geometric setting is concerned, the combined problem of disturbance rejection and input-output decoupling for linear time invariant systems by static state feedback has been first discussed in [1] and [3] almost 20 years ago. This problem has been recently revisited in [9] while the structural approach has been used in [2] in order to obtain easy to verify solvability conditions.

As the main result of the research referenced above, a nice property has been found. Indeed, when no stability constraint is imposed it

Manuscript received December 21, 1993; revised May 6, 1994. This work was supported in part by National Council of Science and Technology of Mexico, the Advanced Studies and Research Center of the IPN of Mexico and ESPRIT Basic Research Project No. 8924 (SESDIP).

J. C. Martinez Garcia was with the LAN, URA CNRS 823, Ecole Centrale de Nantes, Université de Nantes, 1 rue de la Noë, F-44072 Nantes Cedex 03, France, and is now with CINESTAV, Mexico.

M. Malabre is with the LAN, URA CNRS 823, Ecole Centrale de Nantes, Université de Nantes, 1 rue de la Noë, F-44072 Nantes Cedex 03, France. IEEE Log Number 9407221.

has been established that the combined problem is solvable if and only if each problem, separately, has a solution. Intuitively, when the internal stability of the closed-loop system is required, this separation solvability should still hold. To our knowledge, this result has never been established. The aim of this paper is to bridge that gap through a geometric approach.

First of all, we shall present some basic tools and the geometric solvability conditions of both the regular row by row decoupling problem with stability and the disturbance rejection problem with stability, where the notion of supremal internally stabilizable (A, B) -invariant subspace will play an important role.

In the second part of the paper we shall present the solution of the combined problem, proving that regular row by row decoupling with stability can be obtained using a static state feedback control law chosen in a particular family (built up from a particular set of internally stabilizable (A, B) -invariant subspaces), which also rejects automatically the disturbance, if this latter problem is solvable. This "separation property" is proved under the assumption that the system without disturbance is controllable. This is indeed the usual assumption when studying decoupling.

II. BASIC CONCEPTS

Let us consider a linear time-invariant system described by

$$\begin{cases} \dot{x}(t) = Ax(t) + Bu(t), & t \geq 0, \\ y(t) = Cx(t), & t \geq 0 \end{cases} \quad (1)$$

with $A: \mathcal{X} \rightarrow \mathcal{X}$, $B: \mathcal{U} \rightarrow \mathcal{X}$, $C: \mathcal{X} \rightarrow \mathcal{Y}$ ($\dim(\mathcal{X}) = n$, $\dim(\mathcal{U}) = m$, $\dim(\mathcal{Y}) = p$) and denoted (A, B, C) .

In what follows we shall use the following notation: for a given map, say B , we shall denote \mathcal{B} its image. For a given map, say C , the kernel is noted as $\text{Ker}C$.

A subspace $\mathcal{V} \subset \mathcal{X}$ is said to be (A, B) -invariant if and only if $A\mathcal{V} \subset \mathcal{V} + \mathcal{B}$. We shall denote $\mathfrak{I}(A, B; S)$ the family of all the (A, B) -invariant subspaces included in the subspace $S \subset \mathcal{X}$. If $\mathcal{V} \in \mathfrak{I}(A, B; S)$, there exists at least a map $F: \mathcal{X} \rightarrow \mathcal{U}$ (called a friend of \mathcal{V}) such that $(A + BF)\mathcal{V} \subset \mathcal{V} \subset S$. The family of all friends of \mathcal{V} is written as $\mathbf{F}(\mathcal{V})$.

Let $\mathcal{V} \in \mathfrak{I}(A, B; S)$ and let us denote $\mathcal{R}_{\mathcal{V}}$ the supremal (A, B) -controllability subspace contained in \mathcal{V} . Then, the following statements are equivalent:

- $\mathcal{V} \in \mathfrak{I}(A, B; S)$ is an internally stabilizable (A, B) -invariant subspace.
- There exists a map $F \in \mathbf{F}(\mathcal{V})$ such that $\sigma(A + BF|_{\mathcal{V}}) \subset \mathbb{C}_-$, where $A + BF|_{\mathcal{V}}$ denotes the double restriction of $A + BF$ to \mathcal{V} and \mathbb{C}_- is the open left-half complex plane.
- $\sigma_{\mathcal{V}} := \sigma(\overline{A + BF})$ satisfies $\sigma_{\mathcal{V}} \subset \mathbb{C}_-$, where $\overline{A + BF}$ is the map induced in $\mathcal{V}/\mathcal{R}_{\mathcal{V}}$ by $A + BF$ ($\sigma_{\mathcal{V}}$ is independent of the choice of $F \in \mathbf{F}(\mathcal{V})$, see Property A.1 in the Appendix).

Assuming that (A, B) is stabilizable and being $\mathcal{V} \in \mathfrak{I}(A, B; S)$ an internally stabilizable (A, B) -invariant subspace, there exists at least a map $F: \mathcal{X} \rightarrow \mathcal{U}$ belonging to $\mathbf{F}(\mathcal{V})$ such that $\sigma(A + BF) \subset \mathbb{C}_-$ (see for instance [10]). In that case, we shall say that F belongs to the family $\mathbf{F}_s(\mathcal{V})$.

A set of (A, B) -invariant subspaces $\{\mathcal{V}_1, \mathcal{V}_2, \dots, \mathcal{V}_k\}$ is called compatible if there exists at least one common friend for all of them, i.e., $\bigcap_{i=1}^k \mathbf{F}(\mathcal{V}_i) \neq \emptyset$. If the family $\{\mathcal{V}_1, \mathcal{V}_2, \dots, \mathcal{V}_k\}$ is compatible, it is not difficult to show that their radical, say $\hat{\mathcal{V}}$ defined as $\hat{\mathcal{V}} := \bigcap_{i=1}^k \sum_{j \neq i} \mathcal{V}_j$, is (A, B) -invariant and $\bigcap_{i=1}^k \mathbf{F}(\mathcal{V}_i) \subset \bigcap_{i=1}^k \mathbf{F}(\mathcal{V}_i + \hat{\mathcal{V}})$ (see for instance [11, Chapter 10]).

If $\bigcap_{i=1}^k \mathbf{F}(\mathcal{V}_i) = \mathbf{F}(\hat{\mathcal{V}}) \cap \bigcap_{i=1}^k \mathbf{F}(\mathcal{V}_i + \hat{\mathcal{V}})$, then $\{\mathcal{V}_1, \mathcal{V}_2, \dots, \mathcal{V}_k\}$ is called strongly compatible [8].

III. PROBLEMS STATEMENTS

A. Decoupling

Some Definitions: First of all we shall define the Block Decoupling Problem via regular static state feedback (BDP).

Definition 1 (BDP): Given a controllable system (A, B, C) and according to a given block partition $\{C_1, C_2, \dots, C_k\}$ of C , the block decoupling problem is then defined as follows:

"Find conditions for the existence of static state feedback control laws $u(t) = Fx(t) + \sum_{i=1}^k G_i v_i(t)$ such that each block input $v_i(t)$ completely controls the block output $y_i(t) = C_i x(t)$ without affecting the $k - 1$ other block-outputs $y_j(t)$, $j \neq i$, under the constraint $G = [G_1 \ G_2 \ \dots \ G_k]$ regular, i.e., G invertible."

The number of columns in each block G_i is not fixed *a priori*. If F and G , regular, exist for the block partition $\{C_1, C_2, \dots, C_k\}$, then we shall say that (A, B, C) is a regularly block decouplable system.

Definition 2 (RBRDP): When $k = p$, BDP becomes the so-called (regular) Row By Row Decoupling Problem. Let us recall that in that case right invertibility of the system is an obvious necessary condition for RBRDP to be solvable.

Definition 3 (RBRDPS): When we add the constraint $\sigma(A + BF) \subset \mathbb{C}_-$ to RBRDP we have the so-called (regular) row by row decoupling problem with stability.

To give the solvability condition of RBRDPS in geometric terms, let us first introduce some notation. Let c_i be the i th row of C and let us denote:

- \mathcal{V}^* , respectively, \mathcal{V}_i^* , respectively, \mathcal{W}_i^* , the supremal (A, B) -invariant subspace contained in $\text{Ker}C$, respectively, $\text{Ker}c_i$, respectively, $\bigcap_{j \neq i} \text{Ker}c_j$.
- \mathcal{V}_{stab}^* , respectively, $\mathcal{V}_{i,stab}^*$, respectively, $\mathcal{W}_{i,stab}^*$, the supremal internally stabilizable (A, B) -invariant subspace contained in $\text{Ker}C$, respectively, $\text{Ker}c_i$, respectively, $\bigcap_{j \neq i} \text{Ker}c_j$.
- \mathcal{R}^* , respectively, \mathcal{R}_i^* , respectively, \mathcal{T}_i^* , the supremal (A, B) -controllability subspace contained in $\text{Ker}C$, respectively, $\text{Ker}c_i$, respectively, $\bigcap_{j \neq i} \text{Ker}c_j$.

Then we have the following theorem.

Theorem 1 [6, Theorem 3]. Assuming that (A, B) is controllable, RBRDPS is solvable if and only if

$$\begin{cases} \text{i)} & \mathcal{V}^* = \bigcap_{i=1}^p \mathcal{V}_i^* \\ \text{ii)} & \bigcap_{i=1}^p \mathcal{R}_i^* \subset \mathcal{V}_{stab}^* \end{cases}$$

Remark 1 It has to be noted that if RBRDP is solvable, $\bigcap_{i=1}^p \mathcal{R}_i^*$ is equal to the radical of $\{\mathcal{T}_1^*, \mathcal{T}_2^*, \dots, \mathcal{T}_p^*\}$ (see for instance [4, Corollary V.1]).

In an equivalent way, we have the following theorem.

Theorem 2 [6, Theorem 4]. Assuming that (A, B) is controllable, RBRDPS is solvable if and only if

$$\begin{cases} \text{i)} & \mathcal{V}^* = \bigcap_{i=1}^p \mathcal{V}_i^* \\ \text{ii)} & \mathcal{V}_{stab}^* = \bigcap_{i=1}^p \mathcal{V}_{i,stab}^* \end{cases}$$

If RBRDPS is solvable we shall say that (A, B, C) is a regularly row by row decouplable system with stability.

B. Disturbance Rejection

Let us now consider the following linear time-invariant disturbed system

$$\begin{cases} \dot{x}(t) = Ax(t) + Bu(t) + Ed(t), & t \geq 0, \\ y(t) = Cx(t), & t \geq 0 \end{cases}$$

where A, B , and C are as defined in (1) and $E: \mathcal{D} \rightarrow \mathcal{X}$ ($\dim(\mathcal{D}) = q$). The disturbance input, $d(t)$, may or may not be

measured. We shall denote this system by (A, B, C, E) .

The disturbance rejection problem with stability (DRPS) is then defined as follows.

Definition 4 (DRP-DRPS): Given a system (A, B, C, E) , find conditions for the existence of a static state feedback control law $u(t) = Fx(t) + Hd(t)$ such that $y(t)$ does not depend on the disturbance (DRP) and the closed-loop system is internally stable (DRPS).

In what follows we shall denote \mathcal{E} the image of E . The known classic geometric solvability condition of DRPS is given by the following theorem.

Theorem 3 [11, Theorem 5.8]: Assuming that (A, B) is controllable, DRPS is solvable if and only if $\mathcal{E} \subset \mathcal{V}_{stab}^*$.

Note that Theorem 3 is still valid if (A, B) is just stabilizable. If the disturbance is not measured ($H = 0$), the well-known geometric solution is $\mathcal{E} \subset \mathcal{V}_{stab}^*$.

Finally, as concerns the set where the solutions (feedbacks F) can be found, (if any), it is quite well known that, in both cases (disturbance measured or not), it is given by $\mathbf{F}_s(\mathcal{V}_{stab}^*)$.

C. Simultaneous Disturbance Rejection and Regular Row by Row Decoupling Problem With Stability (SDRDPS)

Let us consider again the disturbed linear-time invariant system (A, B, C, E)

$$\begin{cases} \dot{x}(t) = Ax(t) + Bu(t) + Ed(t), & t \geq 0 \\ y(t) = Cx(t), & t \geq 0. \end{cases}$$

Because of decoupling requirements, we shall assume that the system without disturbance (A, B, C) is controllable and right invertible.

Definition 5 (SDRDPS): Find conditions for the existence of a static state feedback control law $u(t) = Fx(t) + Gv(t) + Hd(t)$, with $G := [G_1 \ G_2 \ \dots \ G_p]$ regular and $v(t) = [v_1^T(t) \ v_2^T(t) \ \dots \ v_p^T(t)]^T$, where $v_i(t)$ are block input vectors (since $m \geq p$) and such that $y(t)$ does not depend on the disturbance, the closed-loop system is decoupled from $v(t)$ to $y(t)$ and is internally stable.

IV. SOLUTION OF SDRDPS

For that solution, we shall characterize a family of control laws which solve SDRDPS. Before that, and in order to introduce our extension, we shall quickly recall the formal statement of the decoupling problem and the way the combined problem is solved, when no stability constraint is imposed.

To express the objective of decoupling formally, let $\{T_1, T_2, \dots, T_p\}$ be the set of subspaces which $v_i(t)$, $i \in \{1, 2, \dots, p\}$, can control. Thus T_i is the (A, B) -controllability subspace given by $T_i = (A + BF \mid B \operatorname{Im} G_i)$, $i \in \{1, 2, \dots, p\}$.

Now, the objective of decoupling can be established as follows (see for instance [11, Chapter 9]):

"Find conditions for the existence of compatible (A, B) -controllability subspaces T_i included in $\bigcap_{j \neq i} \operatorname{Ker} c_j$ and satisfying $T_i + \operatorname{Ker} c_i = \mathcal{X}$, for all $i \in \{1, 2, \dots, p\}$."

A set of controllability subspaces $\{T_1, T_2, \dots, T_p\}$ satisfying these conditions is called a solution to the row by row decoupling problem. Let us recall the following theorem.

Theorem 4 [8, Theorem 7]: A regular solution to the Row by Row Decoupling Problem exists if and only if $\mathcal{B} = \sum_{i=1}^p \mathcal{B} \cap T_i^*$. If so, $\{T_1^*, T_2^*, \dots, T_p^*\}$ is a strongly compatible solution.

A decoupling solution (if any) $F : \mathcal{X} \rightarrow \mathcal{U}$ can be picked up in the family $\bigcap_{i=1}^p \mathbf{F}(T_i^*)$. G is usually directly deduced from $\operatorname{Im} BG_i := \mathcal{B} \cap T_i^*$.

The first important result for the solvability of the simultaneous disturbance rejection and regular row by row decoupling problem

when no stability constraint is imposed (SDRDPS), is the following separation property.

Theorem 5 [1, Theorem 3]: SDRDP is solvable if and only if both RBRDP and DRP are solvable separately.

We shall here add the stability requirement. In this case, asking for the solvability condition of RBRDPS is strictly equivalent to asking for conditions of existence of a nonempty family $\bigcap_{i=1}^p \mathbf{F}_s(T_i^*) \subset \bigcap_{i=1}^p \mathbf{F}(T_i^*)$. By Theorem 1, we know that $\bigcap_{i=1}^p \mathbf{F}_s(T_i^*)$ is nonempty if and only if $\bigcap_{i=1}^p \mathcal{R}_i^* \subset \mathcal{V}_{stab}^*$.

To solve the simultaneous disturbance rejection and row by row decoupling problem with stability, we shall proceed as in the case when no stability constraint is imposed, i.e., we shall characterize a subfamily of $\bigcap_{i=1}^p \mathbf{F}_s(T_i^*)$, in terms of internally stabilizable (A, B) -invariant subspaces, in such a way that any map $F : \mathcal{X} \rightarrow \mathcal{U}$ belonging to that subfamily will also automatically reject the disturbance, provided that this latter problem is solvable.

The result established by the following theorem will play a key role in the solution of the simultaneous disturbance rejection and regular row by row decoupling problem with stability. Let $\widehat{\mathcal{W}}_{stab}^*$ denote the radical of $\{\mathcal{W}_{1\text{stab}}^*, \mathcal{W}_{2\text{stab}}^*, \dots, \mathcal{W}_{p\text{stab}}^*\}$.

Theorem 6: Let (A, B, C) be a regularly row by row decouplable system with stability. There then always exists a common stabilizing friend for the family $\{\widehat{\mathcal{W}}_{stab}^*, \widehat{\mathcal{W}}_{stab}^* + \mathcal{W}_{1\text{stab}}^*, \widehat{\mathcal{W}}_{stab}^* + \mathcal{W}_{2\text{stab}}^*, \dots, \widehat{\mathcal{W}}_{stab}^* + \mathcal{W}_{p\text{stab}}^*\}$.

The proof of this theorem will rest upon the following results, which proofs are in the Appendix.

Theorem 7: Let both $\mathcal{V}_1, \mathcal{V}_2$ be internally stabilizable (A, B) -invariant subspaces such that $\mathcal{V}_1 \subset \mathcal{V}_2$. Then, for any $F_1 \in \mathbf{F}(\mathcal{V}_1)$ such that $\sigma(A + BF_1 \mid \mathcal{V}_1) \subset \mathcal{C}_-$, there exists a map $F_2 \in \mathbf{F}(\mathcal{V}_2)$ such that $F_2 \mid \mathcal{V}_1 = F_1 \mid \mathcal{V}_1$ and $\sigma(A + BF_2 \mid \mathcal{V}_2) \subset \mathcal{C}_-$, i.e., F_2 is such that $(A + BF_2)\mathcal{V}_1 \subset \mathcal{V}_1$, $(A + BF_2)\mathcal{V}_2 \subset \mathcal{V}_2$ and $\sigma(A + BF_2 \mid \mathcal{V}_2) \subset \mathcal{C}_-$.

Lemma 1: Let (A, B, C) be a regularly row by row decouplable system with stability, then $\widehat{\mathcal{W}}_{stab}^* = \bigcap_{i=1}^p \mathcal{W}_{i\text{stab}}^* = \mathcal{V}_{stab}^*$.

Property 1: Let (A, B, C) be a regularly row by row decouplable system with stability, then $\mathcal{X} = \sum_{i=1}^p \mathcal{W}_{i\text{stab}}^*$.

Proof of Theorem 6: From Property 1 we have that the state space \mathcal{X} can be partitioned as

$$\mathcal{X} = \sum_{i=1}^p \mathcal{W}_{i\text{stab}}^* = \sum_{i=1}^p \left(\widehat{\mathcal{W}}_{stab}^* + \sum_{j=1}^i \mathcal{W}_{j\text{stab}}^* \right).$$

Note that $(\widehat{\mathcal{W}}_{stab}^* + \sum_{j=1}^i \mathcal{W}_{j\text{stab}}^*)$, for all $i \in \{1, 2, \dots, p\}$, is an internally stabilizable (A, B) -invariant subspace. Since $\widehat{\mathcal{W}}_{stab}^*$ is an internally stabilizable (A, B) -invariant subspace (indeed, we have from Lemma 1 that $\widehat{\mathcal{W}}_{stab}^* = \mathcal{V}_{stab}^*$), we can always find a map $F_0 \in \mathbf{F}(\widehat{\mathcal{W}}_{stab}^*)$ such that $\sigma(A + BF_0 \mid \widehat{\mathcal{W}}_{stab}^*) \subset \mathcal{C}_-$.

By Theorem 7, there exists a map $F_1 \in \mathbf{F}(\widehat{\mathcal{W}}_{stab}^* + \mathcal{W}_{1\text{stab}}^*)$ such that

$$\begin{aligned} F_1 \mid \widehat{\mathcal{W}}_{stab}^* &= F_0 \mid \widehat{\mathcal{W}}_{stab}^* \\ \text{and } \sigma(A + BF_1 \mid (\widehat{\mathcal{W}}_{stab}^* + \mathcal{W}_{1\text{stab}}^*)) &\subset \mathcal{C}_-. \end{aligned}$$

Applying again Theorem 7, we can find a map $F_2 \in \mathbf{F}(\widehat{\mathcal{W}}_{stab}^* + \mathcal{W}_{1\text{stab}}^* + \mathcal{W}_{2\text{stab}}^*)$ such that

$$F_2 \mid (\widehat{\mathcal{W}}_{stab}^* + \mathcal{W}_{1\text{stab}}^*) = F_1 \mid (\widehat{\mathcal{W}}_{stab}^* + \mathcal{W}_{1\text{stab}}^*)$$

and

$$\sigma(A + BF_2 \mid (\widehat{\mathcal{W}}_{stab}^* + \mathcal{W}_{1\text{stab}}^* + \mathcal{W}_{2\text{stab}}^*)) \subset \mathcal{C}_-.$$

Following the same procedure we obtain a sequence of maps

$$F_i \in \mathbf{F}\left(\widehat{\mathcal{W}}_{stab}^* + \sum_{j=1}^i \mathcal{W}_{j\text{stab}}^*\right), \quad \forall i \in \{1, 2, \dots, p\}$$

such that

$$F_i \left| \left(\widehat{\mathcal{W}}_{stab}^* + \sum_{j=1}^{i-1} \mathcal{W}_{stab}^* \right) \right. = F_{i-1} \left| \left(\widehat{\mathcal{W}}_{stab}^* + \sum_{j=1}^{i-1} \mathcal{W}_{stab}^* \right) \right.$$

and $\sigma(A + BF_i | \widehat{\mathcal{W}}_{stab}^* + \sum_{j=1}^i \mathcal{W}_{stab}^*) \subset \mathbb{C}_-$.

Finally, $F = F_p$ is the desired map.

From Lemma 1 we note that $\widehat{\mathcal{W}}_{stab}^* \subset \mathcal{W}_{stab}^*$, for all $i \in \{1, 2, \dots, p\}$. Consequently $\bigcap_{i=1}^p F(\mathcal{W}_{stab}^*) = \bigcap_{i=1}^p F(\widehat{\mathcal{W}}_{stab}^* + \mathcal{W}_{stab}^*)$.

Thus, the result established by Theorem 6 can be rewritten as follows.

Theorem 8: Let (A, B, C) be a regularly row by row decouplable system with stability, then the family $F_s(\widehat{\mathcal{W}}_{stab}^*) \cap \bigcap_{i=1}^p F_s(\mathcal{W}_{stab}^*)$ is nonempty.

Before considering the Simultaneous Regular Row By Row Decoupling and Disturbance Rejection Problem with Stability, let us first clarify the connection between the family $\bigcap_{i=1}^p F_s(\mathcal{W}_{stab}^*)$ and the family $\bigcap_{i=1}^p F_s(T_i^*)$ (proved in the Appendix).

Lemma 2: For any system (A, B, C) , the following inclusion always holds

$$F(\mathcal{W}_{stab}^*) \subset F(T_i^*), \quad \forall i \in \{1, 2, \dots, p\}.$$

An obvious corollary is the following.

Corollary 1: $F_s(\mathcal{W}_{stab}^*) \subset F_s(T_i^*)$, for all $i \in \{1, 2, \dots, p\}$.

We can now present our main result.

A. SDRDPS. The Final Result

Theorem 9: The simultaneous regular row by row decoupling and disturbance rejection problem with stability has a solution if and only if both the regular row by row decoupling problem with stability and the disturbance rejection problem with stability are solvable separately.

Proof of Theorem 9: Necessity is obvious. For sufficiency suppose that system (A, B, C) is regularly row by row decouplable with stability, then by Theorem 8, the family $F_s(\widehat{\mathcal{W}}_{stab}^*) \cap \bigcap_{i=1}^p F_s(\mathcal{W}_{stab}^*)$ is nonempty. By Corollary 1, the inclusion $F_s(\mathcal{W}_{stab}^*) \subset F_s(T_i^*)$, for all $i \in \{1, 2, \dots, p\}$, always holds and consequently

$$\bigcap_{i=1}^p F_s(\mathcal{W}_{stab}^*) \subset \bigcap_{i=1}^p F_s(T_i^*).$$

Since

$$F_s(\widehat{\mathcal{W}}_{stab}^*) \cap \bigcap_{i=1}^p F_s(\mathcal{W}_{stab}^*) \subset \bigcap_{i=1}^p F_s(\mathcal{W}_{stab}^*) \subset \bigcap_{i=1}^p F_s(T_i^*)$$

any map $F \in F_s(\widehat{\mathcal{W}}_{stab}^*) \cap \bigcap_{i=1}^p F_s(\mathcal{W}_{stab}^*)$, with a suitable map $G: \mathcal{U} \rightarrow \mathcal{U}$, will decouple, while insuring internal stability of the closed-loop system.

Now, if the disturbance rejection problem with stability is solvable, any map $F \in F_s(\widehat{\mathcal{W}}_{stab}^*) \cap \bigcap_{i=1}^p F_s(\mathcal{W}_{stab}^*)$, with (eventually, depending on the fact that $d(t)$ is measured or not) a suitable map $H: \mathcal{D} \rightarrow \mathcal{U}$, also rejects the disturbance. Indeed, from Lemma 1

we have $F(\widehat{\mathcal{W}}_{stab}^*) = F(\mathcal{V}_{stab}^*)$ and then

$$\begin{aligned} F_s(\widehat{\mathcal{W}}_{stab}^*) \cap \bigcap_{i=1}^p F_s(\mathcal{W}_{stab}^*) \\ = F_s(\mathcal{V}_{stab}^*) \cap \bigcap_{i=1}^p F_s(\mathcal{W}_{stab}^*) \subset F_s(\mathcal{V}_{stab}^*) \end{aligned}$$

which ends the proof.

V. CONCLUDING REMARKS

We have considered here the simultaneous disturbance rejection and regular row by row decoupling problem with stability (SDRDPS). We have proved that the separation property (which states that the simultaneous problem is solvable if and only if each problem is solvable separately) is still true when internal stability is required. This has been done under the non restrictive assumption that the system without disturbance is controllable. The weaker assumption of stabilizability should be sufficient, but most of the results related to decoupling which have been used here had been previously stated within this controllability assumption. Adaptation to this broader situation should be quite easy, just leading to heavier development.

Thanks to this result, it will be possible to exploit the recent geometric and structural solutions of DRPS [5, Theorem 7] and RBRDPS [6, Theorem 6] to propose a synthetic solution for SDRDPS in terms of infinite and unstable zeros.

This will be detailed in a future work.

APPENDIX

A. Proof of Theorem 7

It will rest upon the following property

Property A.1 [11, Theorem 5.7 and Corollary 5.2] Let $\mathcal{V} \in \mathcal{J}(A, B; \mathcal{X})$ be given. For any $F \in \mathbf{F}(\mathcal{V})$ write $\overline{A + BF}$ for the map induced in $\mathcal{V}/R_{\mathcal{V}}$ by $A + BF$. Then $\overline{A + BF}$ is independent of $F \in \mathbf{F}(\mathcal{V})$ and $\sigma(A + BF | \mathcal{V}) = \sigma_1 \cup \sigma_{\mathcal{V}}$, where $\sigma_1 := \sigma(A + BF | R_{\mathcal{V}})$ is freely assignable by suitable choice of $F \in \mathbf{F}(\mathcal{V})$ and $\sigma_{\mathcal{V}} := \sigma(\overline{A + BF})$ is fixed for all $F \in \mathbf{F}(\mathcal{V})$. A subspace $\mathcal{V} \in \mathcal{J}(A, B; \mathcal{X})$ is thus internally stabilizable if and only if $\sigma_{\mathcal{V}} \subset \mathbb{C}_-$.

Property A.2 [7, Lemma A.2]: Let $\mathcal{V}_1, \mathcal{V}_2 \in \mathcal{J}(A, B; \mathcal{X})$ be given. Let us denote $\overline{A + BF_2}$ the map induced by $A + BF_2$ in $\mathcal{V}_2/\mathcal{V}_1$. If $\mathcal{V}_1 \subset \mathcal{V}_2$ then for any map $F_1 \in \mathbf{F}(\mathcal{V}_1)$, there exists a map $F_2 \in \mathbf{F}(\mathcal{V}_2)$ such that $F_2 | \mathcal{V}_1 = F_1 | \mathcal{V}_1$. Moreover, if $\mathcal{V}_2 = \mathcal{V}_1 + \mathcal{R}_{\mathcal{V}_2}$, then $\sigma(\overline{A + BF_2})$ is freely assignable by suitable choice of $F_2 \in \mathbf{F}(\mathcal{V}_2)$ and $\sigma_{\mathcal{V}_2} \subset \sigma_{\mathcal{V}_1}$.

Proof of Theorem 7: Let $F_1 \in \mathbf{F}(\mathcal{V}_1)$ be a map such that $\sigma(A + BF_1 | \mathcal{V}_1) \subset \mathbb{C}_-$. By Property A.2, we can choose a map $F_c \in \mathbf{F}(\mathcal{L} := \mathcal{V}_1 + \mathcal{R}_{\mathcal{V}_2})$ such that $F_c | \mathcal{V}_1 = F_1 | \mathcal{V}_1$ and $\sigma(\overline{A + BF_c}) \subset \mathbb{C}_-$, where $\overline{A + BF_c}$ is the map induced by $A + BF_c$ in $\mathcal{L}/\mathcal{V}_1$. Applying again Property A.2, we can choose a map $F_2 \in \mathbf{F}(\mathcal{V}_2)$ such that $F_2 | \mathcal{L} = F_c | \mathcal{L}$.

Let us now denote $\overline{A + BF_2}$ the map induced by $A + BF_2$ in $\mathcal{V}_2/\mathcal{L}$. Note that $\sigma(A + BF_2 | \mathcal{V}_2) = \sigma(A + BF_1 | \mathcal{V}_1) \cup \sigma(\overline{A + BF_c}) \cup \sigma(\overline{A + BF_2})$.

Since the internal stabilizability of the subspace \mathcal{V}_2 means that $\sigma_{\mathcal{V}_2} \subset \mathbb{C}_-$ (see Property A.1), and since $\sigma(\overline{A + BF_c}) \subset \sigma_{\mathcal{V}_2}$, we obtain $\sigma(A + BF_2 | \mathcal{V}_2) \subset \mathbb{C}_-$, which ends the proof.

B. Proof of Lemma 1

To prove the result established in Lemma 1 we shall use some nice properties of regularly row by row decouplable systems with stability.

Property B.1: Let (A, B, C) be a regularly row by row decouplable system with stability, then $\mathcal{V}_{i \text{ stab}}^* = \sum_{j \neq i} \mathcal{W}_j^* \text{ stab}$, for all $i \in \{1, 2, \dots, p\}$.

Now, to prove this, we shall need some properties of controllable regularly block decouplable systems. Let us first complete our previous notation.

Let \bar{C}_i be the C matrix without the i th block, noted C_i , and let us denote:

- $\mathcal{R}_i^*(\text{Ker } \bar{C}_i)$, respectively, $\mathcal{T}_i^*(\text{Ker } \bar{C}_i)$, the supremal (A, B) -controllability subspace contained in $\text{Ker } C_i$, respectively, $\text{Ker } \bar{C}_i$.

Property B.2 [4, Properties V.1 and V.3]: Let (A, B, C) be a controllable regularly block decouplable system, then

$$\sum_{i=1}^k \mathcal{T}_i^*(\text{Ker } \bar{C}_i) = \mathcal{X} \text{ and } \mathcal{R}_i^*(\text{Ker } C_i) = \sum_{j \neq i} \mathcal{T}_j^*(\text{Ker } \bar{C}_j), \quad \forall i \in \{1, 2, \dots, k\}.$$

Property B.2 let us write the following.

Property B.3: Let (A, B, C) be a controllable regularly row by row decouplable system. For any $j \in \mathbf{l}$ and any $z \in \mathbf{r}$, where \mathbf{l} and \mathbf{r} are any sets contained in $\{1, 2, \dots, p\}$ such that $\mathbf{l} \cap \mathbf{r} = \emptyset$, we have

$$\bigcap_{j \in \mathbf{l}} \mathcal{V}_j^* \text{ stab} + \bigcap_{z \in \mathbf{r}} \mathcal{V}_z^* \text{ stab} = \mathcal{X}.$$

Proof of Property B.3: Build a block, say C_{H_j} , formed with the rows of C which index belongs to \mathbf{l} and build a block, say C_{H_z} , formed with the rows of C which index belongs to \mathbf{r} . Let us now denote the supremal (A, B) -controllability subspaces contained in $\text{Ker } C_{H_j}$ and $\text{Ker } C_{H_z}$ by $\mathcal{R}_{H_j}^*(\text{Ker } C_{H_j})$ and $\mathcal{R}_{H_z}^*(\text{Ker } C_{H_z})$, respectively. From Property B.2 we have $\mathcal{R}_{H_j}^*(\text{Ker } C_{H_j}) + \mathcal{R}_{H_z}^*(\text{Ker } C_{H_z}) = \mathcal{X}$. Since $\mathcal{R}_{H_j}^*(\text{Ker } C_{H_j}) \subset \bigcap_{j \in \mathbf{l}} \mathcal{V}_j^* \text{ stab}$ and $\mathcal{R}_{H_z}^*(\text{Ker } C_{H_z}) \subset \bigcap_{z \in \mathbf{r}} \mathcal{V}_z^* \text{ stab}$, we get $\bigcap_{j \in \mathbf{l}} \mathcal{V}_j^* \text{ stab} + \bigcap_{z \in \mathbf{r}} \mathcal{V}_z^* \text{ stab} = \mathcal{X}$.

Proof of Property B.1: Note that Property B.1 obviously holds for $p = 2$. Let us give the proof for $p = 3$.

Since (A, B, C) is regularly row by row decouplable with stability, the same obviously holds for any selection of outputs within C , namely for (A, B, \bar{C}_i) , for all $i \in \{1, 2, \dots, p\}$. Theorem 2 thus implies that $\mathcal{W}_j^* \text{ stab} = \bigcap_{k \neq j} \mathcal{V}_k^* \text{ stab}$ for any $j = 1, 2, \dots, p$. Then

$$\begin{aligned} \sum_{j \neq 1} \mathcal{W}_j^* \text{ stab} &= \mathcal{W}_2^* \text{ stab} + \mathcal{W}_3^* \text{ stab} \\ &= \mathcal{V}_1^* \text{ stab} \cap \mathcal{V}_3^* \text{ stab} + \mathcal{V}_1^* \text{ stab} \cap \mathcal{V}_2^* \text{ stab}. \end{aligned}$$

From Property B.3 we have that $\mathcal{V}_3^* \text{ stab} + \mathcal{V}_1^* \text{ stab} \cap \mathcal{V}_2^* \text{ stab} = \mathcal{X}$ and consequently $\mathcal{V}_1^* \text{ stab} \cap (\mathcal{V}_3^* \text{ stab} + \mathcal{V}_1^* \text{ stab} \cap \mathcal{V}_2^* \text{ stab}) = \mathcal{V}_1^* \text{ stab} \cap \mathcal{V}_1^* \text{ stab} + \mathcal{V}_1^* \text{ stab} \cap \mathcal{V}_2^* \text{ stab} = \mathcal{V}_1^* \text{ stab} \cap \mathcal{X} = \mathcal{V}_1^* \text{ stab}$. From this follows that $\sum_{j \neq 1} \mathcal{W}_j^* \text{ stab} = \mathcal{V}_1^* \text{ stab}$.

In a similar way we can show that $\sum_{j \neq 2} \mathcal{W}_j^* \text{ stab} = \mathcal{V}_2^* \text{ stab}$ and $\sum_{j \neq 3} \mathcal{W}_j^* \text{ stab} = \mathcal{V}_3^* \text{ stab}$.

A similar treatment can be applied for the case $p \geq 3$. \square

We can now achieve the proof of Lemma 1

Since (A, B, C) is regularly row by row decouplable with stability it is easy to see from Theorem 2 that $\mathcal{W}_i^* \text{ stab} = \bigcap_{j \neq i} \mathcal{V}_j^* \text{ stab}$, for all $i \in \{1, 2, \dots, p\}$, and consequently $\bigcap_{i=1}^p \mathcal{W}_i^* \text{ stab} = \bigcap_{i=1}^p \bigcap_{j \neq i} \mathcal{V}_j^* \text{ stab} = \bigcap_{i=1}^p \mathcal{V}_i^* \text{ stab} =: \mathcal{V}_{\text{stab}}^*$. From this, Property B.1 and Theorem 2 we have

$$\widehat{\mathcal{W}_{\text{stab}}^*} := \bigcap_{i=1}^p \sum_{j \neq i} \mathcal{W}_j^* \text{ stab} = \bigcap_{i=1}^p \mathcal{V}_i^* \text{ stab} = \mathcal{V}_{\text{stab}}^* = \bigcap_{i=1}^p \mathcal{W}_i^* \text{ stab}. \quad \square$$

C. Proof of Property 1

Direct from Property B.2. Indeed

$$\mathcal{X} = \sum_{i=1}^p \mathcal{T}_i^* \subset \sum_{i=1}^p \mathcal{W}_i^* \text{ stab}.$$

D. Proof of Lemma 2

Lemma 2 is direct from the following results.

Theorem D.1: Let $\mathcal{V}_{\text{stab}}^*(S)$ be the supremal internally stabilizable (A, B) -invariant subspace contained in S and let $\mathcal{R}^*(S)$ be the supremal (A, B) -controllability subspace contained in S . For any $F \in \mathbf{F}(\mathcal{V}_{\text{stab}}^*(S))$ we have

$$\mathcal{R}^*(S) = \langle A + BF \mid \mathcal{B} \cap \mathcal{V}_{\text{stab}}^*(S) \rangle.$$

Proof of Theorem D.1: Let $\mathcal{V}^*(S)$ be the supremal (A, B) -invariant subspace contained in S . Note that

$$\mathcal{B} \cap \mathcal{V}_{\text{stab}}^*(S) = \mathcal{B} \cap \mathcal{V}^*(S) = \mathcal{B} \cap \mathcal{R}^*(S).$$

Indeed, $\mathcal{B} \cap \mathcal{R}^*(S) \subset \mathcal{B} \cap \mathcal{V}_{\text{stab}}^*(S) \subset \mathcal{B} \cap \mathcal{V}^*(S) = \mathcal{B} \cap \mathcal{R}^*(S)$ (see [11, Theorem 5.5]). With $F \in \mathbf{F}(\mathcal{V}_{\text{stab}}^*(S))$, write $\mathcal{R} := \langle A + BF \mid \mathcal{B} \cap \mathcal{V}_{\text{stab}}^*(S) \rangle$.

Property A.2 states the existence of a map $F' \in \mathbf{F}(\mathcal{V}^*(S))$ such that $F \mid \mathcal{V}_{\text{stab}}^*(S) = F' \mid \mathcal{V}_{\text{stab}}^*(S)$. Then $\mathcal{R} = \langle A + BF' \mid \mathcal{B} \cap \mathcal{V}_{\text{stab}}^*(S) \rangle = \langle A + BF' \mid \mathcal{B} \cap \mathcal{V}^*(S) \rangle =: \mathcal{R}^*(S)$, since $\mathcal{R}^*(S) = \langle A + BF' \mid \mathcal{B} \cap \mathcal{V}^*(S) \rangle$, for any $F' \in \mathbf{F}(\mathcal{V}^*(S))$ [11, Theorem 5.5], which ends the proof.

Corollary D.1:

$$\mathbf{F}(\mathcal{V}_{\text{stab}}^*(S)) \subseteq \mathbf{F}(\mathcal{R}^*(S)).$$

Robust Controller Design for Delay Systems in the Gap-Metric

Akira Kojima and Shintaro Ishijima

Abstract—A robust stabilization problem in the gap-metric is discussed for a system with delays in control. We derive a design procedure of robust controllers based on finite-dimensional Riccati equations and it is shown that the resulting controller has a structure of observer-based predictive action. By employing completing the square argument, a game theoretic interpretation is also provided on the trade-off between the initial-uncertainties and attenuating the disturbance caused by plant uncertainties.

I. INTRODUCTION

In recent years, a robust stabilization problem in the gap-metric has received much attention [7], [17] and, for finite-dimensional systems, it is recognized that the design procedure enables us to take a trade-off between the robustness and the performance of closed-loop system [18]. Moreover, this argument has a merit to obtain a control law in a closed formula, which has a well-known feature of LQG-controllers.

For a class of infinite-dimensional systems, the robust stabilization problem in the gap-metric has been studied by various authors [3], [8], [19]. In [3], the maximum robustness margin and the admissible controllers are derived based on an input/output argument; alternatively an operator theory derivation is applied in [8] and provides a number of results on the gap and graph metrics. Especially for a system with delays in control: $\Sigma_P(s) = R(s) \cdot e^{-sh}$, a closed formula is given for the evaluation of maximum robustness margin [19].

Even for the time delay systems, however, the design procedure of robust controller is not solved in the general setting. In [8], the procedure is derived for single-input/single-output (SISO) first-order input delay systems and, in [19], a sequence of finite-dimensional controllers, which approach optimality, is given for SISO retarded delay systems. Very recently in the preparation of this article, alternative design procedure is reported for SISO input delay systems [6] associated with [8]. It should be also noted that, even if we employ H^∞ optimization method for the infinite-dimensional systems [11], [24], the computational work needed to check the solvability involves quite enormous calculations.

In this paper, we focus on the following class of input delays systems

$$\begin{aligned}\Sigma_P: \quad & \dot{x}(t) = Ax(t) + Bu(t-h) \\ & y(t) = Cx(t), \\ & u(t) \in R^m, x(t) \in R^n, y(t) \in R^r\end{aligned}$$

and consider the robust stabilization problem in the gap-metric. Our objective in this paper is to derive a design procedure of robust controllers based on finite-dimensional Riccati equations. The derived control law has a structure of observer-based predictive action

$$\begin{aligned}u(t) &= K_0 \hat{x}(t) + \int_{-h}^0 K_1(\beta) u(t+\beta) d\beta \\ \dot{\hat{x}}(t) &= A \hat{x}(t) + Bu(t-h) + L(y(t) - C \hat{x}(t))\end{aligned}$$

and the procedure does not require the restrictions on the degree of plant and the number of input/output channels. A game theoretic interpretation is also provided on the trade-off between the initial-uncertainties and attenuating the disturbance caused by plant uncertainties.

In the following, we first reformulate the robust stabilization problem as an H^∞ output feedback problem for time delay systems. Then applying completing the square argument of particular quadratic forms [22], [13], [2], we directly derive a robust control law based on auxiliary operator type Riccati equations. The approach employed here also enables us to clarify the corresponding worst-case disturbance and, further, provides game-theoretic interpretations on the trade-off between attenuating the disturbance and the initial uncertainties. Finally, we show that the solutions to the operator-type Riccati equations are constructively given based on finite-dimensional Riccati equations and summarize the design procedure.

II. FORMULATION AND PRELIMINARIES

For a system with delays in control

$$\begin{aligned}\Sigma_P: \quad & \dot{x}(t) = Ax(t) + Bu(t-h) \\ & y(t) = Cx(t), \\ & u(t) \in R^m, x(t) \in R^n, y(t) \in R^r\end{aligned}\tag{1}$$

let $\Sigma_P(s) := R(s) \cdot e^{-sh} = \tilde{M}^{-1}(\tilde{N} \cdot e^{-sh})$ and $[\tilde{M}, \tilde{N}]$ be the normalized left coprime factorization of the rational part $R(s)$. Then it is clarified by [19] that the maximum robustness margin is analytically given in the following way.

Fact 1 (Partington et al. [19]): Let $[\tilde{N}, \tilde{M}] := [0, I] + C_H(sI - A_H)^{-1} [B_H, H_H]$ and σ_1 be the largest solution to the equation

$$\det \left\{ \begin{aligned} & [-\sigma^{-1} Q_H, I] \\ & \cdot \exp \left(\begin{bmatrix} A_H & \sigma^{-1} B_H B_H^T \\ -\sigma^{-1} C_H^T C_H & -A_H^T \end{bmatrix} \cdot h \right) \\ & \cdot \begin{bmatrix} \sigma^{-1} P_H \\ I \end{bmatrix} \end{aligned} \right\} = 0$$

where P_H and Q_H satisfy the Lyapunov equations respectively

$$\begin{aligned}A_H P_H + P_H A_H^T + B_H B_H^T + H_H H_H^T &= 0, \\ A_H^T Q_H + Q_H A_H + C_H^T C_H &= 0.\end{aligned}$$

Then the maximum robustness margin in the gap-metric is given by $\epsilon_{opt} = \sqrt{1 - \sigma_1^2}$.

The analytic result stated above provides deep insight on the effect of time delay h and, further, promises the first stage to attack the robust controller design problem in the gap-metric. Our objective in this paper is to derive a design procedure of robust controllers in the framework of finite-dimensional operations.

Robust Controller Design Problem

For the time delay system Σ_P , derive a design procedure of robust controllers such that the closed-loop system is stabilized against the perturbations $\{\Delta := \Delta = [\Delta_M, \Delta_N]\}$

$$\begin{aligned}\Sigma_P^\Delta(s) &= (\tilde{M} + \Delta_M)^{-1} (\tilde{N} \cdot e^{-sh} + \Delta_N) \\ \{\Delta &= [\Delta_M, \Delta_N]; \Delta \in H^\infty, \|\Delta\|_\infty < \epsilon\}, \\ &\epsilon < \epsilon_{opt} < 1\end{aligned}\tag{2}$$

where $[\tilde{M}, \tilde{N}]$ are the normalized left coprime factors of the rational part $R(s)$ and $\{\Sigma_P^\Delta\}$ indicates the plant set with the radius ϵ in the H^∞ gap-metric.

On the realization of nominal plant Σ_P (1), we make a following assumption:

A1) (C, A, B) is observable and controllable.

The robust stabilization problem stated here is well posed as an H^∞ optimization problem to find a stabilizing law $K(s)$ which satisfies the following condition

$$\left\| \begin{bmatrix} I \\ K \end{bmatrix} (I - \Sigma_P K)^{-1} \hat{M}^{-1} \right\|_\infty < \epsilon^{-1}. \quad (3)$$

Moreover condition (3) is equivalently reformulated as follows

$$\left\| \begin{bmatrix} I \\ K \end{bmatrix} (I - \Sigma_P K)^{-1} \hat{M}^{-1} [\hat{M}, \hat{N} \cdot e^{-sh}] \right\|_\infty = \left\| \begin{bmatrix} I \\ K \end{bmatrix} (I - \Sigma_P K)^{-1} [I, R \cdot e^{-sh}] \right\|_\infty < \epsilon^{-1} \quad (4)$$

where the delay term e^{-sh} in the left hand side is artificially introduced in order to finally reduce the design procedure into finite-dimensional operations.

In the sequel, we define an augmented time delay system associated with (4)

$$\begin{aligned} \Sigma: \quad \dot{x}(t) &= Ax(t) + Bw_2(t-h) + Bu(t-h) \\ z_1(t) &= Cx(t) + w_1(t) \\ z_2(t) &= u(t) \\ y(t) &= Cx(t) + w_1(t) \end{aligned} \quad (5)$$

and discuss an H^∞ output feedback problem for the system Σ . Namely, the problem is to find an admissible output feedback law such that:

- C1) the closed-loop system is internally stable, and
- C2) the closed-loop transfer function from the disturbance $w := [w_1^T, w_2^T]^T$ to the regulated output $z := [z_1^T, z_2^T]^T: \Sigma_{zw}(s)$ satisfies $\|\Sigma_{zw}\|_\infty < \gamma$ for a given constant $\gamma := \epsilon^{-1}$, $\epsilon < \epsilon_{opt} < 1$.

By employing a state-space setup investigated in [10], [20], [21], we next describe the time delay system Σ on appropriately defined Hilbert space. On a Hilbert space $\mathcal{X} := R^n \times L_2(-h, 0; R^m)$ endowed with the inner product

$$\begin{aligned} \langle \psi, \phi \rangle &:= \psi^0 T \phi^0 + \int_{-h}^0 \psi^{1T}(\beta) \phi^1(\beta) d\beta, \\ \psi &= \begin{bmatrix} \psi^0 \\ \psi^1 \end{bmatrix} \in \mathcal{X}, \quad \phi = \begin{bmatrix} \phi^0 \\ \phi^1 \end{bmatrix} \in \mathcal{X} \end{aligned} \quad (6)$$

the augmented system Σ can be written in a form of an evolution equation [10], [20], [21]

$$\begin{aligned} \Sigma: \quad \dot{\hat{x}}(t) &= \mathcal{A}\hat{x}(t) + \mathcal{B}w_2(t) + \mathcal{B}u(t) \\ z_1(t) &= \mathcal{C}\hat{x}(t) + w_1(t) \\ z_2(t) &= u(t) \\ y(t) &= \mathcal{C}\hat{x}(t) + w_1(t). \end{aligned} \quad (7)$$

The operator \mathcal{A} is an infinitesimal generator defined as follows

$$\mathcal{A}\phi = \begin{bmatrix} A\phi^0 + B\phi^1(-h) \\ \phi^{1'} \end{bmatrix}, \quad \mathcal{D}(\mathcal{A}) = \{\phi \in \mathcal{X} : \phi^1 \in W^{1,2}(-h, 0; R^m), \phi^1(0) = 0\} \quad (8)$$

where $W^{1,2}$ denotes the Sobolev space of R^m -valued, absolutely continuous functions with square integrable derivatives on $[-h, 0]$. The adjoint operator \mathcal{A}^* is given by

$$\begin{aligned} \mathcal{A}^* \psi &= \begin{bmatrix} A^T \psi^0 \\ -\psi^{1'} \end{bmatrix}, \\ \mathcal{D}(\mathcal{A}^*) &= \{\psi \in \mathcal{X} : \psi^1 \in W^{1,2}(-h, 0; R^m), \psi^1(-h) = B^T \psi^0\} \end{aligned} \quad (9)$$

and, extending the state space \mathcal{X} to $\mathcal{V} := \mathcal{D}(\mathcal{A}^*)^*$, it is verified that $\mathcal{D}_{\mathcal{V}}(\mathcal{A}) = \mathcal{X}$ and the separate Hilbert space \mathcal{V}^* , \mathcal{X} and \mathcal{V} are with continuous, dense injections satisfying

$$\mathcal{V}^* \subset \mathcal{X} \subset \mathcal{V} \quad (\mathcal{X} = \mathcal{X}^*).$$

The input/output operators \mathcal{B} and \mathcal{C} are defined as follows

$$\begin{aligned} \mathcal{B}: R^m &\rightarrow \mathcal{V}, \quad \mathcal{B}^* \psi = \psi^1(0) \quad (\psi \in \mathcal{V}^* = \mathcal{D}(\mathcal{A}^*)) \\ \mathcal{C}: \mathcal{X} &\rightarrow R^r, \quad \mathcal{C}\phi = C\phi^0 \quad (\phi \in \mathcal{X}). \end{aligned} \quad (10)$$

III. ROBUST CONTROLLER DESIGN

In this section, we first construct an admissible control law based on auxiliary operator type Riccati equations. By employing completing the square argument of particular quadratic forms [22], [13], [2], the control law is directly derived together with the corresponding worst-case disturbance. Then it is clarified that the solution to the operator Riccati equations are constructively given based on finite-dimensional Riccati equations.

The admissible control law for the posed H^∞ output feedback problem is formally characterized as follows.

Theorem 2: Let $P > 0$ ($P \in \mathcal{L}(\mathcal{X})$) and $S > 0$ ($S \in \mathcal{L}(\mathcal{V}, \mathcal{V}^*)$) be the stabilizing solutions to the operator Riccati equations

$$\begin{aligned} P\mathcal{A}^* \psi + \mathcal{A}P\psi - PC^*CP\psi + \mathcal{B}\mathcal{B}^* \psi &= 0, \quad \psi \in \mathcal{V}^* \quad (11) \\ S\left(\mathcal{A} + \frac{1}{\gamma^2 - 1} \cdot PC^*C\right)\phi &+ \left(\mathcal{A} + \frac{1}{\gamma^2 - 1} \cdot PC^*C\right)^* \cdot S\phi - S\mathcal{B}\mathcal{B}^*S\phi \\ &+ \frac{1}{\gamma^2 - 1} \cdot SPC^*CPS\phi + \frac{\gamma^2}{\gamma^2 - 1} C^*C\phi = 0, \end{aligned} \quad \phi \in \mathcal{X} \quad (12)$$

then an admissible control law satisfying (C1) and (C2) is given by

$$\begin{aligned} u(t) &= -\mathcal{B}^* S \hat{x}(t) \\ \dot{\hat{x}}(t) &= \mathcal{A}\hat{x}(t) + \mathcal{B}u(t) + PC^*(y(t) - \mathcal{C}\hat{x}(t)), \\ \hat{x}(0) &= 0. \end{aligned} \quad (13)$$

In saying the stabilizing solutions P and S , we mean that the operators $\mathcal{A} - PC^*C$, $\mathcal{A} - \mathcal{B}\mathcal{B}^*S + (1/(\gamma^2 - 1)) \cdot PC^*C(I + PS)$ generate exponentially stable semigroups.

Remark 1: For the linear operator $S \in \mathcal{L}(\mathcal{V}, \mathcal{V}^*)$, the positive definiteness $S > 0$ requires that $S = S^* \in \mathcal{L}(\mathcal{V}, \mathcal{V}^*)$ and, for given $\phi \neq 0$ ($\phi \in \mathcal{V}$), $\langle \phi, S\phi \rangle_{\mathcal{V}, \mathcal{V}^*} > 0$ hold. The properties of Hilbert adjoint operations between \mathcal{V} and \mathcal{V}^* are found in [24, Section 2.5].

Before describing the complete proof, we give here some preliminaries and motivations. The Riccati equation (11) is with the unbounded operator $\mathcal{B}\mathcal{B}^*$ and the structure of solution is not generally clarified [20]. However, in case we deal with the augmented system Σ , the solution $P > 0$ ($P \in \mathcal{L}(\mathcal{X})$) is constructively given based on finite-dimensional Riccati equation.

Lemma 3: Let $P > 0$ be the solution to the finite-dimensional Riccati equation

$$PA^T + AP - PC^T CP + BB^T = 0 \quad (14)$$

then the stabilizing solution $P > 0$ ($P \in \mathcal{L}(\mathcal{X})$) to (11) is given by

$$P = \begin{bmatrix} P & 0 \\ 0 & I \end{bmatrix} \in \mathcal{L}(\mathcal{X}) \quad (15)$$

and there exists a bounded inverse on \mathcal{X} .

Proof Direct verified by substituting the solution (15) to (11) Q.E.D.

The above lemma guarantees the existence of bounded inverse $P^{-1} \in \mathcal{L}(\mathcal{V})$ and enables us to directly apply completing the square argument associated with the operators S and P^{-1} [22]–[23].

Proof of Theorem 2 Let $\epsilon = \tau - \bar{\tau}$ and describe the closed loop system with respect to the state \underline{x}, ϵ

$$\begin{aligned} \Sigma: \quad \begin{bmatrix} \underline{x}(t) \\ \epsilon(t) \end{bmatrix} &= \begin{bmatrix} \mathcal{A} - \mathcal{B}\mathcal{K}^*S & \mathcal{P}\mathcal{C}^*\mathcal{C} \\ 0 & \mathcal{A} - \mathcal{P}\mathcal{C}^*\mathcal{C} \end{bmatrix} \begin{bmatrix} \underline{x}(t) \\ \epsilon(t) \end{bmatrix} \\ &+ \begin{bmatrix} \mathcal{P}\mathcal{C}^* & 0 \\ -\mathcal{P}\mathcal{C}^*\mathcal{B} & 0 \end{bmatrix} u(t) \\ \dot{\epsilon}(t) &= \begin{bmatrix} \mathcal{C} & \mathcal{C} \\ -\mathcal{B}^*S & 0 \end{bmatrix} \begin{bmatrix} \underline{x}(t) \\ \epsilon(t) \end{bmatrix} \\ &+ \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix} u(t) \\ u(t) &= \begin{bmatrix} u_1(t) \\ u_2(t) \end{bmatrix}, \quad \dot{\epsilon}(t) = \begin{bmatrix} \dot{\epsilon}_1(t) \\ \dot{\epsilon}_2(t) \end{bmatrix} \quad (16) \end{aligned}$$

In the following we will show that the closed loop system Σ satisfies the conditions C1) and C2).

Internal Stability C1) Since $S > 0$ and $P > 0$ are the stabilizing solutions, it is easily verified that the operators $\mathcal{A} - \mathcal{B}\mathcal{K}^*S$ and $\mathcal{A} - \mathcal{P}\mathcal{C}^*\mathcal{C}$ generate exponentially stable semigroups. While the operator $\mathcal{P}\mathcal{C}^*\mathcal{C}$ is bounded. Hence it follows that the closed loop system is internally stable [12].

Disturbance Attenuation C2) To verify the inequality $\|\Sigma\|_{\infty} \leq \gamma$, i.e. $\|\dot{\epsilon}\|_2 \leq \gamma \|\dot{u}\|_2$, $u \neq 0$ we first focus on the restricted class of disturbances

$$u \in C^1([0, \infty), R^{+}) \cap I([0, \infty), R^{+}) \quad (17)$$

which is continuously differentiable and denote the disturbances as $u \in C^1 I([0, \infty), R^{+})$. The space $C^1 I([0, \infty), R^{+})$ is dense in $I([0, \infty), R^{+})$ and it is known that if $\underline{x}(0), \epsilon(0) \in \mathcal{D}(\mathcal{A})$ and $u \in C^1 I([0, \infty), R^{+})$ the solution $[\underline{x}(t), \epsilon(t)]$ ($t > 0$) is everywhere differentiable [4]. Consider the functional

$$V(t) = \langle \underline{x}(t), S\underline{x}(t) \rangle + \langle \epsilon(t), \mathcal{P}^{-1}\epsilon(t) \rangle$$

on V then differentiating both sides with respect to t inserting (11) and (12) we have

$$\begin{aligned} \dot{V}(t) &= -\|\dot{\epsilon}\|_2^2 + \gamma^2 \|\dot{u}\|_2^2 - \langle \dot{\epsilon}, -\mathcal{B}^*S\mathcal{P}^{-1}\epsilon \rangle \\ &- (\gamma^2 - 1) \left\| u_1 + \mathcal{C}\epsilon - \frac{1}{\gamma^2 - 1} \mathcal{C}(I + \mathcal{P}S)\underline{x} \right\|_2^2 \end{aligned}$$

Integrating both sides with respect to t over the interval $[0, \infty)$ we finally obtain

$$\begin{aligned} \langle \underline{x}(\infty), S\underline{x}(\infty) \rangle + \langle \epsilon(\infty), \mathcal{P}^{-1}\epsilon(\infty) \rangle &- \langle \underline{x}(0), S\underline{x}(0) \rangle - \langle \epsilon(0), \mathcal{P}^{-1}\epsilon(0) \rangle \\ &= -\|\dot{\epsilon}\|_2^2 + \gamma^2 \|\dot{u}\|_2^2 - \int_0^\infty \left\| u_1 + \mathcal{C}\epsilon - \frac{1}{\gamma^2 - 1} \mathcal{C}(I + \mathcal{P}S)\underline{x} \right\|_2^2 dt \quad (18) \end{aligned}$$

Since Σ is shown to be internally stable, $\underline{x}(\infty) = \epsilon(\infty) = 0$ and without loss of generality in the input-output analysis we can assume the initial state as $\underline{x}(0) = \epsilon(0) = 0$. Hence it follows from the equality (18) that

$$\|\dot{\epsilon}\|_2 \leq \gamma \|\dot{u}\|_2, \quad u \neq 0 \quad (19)$$

holds for the continuously differentiable disturbances $u \in C^1 I([0, \infty), R^{+})$, $u \neq 0$.

For given $u \in L_2([0, \infty), R^{+})$, there exists a sequence $\{u_n\} \subset C^1 I([0, \infty), R^{+})$ which converges to $u \in L_2([0, \infty), R^{+})$. Hence it then follows from the fact that $\underline{x}(t), \epsilon(t)$ ($t > 0$) continuously depends on $\{u_n\}$ that (19) holds for all the disturbances, $u \in I([0, \infty), R^{+})$, $u \neq 0$. Q.E.D.

Remark 2 Equality (18) clarifies the worst-case disturbance in the H^∞ output feedback setting. The worst-case disturbance $u = u^0$ is given by

$$\begin{aligned} u^0 &= \begin{bmatrix} u_1^0 \\ u_2^0 \end{bmatrix}, \quad u_1^0 = -\mathcal{C}\epsilon + \frac{1}{\gamma^2 - 1} \mathcal{C}(I + \mathcal{P}S)\underline{x} \\ u_2^0 &= \mathcal{B}^*S\mathcal{P}^{-1}\epsilon \end{aligned}$$

and with the control (13) say $u = u^0$ the strategies (u^0, u^0) form a saddle point as follows [22]–[13]

$$\begin{aligned} J(u, u) &= \|\dot{\epsilon}\|_2^2 - \gamma^2 \|\dot{u}\|_2^2 \\ J(u^0, u) &\leq J(u^0, u^0) \leq J(u, u^0) \end{aligned}$$

Remark 3 The completing the square argument employed here provide direct interpretations on the trade off between attenuating the disturbance and the initial uncertainties.

Let $\epsilon(0) = \epsilon_0$, $u(\tau) = u_\epsilon(\tau)$ ($-h \leq \tau < 0$) be the initial uncertainties of plant and apply completing the square argument in like fashion. Then we have the following inequality on the disturbance and the initial uncertainty

$$\begin{aligned} \|\dot{\epsilon}\|_2 &\leq \|\dot{u}\|_2 + \left(\epsilon_0^T \mathcal{P}^{-1} \epsilon_0 + \int_{-h}^0 u^T(\tau) u_\epsilon(\tau) d\tau \right)^{1/2} \\ \text{i.e.} \quad \frac{\|\dot{\epsilon}\|_2}{\|\dot{u}\|_2 + \left(\epsilon_0^T \mathcal{P}^{-1} \epsilon_0 + \int_{-h}^0 u^T(\tau) u_\epsilon(\tau) d\tau \right)^{1/2}} &\leq \gamma \quad (20) \end{aligned}$$

In inequality (20) the solution $P > 0$ to the filtering Riccati equation (14) plays a part of weighting matrix between the uncertainty caused by disturbance u and the initial plant uncertainty ϵ . A larger P allows greater initial uncertainty ϵ and the resulting closed loop system has favorable time domain performance [22]–[13].

However, for the time delay systems it should be noted that the effect of initial uncertainties in the input delay segment $u_1(\cdot)$ is independent to the choice of P and causes definite damage to the time domain performance.

The operator Riccati equation (12) has similar structure to those arise in LQ problem for delay systems [5]. In [5] it is shown that the solution $S > 0$ ($S \in \mathcal{L}(\mathcal{V}, \mathcal{V}^*)$) has a form of an integral kernel representation $\{S_0, S_1, S\}$

$$\begin{aligned} (S\alpha)^0 &= S_0\alpha + \int_{-h}^0 S_1(t)\alpha^1(t)dt \\ (S\alpha)^1(\alpha) &= S_1^T(\alpha)\alpha^0 + \int_{-h}^0 S_2(\alpha, t)\alpha^1(t)dt \\ &-h \leq \alpha \leq 0 \end{aligned}$$

With the integral kernel representation of operator $S \in \mathcal{L}(\mathcal{V}, \mathcal{V}^*)$ the control law (13) is described by

$$\begin{aligned} u(t) &= K_0 \underline{x}(t) + \int_{-h}^0 K_1(t) u(t+\tau) d\tau \\ \underline{x}(t) &= A \underline{x}(t) + B u(t-h) + \mathcal{P}\mathcal{C}^T(u(t) - \mathcal{C} \underline{x}(t)) \\ K_0 &= -S_1^T(0), \quad K_1(\cdot) = -S_2(\cdot, 0) \quad (21) \end{aligned}$$

and has a feature of observer-based predictive controller. The feedback gains K_0 and $K_1(\cdot)$ are the parameters defined by the integral kernel representation $\{S_0, S_1, S_2\}$.

Next we will show that the stabilizing solution $S > 0$ ($S \in \mathcal{L}(\mathcal{V}, \mathcal{V}^*)$) is constructively given based on finite-dimensional Riccati equation. The following result enables us to avoid the direct calculation of (12) (see also [23]).

Theorem 4: Let $\mathcal{M} > 0$ ($\mathcal{M} \in \mathcal{L}(\mathcal{V}, \mathcal{V}^*)$) be the stabilizing solution to the operator Riccati equation

$$\mathcal{M}A\phi + A^*\mathcal{M}\phi - \mathcal{M}BB^*\mathcal{M}\phi + C^*C\phi = 0, \quad \phi \in \mathcal{X} \quad (22)$$

then, for given constant $\gamma > (1 + \lambda_{\max}(\mathcal{M}\mathcal{P}))^{1/2}$, the stabilizing solution $S > 0$ to (12) is described by

$$S := \left(I - \frac{1}{\gamma^2} \cdot (I + \mathcal{M}\mathcal{P}) \right)^{-1} \mathcal{M}.$$

Furthermore, based on a solution $M > 0$ to the finite-dimensional Riccati equation

$$MA + A^T M - MBB^T M + C^T C = 0 \quad (23)$$

the stabilizing solution $\mathcal{M} > 0$ ($\mathcal{M} \in \mathcal{L}(\mathcal{V}, \mathcal{V}^*)$) to (22) is constructively given as follows

$$(\mathcal{M}\phi)^0 := M_0\phi^0 + \int_{-h}^0 M_1(\beta)\phi^1(\beta) d\beta \quad (24)$$

$$(\mathcal{M}\phi)^1(\alpha) := M_1^T(\alpha)\phi^0 + \int_{-h}^0 M_2(\alpha, \beta)\phi^1(\beta) d\beta, \quad -h \leq \alpha \leq 0 \quad (25)$$

$$M_0 = e^{A^T h} M e^{A h} + \int_{-h}^0 e^{A^T(\xi+h)} C^T C e^{A(\xi+h)} d\xi$$

$$M_1(\beta) = e^{A^T h} M e^{-A\beta} B + \int_{\beta}^0 e^{A^T(\xi+h)} C^T C e^{A(\xi-\beta)} d\xi$$

$$M_2(\alpha, \beta) = B^T e^{-A^T \alpha} M e^{-A\beta} B + \int_{\max(\alpha, \beta)}^0 B^T e^{A^T(\xi-\alpha)} C^T C e^{A(\xi-\beta)} B d\xi.$$

Proof: Based on (11) and (22), it is verified that the equality

$$\begin{aligned} & \mathcal{M} \left(A + \frac{1}{\gamma^2 - 1} \cdot PC^*C \right) \left(I - \frac{1}{\gamma^2} \cdot (I + \mathcal{P}\mathcal{M}) \right) \phi \\ & + \left(I - \frac{1}{\gamma^2} \cdot (I + \mathcal{M}\mathcal{P}) \right) \left(A + \frac{1}{\gamma^2 - 1} \cdot PC^*C \right)^* \mathcal{M}\phi \\ & - \mathcal{M}BB^*\mathcal{M}\phi + \frac{1}{\gamma^2 - 1} \cdot \mathcal{M}PC^*CP\mathcal{M}\phi + \frac{\gamma^2}{\gamma^2 - 1} \\ & \cdot \left(I - \frac{1}{\gamma^2} \cdot (I + \mathcal{M}\mathcal{P}) \right) C^*C \left(I - \frac{1}{\gamma^2} \cdot (I + \mathcal{P}\mathcal{M}) \right) \\ & \cdot \phi = 0 \end{aligned}$$

holds for $\phi \in \mathcal{X}$. Hence, interpreting $\mathcal{P}\mathcal{M}$ and $\mathcal{M}\mathcal{P}$ on \mathcal{X} , the operator $S := (I - (1/\gamma^2) \cdot (I + \mathcal{M}\mathcal{P}))^{-1} \mathcal{M}$ with the stabilizing solutions $\mathcal{M} > 0$, $\mathcal{P} > 0$ is shown to be positive definite for given $\gamma > (1 + \lambda_{\max}(\mathcal{M}\mathcal{P}))^{1/2}$. It follows from the equality

$$\begin{aligned} & \left(A - BB^* + \frac{1}{\gamma^2 - 1} \cdot PC^*C(I + \mathcal{P}S) \right) \\ & \cdot \left(I - \frac{1}{\gamma^2} \cdot (I + \mathcal{P}\mathcal{M}) \right) \phi \\ & = \left(I - \frac{1}{\gamma^2} \cdot (I + \mathcal{P}\mathcal{M}) \right) (A - B^*B\mathcal{M})\phi \end{aligned}$$

that the operator $S > 0$ is a stabilizing solution.

Now, we will verify that the parameters $\{M_0, M_1, M_2\}$ meet the integral kernel representation of operator \mathcal{M} . Using the representations (24) and (25), (22) is written as partial differential equations

$$M_0 A + A^T M_0 - M_1(0)M_1^T(0) + C^T C = 0, \quad M_0 = M_0^T \quad (26)$$

$$-\frac{d}{d\beta} M_1(\beta) + A^T M_1(\beta) - M_1(0)M_2(0, \beta) = 0, \quad (27)$$

$$-\left(\frac{\partial}{\partial \alpha} + \frac{\partial}{\partial \beta} \right) M_2(\alpha, \beta) - M_2(\alpha, 0)M_2(0, \beta) = 0, \quad M_2(\alpha, \beta) = M_2^T(\beta, \alpha). \quad (28)$$

And further, since $\mathcal{M}\phi \in \mathcal{V}^* = \mathcal{D}(A^*)$, the following boundary conditions are required

$$M_1(-h) = M_0 B, \quad M_2(-h, \beta) = B^T M_1(\beta) \quad (-h \leq \beta \leq 0). \quad (29)$$

Hence, substituting directly, it is verified that the parameters $\{M_0, M_1, M_2\}$ meet the integral kernel representation of operator $\mathcal{M} \in \mathcal{L}(\mathcal{V}, \mathcal{V}^*)$.

Next, we will show that the solution $\{M_0, M_1, M_2\}$ is positive definite and the stabilizing solution. Since the inequality

$$\begin{aligned} \langle \phi, \mathcal{M}\phi \rangle &= m^T(0) M m(0) + \int_{-h}^0 m^T(\xi) C^T C m(\xi) d\xi > 0 \\ m(\xi) &:= e^{A(\xi+h)} \phi^0 + \int_{-h}^{\xi} e^{A(\xi-\beta)} B \phi^1(\beta) d\beta \end{aligned}$$

holds for all $\phi \neq 0$ ($\phi \in \mathcal{V}$) (note that (C, A, B) is observable and controllable), the operator \mathcal{M} is shown to be positive definite. While the system

$$\begin{aligned} \dot{p}(t) &= Ap(t) + Bv(t-h) \\ v(t) &= -B^T M \left\{ e^{A h} p(t) + \int_{-h}^0 e^{-A\beta} B v(t+\beta) d\beta \right\} \end{aligned}$$

associated with the infinitesimal generator $A - BB^*M$ has stable poles $\lambda(A - BB^*M)$, hence the operator \mathcal{M} is shown to be the stabilizing solution to (22). Q.E.D.

Remark 4: The value $(1 + \lambda_{\max}(\mathcal{M}\mathcal{P}))^{1/2}$ stated in Theorem 4 qualifies the alternative analytic representation of the maximum robustness margin ϵ_{opt} (see [3]). Since the operator $\mathcal{M}\mathcal{P}$ is compact, it is also possible to approach the value ϵ_{opt} based on the finite-rank approximation of operator $\mathcal{M}\mathcal{P}$.

By Theorem 4, it is shown that the operator S is constructively given based on finite-dimensional Riccati equations. However it should be noted that, in return for avoiding the direct calculation of (12), it arises infinite-dimensional manipulation concerning with the compact operator $\mathcal{M}\mathcal{P}$. Based on the previous results stated in Theorems 2 and 4, the design procedure is summarized in the following way.

Theorem 5 (Main Result): For a prescribed margin of the required robust stability ϵ ($\epsilon < \epsilon_{opt} < 1$, see Fact 1), the robust controller

$$\begin{aligned} u(t) &= K_0 \underline{x}(t) + \int_{-h}^0 K_1(\beta) u(t+\beta) d\beta \\ \dot{\underline{x}}(t) &= A \underline{x}(t) + Bu(t-h) + L(y(t) - C \underline{x}(t)) \end{aligned}$$

is obtained based on the following procedure.

Step 1: Calculate the solutions $M > 0$, $P > 0$ to the finite-dimensional Riccati equations

$$\begin{aligned} MA + A^T M - MBB^T M + C^T C &= 0, \\ PA^T + AP - PC^T CP + BB^T &= 0 \end{aligned}$$

and let $L := PC^T$.

Step 2 Define the operators $\mathcal{M} \in \mathcal{L}(\mathcal{V}, \mathcal{V}^*)$ (Theorem 4) and $\mathcal{P} \in \mathcal{L}(\mathcal{V})$ (Lemma 3) calculate the following operator

$$\begin{aligned} S &= (I - \epsilon^2 (I + \mathcal{M}\mathcal{P}))^{-1} \mathcal{M} \\ &= \frac{1}{1 - \epsilon^2} (I - T)^{-1} \mathcal{M} \\ T &= \frac{\epsilon^2}{1 - \epsilon^2} \mathcal{M}\mathcal{P} \end{aligned} \quad (30)$$

Since the operator $T \in \mathcal{L}(\mathcal{V})$ is compact, we can construct a sequence of finite-rank operators $\{T_n\}$ which converge to T in the sense of the uniform operator topology $\|T - T_n\| \rightarrow 0$. It follows from the fact $\|(I - T_n)^{-1} - (I - T)^{-1}\| \rightarrow 0$ that the sequence $\{S_n\}$, $S_n = (1/(1 - \epsilon^2)) (I - T_n)^{-1} \mathcal{M}$ also converges to S in the sense of the uniform operator topology.

On the finite rank approximation of operator T the averaging method [1], [9] is applicable. In this case the manipulation of operator $(I - T)^{-1}$ is reduced to the calculation of inverse matrix.

Step 3 Based on the integral kernel representation of $S \in \mathcal{L}(\mathcal{V}, \mathcal{V}^*)$ determine the feedback gains $K_0, K_1(\cdot)$

$$K = -S_1^*(0), \quad K_1(\cdot) = -S_2(0, \cdot)$$

In case we approximate the operator S by averaging method, say S_n , the parameters $S_1^*(0), S_2(0, \cdot)$ are determined by partitioning the corresponding matrix form representation of S .

IV. CONCLUSION

A robust stabilization problem in the gap metric is discussed for a system with delays in control. We derive a design procedure of robust controllers based on finite-dimensional Riccati equations and it is shown that the resulting controller has a structure of observer based predictive actions. The completing the square argument employed in the derivation enables us to provide game theoretic interpretations on the trade off between the initial uncertainties and attenuating the disturbance.

The approach discussed here is applicable for the H^∞ output feedback problem in more general setting and it is also shown that the admissible control law is constructively given in the framework of finite dimensional operations.

A New Balanced Canonical Form for Stable Multivariable Systems

Bernard Hanzon

1. INTRODUCTION

A new balanced canonical form is presented for stable multivariable linear systems. In [3] overlapping continuous block balanced canonical forms were introduced for the stable single input/single output (SISO) case as a generalization of the balanced canonical form of [9] for the SISO case. In the search for a generalization of these results to the multivariable case a new multivariable balanced

Manuscript received March 15, 1993; revised January 4, 1994.

The author is with the Department of Econometrics, Free University, Amsterdam, Holland.

IEEE Log Number 9407356.

canonical form was discovered, which is of interest in its own right and which will be presented here. The new canonical form has a number of nice properties. The integer invariants that appear in the canonical form are the multiplicities of the Hankel singular values and a number of new invariants, which are in one-to-one bijective correspondence with the Kronecker indexes of subsystems. Truncation of the state vector leads to stable minimal models in canonical form, just as in the case of [9]. In the SISO case the canonical form coincides with Ober's balanced canonical form (up to a different signs convention). The reachability matrix of a system in canonical form with identical singular values is positive upper triangular. For the subclass of stable multivariable all-pass systems a detailed treatment of the canonical form is presented in [4], Section IV.

II. BALANCING, CANONICAL FORMS, AND KRONECKER INDEXES

Let us consider continuous-time multivariable systems of the form

$$\dot{x}_t = Ax_t + Bu_t, \quad (2.1)$$

$$y_t = Cx_t + Du_t \quad (2.2)$$

with $t \in \mathbb{R}$, $u_t \in \mathbb{R}^p$, $x_t \in \mathbb{R}^n$, $y_t \in \mathbb{R}^m$, $A \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times p}$, $C \in \mathbb{R}^{m \times n}$, $D \in \mathbb{R}^{m \times p}$.

Let for each $n \in \{1, 2, 3, \dots\}$ the set C_n be the set of all quadruples $(A, B, C, D) \in \mathbb{R}^{n \times n} \times \mathbb{R}^{n \times p} \times \mathbb{R}^{m \times n} \times \mathbb{R}^{m \times p}$ with the properties: a) (A, B, C, D) is a minimal realization and b) the spectrum of A is contained in the open left-half plane (i.e., A is asymptotically stable). A quadruple (A, B, C, D) or triple (A, B, C) will be called asymptotically stable iff the spectrum of A lies in the open left-half plane (irrespective of minimality or nonminimality).

As is well known, two minimal system representations (A_1, B_1, C_1, D_1) and (A_2, B_2, C_2, D_2) have the same transfer function $G(s) = C_1(sI - A_1)^{-1}B_1 + D_1 = C_2(sI - A_2)^{-1}B_2 + D_2$, and therefore describe the same input-output behavior, iff there exists an $n \times n$ matrix $T \in GL_n(\mathbb{R})$ such that $A_1 = TA_2T^{-1}$, $B_1 = TB_2$, $C_1 = C_2T^{-1}$, $D_1 = D_2$. In that case we say that (A_1, B_1, C_1, D_1) and (A_2, B_2, C_2, D_2) are i/o-equivalent. This is clearly an equivalence relation; write $(A_1, B_1, C_1, D_1) \sim (A_2, B_2, C_2, D_2)$. A unique representation of a linear system can be obtained by deriving a canonical form.

Definition 2.1: A canonical form for an equivalence relation " \sim " on a set X is a map

$$\Gamma: X \rightarrow X$$

which satisfies for all $x, y \in X$:

- i) $\Gamma(x) \sim x$
- ii) $x \sim y \iff \Gamma(x) = \Gamma(y)$

Equivalently a canonical form can be given by the image set $\Gamma(X)$; a subset $B \subseteq X$ describes a canonical form if for each $x \in X$ there is precisely one element $b \in B$ such that $b \sim x$. The mapping $x \mapsto b \in B$, $x \mapsto b$ then describes a canonical form.

Let $(A, B, C, D) \in C_n$. The controllability Grammian W_c is the positive definite symmetric matrix that is given by the integral

$$W_c = \int_0^\infty \exp(At)BB^T \exp(A^T t) dt.$$

As is well known, W_c can be obtained as the unique solution of the following Lyapunov equation

$$AW_c + W_cA^T = -BB^T. \quad (2.3)$$

On a dual fashion, the observability Grammian W_o is the positive definite symmetric matrix that is given by the integral

$$W_o = \int_0^\infty \exp(A^T t)C^T C \exp(At) dt.$$

This matrix is the unique solution of the following Lyapunov equation

$$A^T W_o + W_o A = -C^T C. \quad (2.4)$$

Definition 2.2: Let $(A, B, C, D) \in C_n$, then (A, B, C, D) is called balanced if the corresponding observability and controllability Grammians are equal and diagonal, i.e., there exist positive numbers $\sigma_1, \sigma_2, \dots, \sigma_n$ such that

$$W_o = W_c = \text{diag}(\sigma_1, \dots, \sigma_n) =: \Sigma. \quad (2.5)$$

The numbers $\sigma_1, \dots, \sigma_n$ are called the (Hankel) singular values of the system. It will be convenient to call an arbitrary quadruple $(A, B, C, D) \in \mathbb{R}^{n \times n} \times \mathbb{R}^{n \times p} \times \mathbb{R}^{m \times n} \times \mathbb{R}^{m \times p}$ balanced if the pair of Lyapunov equations $A\Sigma + \Sigma A^T = -BB^T$, $A^T \Sigma + \Sigma A = -C^T C$ has a positive definite solution of the form $\Sigma = \text{diag}(\sigma_1, \dots, \sigma_n)$ (assuming neither asymptotic stability nor minimality).

By a suitable permutation of the components of the state of a balanced system, a representation of the system is obtained for which the singular values are ordered with respect to size: $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_n > 0$. The singular values, ordered in this way, are known to be uniquely determined by the input-output behaviour of the system.

Definition 2.3: A balanced canonical form (on C_n) is a canonical form $\Gamma: C_n \rightarrow C_n$, such that $\Gamma(A, B, C, D)$ is balanced for each quadruple $(A, B, C, D) \in C_n$.

Definition 2.4: Consider a pair (A, B) of matrices $A \in \mathbb{R}^{n \times n}$ and $B \in \mathbb{R}^{n \times p}$. Let $R_n = R_n(A, B) = [B, AB, \dots, A^{n-1}B]$ denote the corresponding reachability matrix. Suppose the pair (A, B) is reachable, i.e., the reachability matrix has rank n . The selection of the first n linearly independent columns is called the Kronecker selection. It has the property that it is a so-called nice selection, which means that if the j th column of R_n is in the selection, then either $j \leq p$ or otherwise the $(j-p)$ th column is also in the selection. For each $i \in \{1, 2, \dots, p\}$ let d_i denote the smallest nonnegative value of j such that the $(jp+i)$ th column is not in the selection. Then we will call (d_1, d_2, \dots, d_p) the dynamical indexes (also called successor indexes) corresponding to the selection. By ordering these according to magnitude, one obtains a nondecreasing sequence of p indexes $\kappa_1 \leq \kappa_2 \leq \dots \leq \kappa_p$ which are called the Kronecker reachability (or controllability) indexes.

With any nice selection corresponds a sequence of integers $p = s_0 \geq s_1 \geq s_2 \geq \dots \geq s_l > s_{l+1} = 0$ which add up to $n+p$ and a sequence of sets of indexes $\{\{i_j(1), i_j(2), \dots, i_j(s_j)\} \subset \{1, 2, \dots, s_{j-1}\}, j = 1, 2, \dots, l\}$ with the property that of the s_{j-1} columns that can be chosen from $A^{j-1}B$ in the nice selection the $i_j(1)$ -th, the $i_j(2)$ -th etc until the $i_j(s_j)$ -th are chosen. Because the Kronecker selection is also a nice selection these quantities are also defined for the Kronecker selection. It is clear that the sequence of sets of indexes determines the Kronecker selection completely and is in bijective correspondence with the sequence of dynamical indexes $\{d_1, d_2, \dots, d_p\}$ that describes the Kronecker selection. It is well-known and can easily be derived from the foregoing that the Kronecker indexes are in one-to-one bijective correspondence with the sequence $\{s_n\}_{n=1}^l$ (cf. e.g., [2]).

Remark: A similar definition holds for the Kronecker selection of rows from the observability matrix of a pair of matrices $(A, C) \in \mathbb{R}^{n \times n} \times \mathbb{R}^{m \times n}$, the corresponding Kronecker observability indexes etc.

The following lemma is basic for our considerations (see e.g., [9]):

Lemma 2.5. Let $M \in \mathbb{R}^{n \times l}$, $\text{rank}(M) = n \leq l$. There exists an orthogonal matrix $Q_0 \in \mathbb{R}^{n \times n}$ and natural numbers $1 \leq$

$i_1 < i_2 < \dots < i_n \leq l$ such that

$$M_0 := Q_0 M = \begin{pmatrix} 0 & \dots & m_{1i_1} & * & \dots & * & \dots & \dots & * \\ 0 & \dots & 0 & 0 & \dots & m_{2i_2} & * & \dots & * \\ \vdots & & \vdots & \vdots & & \vdots & & & \vdots \\ 0 & \dots & 0 & 0 & \dots & 0 & \dots & m_{ni_n} & * \end{pmatrix}$$

with $m_{ji} = 0$ for all $i < i_j$ and $m_{ji} > 0$ for all $j \in 1, 2, \dots, n$; M_0 is unique and Q_0 is unique. Such a matrix will be called positive upper triangular with independency indexes i_1, i_2, \dots, i_n .

A matrix will be called full rank upper triangular if it is positive upper triangular up to multiplication of some (or possibly all or none) of its rows by -1.

III. A BALANCED CANONICAL FORM FOR SYSTEMS WITH IDENTICAL SINGULAR VALUES

The following theorem of [1] is basic for the relation between systems with all singular values equal and stable all-pass systems.

Theorem 3.1: Let $m = p$.

- If a balanced triple (A, B, C) has identical Hankel singular values $\sigma = 1$ then there exists an orthogonal matrix D such that $C = -DB^T$.
- (A, B, C, D) is a balanced asymptotically stable realization of a stable all-pass system iff (A, B, C) is a balanced asymptotically stable triple with identical singular values and D is an orthogonal matrix such that $C = -DB^T$.

It will be useful to extend the usual definition of orthogonal square matrices to rectangular matrices.

Definition 3.2: An $m \times p$ matrix U will be called orthogonal if $U^T U = I_p$ (if $p \leq m$) or $U U^T = I_m$ (if $m \leq p$).

Using this, a balanced realization (A, B, C) of a stable system with identical singular values (with possibly $m \neq p$) can be characterized as follows:

Corollary 3.3: The following three statements are equivalent:

- A triple (A, B, C) is a balanced asymptotically stable realization of a stable system with identical singular values $\sigma > 0$.
- The pair (A, B) is reachable and $A + A^T = -(1/\sigma)BB^T = -(1/\sigma)C^T C$, $\sigma > 0$.
- The pair (A, B) is reachable, $A + A^T = -(1/\sigma)BB^T$, and there exists a (possibly rectangular) orthogonal matrix D such that $C = -DB^T$.

Proof: Without loss of generality one can assume that $m = p$, because if $m \neq p$ than one can add a sufficient number of zero rows to C or zero columns to B to obtain a system with the same number of in- and outputs and clearly if the result holds for the square system obtained in this way, it also holds for the original system. If $m = p$ the theorem follows from the previous theorem together with a theorem of [10], (here applied to the special case where the Lyapunov equation involved has the identity matrix as a solution) which says that if (A, B) satisfies the equation $A + A^T = -BB^T$ then: A is asymptotically stable iff (A, B) is reachable. \square

The following canonical form for the set of stable multivariable all-pass systems of fixed McMillan degree will be important for our constructions.

Theorem 3.4 ([4], Section IV): The following two statements are equivalent: i) A system Π is a stable all-pass system with McMillan degree n . ii) There exists a unique balanced realization $(A, B, C, D) \in \mathcal{C}_n$ of Π of the following form: There are integers $p = s_0 \geq s_1 \geq s_2 \geq \dots \geq s_l > s_{l+1} = 0$ which add up to $n + p$, such that

$$B = \begin{pmatrix} B_1 \\ 0 \end{pmatrix}$$

where B_1 is an $s_1 \times s_0$ positive upper triangular matrix;

$$A = \begin{pmatrix} A_{11} & A_{12} & 0 & \dots & 0 \\ A_{21} & A_{22} & A_{23} & \ddots & \vdots \\ 0 & A_{32} & \ddots & \ddots & 0 \\ \vdots & \ddots & \ddots & \ddots & A_{l-1,l} \\ 0 & \dots & 0 & A_{l,l-1} & A_{l,l} \end{pmatrix}$$

a block tridiagonal matrix with $A_{u,v}$ an $s_u \times s_v$ matrix, $u, v \in \{1, 2, \dots, l\}$, $A_{u,v} = 0$ if $|u - v| > 1$;

$$A_{11} = \tilde{A}_{11} - \frac{1}{2} B_1 B_1^T$$

\tilde{A}_{11} an otherwise arbitrary skew symmetric $s_1 \times s_1$ matrix; $A_{uu} = \tilde{A}_{uu}$ an otherwise arbitrary skew symmetric $s_u \times s_u$ matrix for each $u \in \{2, 3, \dots, l\}$; $A_{u+1,u}$ a positive upper triangular $s_{u+1} \times s_u$ matrix for each $u \in \{1, 2, \dots, l-1\}$; $A_{u,u+1} = -A_{u+1,u}^T$ for each $u \in \{1, 2, \dots, l-1\}$; D an otherwise arbitrary orthogonal $p \times p$ matrix and

$$C = -DB^T.$$

The indexes $s_u, u = 1, \dots, l$ are in bijective correspondence with the Kronecker indexes. The canonical form is balanced and its reachability matrix is positively upper triangular.

For triples (A, B, C) with all Hankel singular values equal to unity, possibly with $m \neq p$, one obtains the same balanced canonical form with the only exception that, while in the case of all-pass systems the matrix C can be determined from B and D , here instead C is an arbitrary solution of the equation

$$C^T C = B B^T = \begin{pmatrix} B_1 B_1^T & 0 \\ 0 & 0 \end{pmatrix}$$

(Note that because $B_1 B_1^T$ is an $s_1 \times s_1$ positive definite matrix, one has $s_1 \leq m, s_1 \leq p$.) It follows that the matrix C can be partitioned as $[C_1, 0]$, C_1 an $m \times s_1$ matrix which is a solution of $C_1^T C_1 = B_1 B_1^T$. Let $\tilde{B}_1 = [(B_1 B_1^T)^{1/2}, 0]$, where the zero matrix is $s_1 \times (p - s_1)$ and $(B_1 B_1^T)^{1/2}$ is the $s_1 \times s_1$ positive definite symmetric square root of $B_1 B_1^T$. Then clearly $C_1^T C_1 = \tilde{B}_1 \tilde{B}_1^T$ and $C^T C = \tilde{B} \tilde{B}^T$ with $\tilde{B} = \begin{pmatrix} \tilde{B}_1 \\ 0 \end{pmatrix}$ an $m \times s_1$ matrix. From the corollary above it follows that there exists an $m \times s_1$ orthogonal matrix D such that $C = -D \tilde{B}^T$ and so $C_1 = -D \tilde{B}_1^T$. Partition $D = [-U, V]$ where U is an $m \times s_1$ orthogonal matrix and V is an $m \times (p - s_1)$ orthogonal matrix. It follows that $C_1 = U (B_1 B_1^T)^{1/2}$. Because $(B_1 B_1^T)^{1/2}$ is positive definite, the relation between C_1 and U is bijective: $U = C_1 (B_1 B_1^T)^{-1/2}$ and therefore U can be used to parametrize C_1 . In this way one obtains a parametrization of the canonical form for systems with one unit singular value: The matrices B and A together have $s_1 + s_2 + \dots + s_l = n$ positive parameters due to the requirement that $B_1, A_{21}, A_{32}, \dots, A_{l,l-1}$ are all positive upper triangular, while all other entries in these positive upper triangular matrices are either prescribed to be zero by the structural indexes, or are free to vary over the real numbers; furthermore the skew symmetric matrices $\tilde{A}_{11}, \tilde{A}_{22}, \dots, \tilde{A}_{l,l}$ have $\sum_{u=1}^l (1/2) s_u (s_u - 1)$ parameters that are free to vary over the real numbers and finally $C_1 = U (B_1 B_1^T)^{1/2}$ is parametrized by the $m \times s_1$ orthogonal matrix U ; the set of all such orthogonal matrices has dimension $s_1 m - (1/2) s_1 (s_1 + 1)$. Of course one could add a feedthrough matrix to the system, which would have mp freely varying real parameters.

If (A, B, C) has all singular values equal to $\sigma > 0$, then $(\bar{A}, \bar{B}, \bar{C}) = (A, B/\sqrt{\sigma}, C/\sqrt{\sigma})$ has all its singular values equal to unity. Requiring $(\bar{A}, \bar{B}, \bar{C})$ to be in the canonical form just described leads to a canonical form for (A, B, C) by taking $(A, B, C) =$

$(\bar{A}, \sqrt{\sigma} \bar{B}, \sqrt{\sigma} \bar{C})$. This canonical form will be used in the sequel. Clearly $\bar{B} \bar{B}^T = B B^T / \sigma$, $\bar{C} \bar{C}^T = C C^T / \sigma$, etc.

IV. A NEW BALANCED CANONICAL FORM FOR STABLE MULTIVARIABLE SYSTEMS

Consider a system with balanced state space representation (A, B, C, D) . The Grammians are equal and of the form

$$\Sigma = \text{diag}(\sigma_1 I_{n(1)}, \sigma_2 I_{n(2)}, \dots, \sigma_k I_{n(k)})$$

where $\sigma_1 > \sigma_2 > \dots > \sigma_k > 0$ are the Hankel singular values of the system and $n(1), n(2), \dots, n(k)$ the corresponding multiplicities. Partition A, B, C , according to $n(1), n(2), \dots, n(k)$ to obtain

$$A = \begin{pmatrix} A(1,1) & A(1,2) & \dots & A(1,k) \\ A(2,1) & A(2,2) & \dots & A(2,k) \\ \vdots & \vdots & \ddots & \vdots \\ A(k,1) & A(k,2) & \dots & A(k,k) \end{pmatrix} \quad (4.6)$$

and

$$B = \begin{bmatrix} B(1) \\ \vdots \\ B(k) \end{bmatrix}, \quad C = [C(1) \ C(2) \ \dots \ C(k)]. \quad (4.7)$$

The following result is very important for the construction of balanced canonical forms.

Theorem 4.1 ([10], [7]): Let (A, B, C, D) be partitioned as above, balanced in the sense of definition 2.2, but not necessarily asymptotically stable and minimal. Then $(A, B, C, D) \in C_n$ iff for each $i \in \{1, 2, \dots, k\}$, $(A(i, i), B(i), C(i), D) \in C_{n(i)}$.

The balancing (Lyapunov) equations for (A, B, C, D) are given in terms of the $A(i, j), B(i), C(j), i = 1, \dots, k, j = 1, \dots, k$ by

$$\begin{aligned} A(i, i) + A(i, i)^T &= -\frac{1}{\sigma_i} B(i) B(i)^T \\ &= -\frac{1}{\sigma_i} C(i)^T C(i) \end{aligned} \quad (4.8)$$

$$A(i, j) \sigma_j + A(j, i)^T \sigma_i = -B(i) B(j)^T \quad (4.9)$$

$$A(i, j) \sigma_i + A(j, i)^T \sigma_j = -C(i)^T C(j) \quad (4.10)$$

where $i \in \{1, \dots, k\}, j \in \{1, \dots, k\}, i \neq j$. Note that the last two equations can be solved in terms of $A(i, j)$ and $A(j, i)$ for given pair $(i, j), i \neq j$ and given $B(i), B(j), C(i), C(j)$, because $\sigma_i \neq \sigma_j$. Therefore, and because of the theorem 4.1, the construction of a balanced canonical form can be reduced to constructing a balanced canonical form for the subsystems $(A(i, i), B(i), C(i)), i = 1, 2, \dots, k$. For each $i \in \{1, \dots, k\}$ such a system is a system with identical singular values, or perhaps one should say with one singular value σ_i . For such systems the canonical form presented in Section III can be used. This leads to the following result.

Theorem 4.2:

a) The following statements are equivalent:

- i) Ξ is a stable input-output-system with p inputs and m outputs and McMillan degree n .

- ii) Ξ has a realization $(A, B, C, D) \in C_n$ of the following form: There are numbers $\sigma_1 > \sigma_2 > \dots > \sigma_k > 0$, the Hankel singular values, and integers $n(1), n(2), \dots, n(k)$, the corresponding multiplicities of the singular values, and for each $i \in \{1, 2, \dots, k\}$ there are integers $p = s_0(i) \geq s_1(i) \geq \dots \geq s_{l(i)}(i) > s_{l(i)+1}(i) = 0$ which add up to $n(i) + p$, such that

$$A = \begin{pmatrix} A(1,1) & A(1,2) & \dots & A(1,k) \\ A(2,1) & A(2,2) & \dots & A(2,k) \\ \vdots & \vdots & \ddots & \vdots \\ A(k,1) & A(k,2) & \dots & A(k,k) \end{pmatrix} \quad (4.11)$$

and

$$B = \begin{bmatrix} B(1) \\ \vdots \\ B(k) \end{bmatrix}, \quad C = [C(1) \ C(2) \ \dots \ C(k)] \quad (4.12)$$

where $A(i, j)$ is an $n(i) \times n(j)$ matrix, $B(i)$ an $n(i) \times p$ matrix and $C(j)$ an $m \times n(j)$ matrix, $i = 1, 2, \dots, k, j = 1, 2, \dots, k$ and the triples $(A(i, i), B(i), C(i))$ have the following form

$$B(i) = \begin{bmatrix} B_1(i) \\ 0 \\ \vdots \\ 0 \end{bmatrix} \quad (4.13)$$

where $B_1(i)$ is an $s_1(i) \times p$ positive upper triangular matrix and see also (4.14), found at the bottom of the page, a block tridiagonal matrix where for each $u, v \in \{1, 2, \dots, l(i)\}$, $A_{u,v}(i, i)$ is an $s_u(i) \times s_v(i)$ matrix, $A_{u,v}(i, i) = 0$ if $|u - v| > 1$; $A_{11}(i, i) = \tilde{A}_{11}(i, i) - (1/2) B_1(i) B_1(i)^T / \sigma_i$, where $\tilde{A}_{11}(i, i)$ is an otherwise arbitrary skew symmetric $s_1(i) \times s_1(i)$ matrix; $A_{uu}(i, i) = \tilde{A}_{uu}(i, i)$ an otherwise arbitrary skew symmetric $s_u(i) \times s_u(i)$ matrix for each $u \in \{2, 3, \dots, l(i)\}$; $A_{u+1,u}(i, i)$ a positive upper triangular $s_{u+1}(i) \times s_u(i)$ matrix for each $u \in \{1, 2, \dots, l(i) - 1\}$; $A_{u,u+1}(i, i) = -A_{u+1,u}(i, i)^T$ for each $u \in \{1, 2, \dots, l(i) - 1\}$, and furthermore

$$C(i) = [C_1(i), 0, \dots, 0] \quad (4.15)$$

where

$$C_1(i) = U(i) (B_1(i) B_1(i)^T)^{1/2} \quad (4.16)$$

in which $U(i)$ is an $m \times s_1(i)$ orthogonal matrix, i.e., $U(i)^T U(i) = I_{s_1(i)}$; furthermore the matrices $A(i, j), i \neq j, j \in \{1, \dots, k\}$ are determined as the unique solution of the linear equations (4.9), (4.10).

- b) For each system Ξ the the realization $(A, B, C, D) \in C_n$ described in ii) above is unique and balanced. This determines a balanced canonical form for i/o-equivalence on C_n .

$$A(i, i) = \begin{pmatrix} A_{1,1}(i, i) & A_{1,2}(i, i) & 0 & \dots & 0 \\ A_{2,1}(i, i) & A_{2,2}(i, i) & A_{2,3}(i, i) & \ddots & \vdots \\ 0 & A_{2,3}(i, i) & \ddots & \ddots & 0 \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & \dots & 0 & A_{l(i), l(i)-1}(i, i) & A_{l(i), l(i)}(i, i) \end{pmatrix} \quad (4.14)$$

Proof: From the introduction to this theorem it is clear that each stable multivariable linear system has a unique, balanced, representation of this form and that i/o-equivalent systems have exactly the same realization. Therefore this determines a balanced canonical form. It remains to be shown that each system of this form is indeed minimal and stable. This follows from theorem 4.1 together with the fact that the canonical form that is used for the systems with identical singular values has the same property: for each choice of the parameters that is allowed the resulting system is minimal and stable (cf. [4], Section IV.). \square

Remarks:

- i) If $s_1 = p$ then one can just as well parametrize $C_1(i)$ by $C_1(i) = U(i)B(i):U(i)$ a (possibly rectangular) orthogonal matrix.
- ii) Truncation of the last $n - k$ components of the state vector corresponds to the truncation mapping

$$(A, B, C, D) \mapsto ((I_k, 0)A(I_k, 0)^T, (I_k, 0)B, C(I_k, 0)^T, D) \quad (4.17)$$

The canonical form presented has the property that if truncation is applied, the result is again in canonical form. Therefore the resulting lower order system is again minimal and stable.

ACKNOWLEDGMENT

Part of the research for this paper was conducted while the author visited the Dept. Engineering, University of Cambridge and the Center for Engineering Mathematics, University of Texas at Dallas. Discussions with J. Maciejowski, R. Ober, and R. Peeters are gratefully acknowledged.

Boundary Fractional Derivative Control of the Wave Equation

Brahima Mbodje and Gérard Montseny

Abstract—The wave equation, with fractional derivative feedback at the boundary, is studied. The existence and uniqueness, as well as the asymptotic decay of the solution towards zero is proved. The method used is motivated by the fact that the input-output relationship of generalized diffusion equations, defined on the infinite spatial domain R with collocated sensor and actuator control, can be expressed in terms of fractional integrals. Compared to other methods, the payoff is as follows: 1) The proofs are simpler. 2) The method used can easily be adapted to a wide class of problems involving fractional derivative or integral operators of the time variable.

I. INTRODUCTION

Over the last decade, there has been a considerable amount of research on the modeling and control of beams and waves, spurred on by the increasing use of flexible structures in space technology. In particular, the issue of boundary control has received a special attention. In the case of boundary velocity control, and when the sensor is a deflection sensor, the control law involves first-order time differentiation of signals proportional to the deflection and/or the slope of the deflection at the boundary. Besides it is well known [3], [8] that uniform exponential decay of energy for the wave and the beam equations can be achieved through boundary velocity control. However, when it comes to implementing such controllers, the noise level in the control law could become intolerable due to the differentiation process to be performed. Therefore, to reduce the level of noise, one is naturally led to consider control laws based on lower order derivatives [1], namely fractional order derivative control laws. Another strong motivation for considering fractional derivative controls may be found in [4]. There it is shown, for a Bernoulli-Euler beam, that the H_∞ optimal wave absorbing problem at the boundary is solved by a fractional derivative compensator of order one-half.

Only a few other authors [10], [13] have employed controls involving fractional derivatives to stabilize distributed parameter systems. However, in their investigation, they almost exclusively resort to finite dimensional approximations and techniques pertaining to the Laplace domain.

Our objective is to study via a novel method based on an auxiliary diffusion equation this more general type of feedback control law. As will be noted, the method used here is applicable to other mathematical models such as the Bernoulli-Euler and the Timoshenko beam equations. But in order to keep computational complexities low, we choose to examine the wave equation.

Fractional Calculus

As in [2], we define the fractional derivative operator of order α , $0 < \alpha \leq 1$, by

$$\frac{d^\alpha f}{dt^\alpha}(t) = \int_0^t \frac{(t-\tau)^{-\alpha}}{\Gamma(1-\alpha)} \frac{df}{d\tau}(\tau) d\tau \quad (1)$$

where Γ denotes the well known Gamma function.

Manuscript received July 22, 1993; revised March 28, 1994.

The authors are with the Laboratoire d'Analyse et d'Architecture des Systèmes du CNRS, 31077 Toulouse Cedex, France.

IEEE Log Number 9407002.

As used in (1), the fractional derivative operator is the inverse operator of the fractional integration defined as follows [9]–[12]

$$[I^\alpha f](t) = \int_0^t \frac{(t-\tau)^{\alpha-1}}{\Gamma(\alpha)} f(\tau) d\tau \quad (2)$$

Note that in contrast to the classical derivative operator, the fractional derivative of $f(t)$ does take into account the whole history of the signal $f(t)$ from time 0 up to time t .

From (1) and (2) it is clear that

$$\frac{d}{dt} f = I^{1-\alpha} \left[\frac{d}{dt} f \right] \quad (3)$$

For extension of the above definitions to the case where $\alpha \in \mathbb{R}^+$ the reader is referred to [9], [12].

In the Laplace transform domain, the fractional derivative operator has the property

$$\mathcal{L} \left[\frac{d}{dt} f \right] = s^{-(1-\alpha)} \mathcal{L} \left[\frac{df}{dt} \right] = s^{-\alpha} \mathcal{L}[f] - s^{-(1-\alpha)} f(0) \quad (4)$$

Notice how this equation reduces to the well known formula in the classical case of $\alpha = 1$.

Also, for $0 < \alpha < 1$ and $0 < \beta < 1$ it can be shown by direct calculation that

$$I \left[\frac{d}{dt} f \right] (t) = f(t) - f(0) \quad (5)$$

$$\frac{d}{dt} \left[\frac{d^{\beta} f}{dt^{\beta}} \right] = \frac{d^{\beta+1} f}{dt^{\beta+1}} \quad \text{if } \frac{d^{\beta} f}{dt^{\beta}}(0) = 0 \quad (6)$$

For a more thorough discussion on the properties of fractional calculus see [9]–[12].

Model Definition

We consider the wave plant described by the following equations (without loss of generality the wave velocity can be set to unity)

$$\partial_t \theta(x, t) - \partial_x^2 \theta(x, t) = 0 \quad 0 < x < 1, t \geq 0 \quad (7)$$

$$\begin{aligned} \theta(0, t) &= 0 & \partial_x \theta(1, t) &= -h \partial_t \theta(1, t) \\ 0 &< \alpha < 1, h > 0 \end{aligned} \quad (8)$$

$$\theta(x, 0) = \theta_0(x) \quad \partial_t \theta(x, 0) = \theta_1(x) \quad (9)$$

where h is the constant involved in the boundary control.

Remarks 1) Equations (7)–(9) are clearly a closed loop system with feedback $I^{1-\alpha} \partial_t \theta(1, t)$. 2) Also, the noise amplification caused by the differentiation process at high frequencies is attenuated by the fractional integration.

Our objectives are to prove existence and uniqueness of the solution of system (7)–(9) as well as the asymptotic decay of its energy to zero. Our analysis falls into three parts.

First of all we shall show that the above system can be replaced by an augmented system obtained by coupling the wave equation with a higher order diffusion equation. As will be seen, the main advantage of tackling the problem in this way (rather than in the usual framework of Volterra partial integrodifferential equations) lies in that the analysis of the augmented model will require only a reasonable amount of functional analysis. In fact, the augmented model may be framed into the operator theoretical form $Z(t) = \mathcal{A}Z(t)$ in an appropriate Hilbert space. This very convenient form will then allow the use of results from semigroup theory. More, the appearance of the fractional derivative operator in the second boundary condition in (8) could make the direct analysis of the original set of equations (7)–(9)

much more complicated, as in that case the search for a Lyapunov functional could be more difficult.

The second part of our investigation is devoted to proving existence and uniqueness of the solution of (7)–(9). The third part is concerned with the asymptotic decay of the solution to zero.

II. AUGMENTED SYSTEM

We now demonstrate how a diffusion equation can be used to reformulate system (7)–(9). Consider the higher order diffusion defined on the spatial domain \mathbb{R} with input \mathcal{U}_d

$$\begin{aligned} \partial_t \varphi(y, t) &= (-1)^{l+1} \partial_y^{l+1} \varphi(y, t) \\ &+ \mathcal{U}_d(t) \delta^{(k)}(y) \quad t > 0, y \in \mathbb{A}, k \in \mathbb{N} \end{aligned} \quad (10)$$

$$\varphi(y, 0) = \varphi_0(y) \quad (11)$$

where $\delta^{(k)}$ denotes the k th derivative of the Dirac delta function.

We define the output of the system as follows

$$\mathcal{Y}_l(t) = \langle \delta^{(k)} \varphi(\cdot, t) \rangle \triangleq (-1)^k \partial_y^k \varphi(0, t) \quad (12)$$

Let $f(\xi) = f_{-}^{\infty} f(y) e^{\xi y} dy$ define the Fourier transform of $f(y)$. The following assertion is important in that it constitutes the idea upon which the remainder of the article is based.

Proposition 1 Let $0 \leq k \leq q-1$ and $\varphi(y, 0) = 0$ then setting $\alpha = (2k+1)/2q$ and $\nu = 2q \sin \alpha \pi$ the input–output relationship of system (10)–(12) is given by

$$\mathcal{Y}_l(t) = \nu^{-1} I^{1-\alpha} \mathcal{U}_d(t) \quad (13)$$

Proof It can readily be shown that the self adjoint operator $\mathcal{A} = (-1)^{l+1} \partial_y^{l+1}$ on the Hilbert space $L^2(\mathbb{R})$ generates a contraction semigroup. Also, from the Fourier transform of (10) we have

$$\partial_t \varphi(\xi, t) = -\xi^{2l+1} \varphi(\xi, t) + (-i)^k \xi^k \mathcal{U}_d(t) \quad (14)$$

Hence

$$\varphi(\xi, t) = e^{-\xi^{2l+1} t} \varphi_0(\xi) + (-i)^k \int_0^t \xi^k e^{-\xi^{2l+1} (t-\tau)} \mathcal{U}_d(\tau) d\tau \quad (15)$$

Now setting $\varphi_0(t) = 0$ (zero initial condition) and using (12) we arrive at the following

$$\mathcal{Y}_l(t) = \frac{1}{\pi} \int_0^t \left[\int_0^{\infty} e^{-(t-\tau)\xi^{2l+1}} \xi^k d\xi \right] \mathcal{U}_d(\tau) d\tau \quad (16)$$

$$= \frac{\Gamma(\alpha)}{2q\pi} \int_0^t \frac{1}{(t-\tau)^{1-\alpha}} \mathcal{U}_d(\tau) d\tau \quad \text{where } \alpha = \frac{2k+1}{2q} \quad (17)$$

which is the result looked for since $\Gamma(1-\alpha)\Gamma(\alpha) = \pi[\sin \alpha \pi]^{-1}$. \square

Remarks 1) We realize that by assigning to k and q varying values α will run through all rationals between 0 and 1. Besides, nonrational values of α and the limiting case $\alpha = 1$ can be achieved by merely allowing k to vary continuously within the interval $0 \leq k \leq q-1/2$ which amounts to considering in (10) fractional derivatives of the Dirac distribution [12] as well. 2) Implementation of a control law based on equation (1) is very difficult in the convolution form. On the contrary, system (10)–(12) may be approximated in a very straightforward way by using standard numerical techniques such as finite differences or elements, which lead to very efficient algorithms [7]. These numerical aspects are not developed here but will be the subject of a future paper.

In view of the foregoing proposition, we can model the fractional derivative term in the second boundary condition in (8) by means of

the diffusion system (10)–(12). System (7)–(9) is therefore completely described by

$$\partial_t^2 \theta(x, t) - \partial_x^2 \theta(x, t) = 0 \quad (18)$$

$$\partial_t \varphi(y, t) + (-1)^l \partial_y^{2l} \varphi(y, t) - \partial_t \partial_x \theta(1-t) \delta^{(k)}(y) = 0 \quad (19)$$

$$\theta(0, t) = 0, \quad \partial_x \theta(1, t) = -h \langle \delta^{(k)}, \varphi \rangle \quad (20)$$

$$\begin{aligned} \theta(x, 0) &= \theta_0(x), \quad \partial_t \theta(x, 0) \\ &= \theta_1(x), \quad \varphi(y, 0) = 0 \end{aligned} \quad (21)$$

Remark As will be seen, system (18)–(21) possesses an infinitesimal generator of a C_0 semigroup. In other words, we have managed to replace a system with an hereditary boundary condition by a nonhereditary system.

III. EXISTENCE AND UNIQUENESS

To analyze (18)–(21) we introduce, as in [8], the following notation

$$H_0^1(0, 1) = \{\theta \in L^2(0, 1) : \partial_x \theta \in L^2(0, 1), \theta(0) = 0\}$$

We consider the Hilbert spaces $H_0^1(1, 0) = L^2(0, 1)$ and $L^2(\mathbb{R})$ equipped with the inner products

$$\begin{aligned} (u|v)_{H_0^1(0, 1)} &= \frac{1}{2} \int_0^1 \partial_x u \partial_x v dx = \frac{1}{2} \int_0^1 u v dx \\ (\varphi|\varphi)_{L^2(\mathbb{R})} &= \frac{h}{2i} \int_{\mathbb{R}} \varphi \varphi^* dx \end{aligned} \quad (22)$$

Our state space will be the Hilbert space $\mathcal{H} = H_0^1(0, 1) \times L^2(0, 1) \times L^2(\mathbb{R})$ with inner product

$$\begin{aligned} ((u, v, \varphi)^T | (u, v, \varphi)^T)_{\mathcal{H}} &= \\ &= (u|u)_{H_0^1(0, 1)} + (v|v)_{L^2(0, 1)} + (\varphi|\varphi)_{L^2(\mathbb{R})} \end{aligned} \quad (23)$$

Setting $\Lambda = (\partial_t \partial_x \theta, \varphi)^T \in \mathcal{H}$ (18)–(21) can be put in the abstract form

$$\frac{d}{dt} \Lambda = \Lambda, \quad \Lambda(0) \in \mathcal{H} \quad (24)$$

where $\Lambda: \mathcal{H} \rightarrow \mathcal{H}$ is the linear unbounded operator defined by

$$\Lambda = \begin{bmatrix} 0 & 1 & 0 \\ \partial_x^2 & 0 & 0 \\ 0 & \partial_x \langle \delta_1(x), \cdot \rangle \delta^{(k)} & (-1)^{l+1} \partial_y^{2l} \end{bmatrix} \quad (25)$$

with $\delta_1(x)$ defined by $\langle \delta_1(x), f(x) \rangle = f(1)$. The domain $D(\Lambda)$ of the operator Λ is given by

$$\begin{aligned} D(\Lambda) &= \{(u, v, \varphi)^T \in \mathcal{H} : u \in H_0^2, v \in H_0^1, \\ &\quad v(1) \delta^{(k)} + (-1)^{l+1} \partial_y^{2l} \varphi \in L^2(\mathbb{R}), \\ &\quad \partial_x u(1) + h \langle \delta^{(k)}, \varphi \rangle = 0\} \end{aligned} \quad (26)$$

Note that $(u, v, \varphi)^T \in D(\Lambda)$ implies $\varphi \in H^l(\mathbb{R})$ since, by assumption $0 \leq k \leq q-1$.

We now prove the following proposition about the dissipativity of system (24).

Proposition 2 Let $\mathcal{E}_d(t) = \|\varphi\|_{L^2(\mathbb{R})}^2$ and $\mathcal{E}_u(t) = \|\theta\|_{H_0^1(0, 1)}^2 + \|\partial_t \theta\|_{L^2(0, 1)}^2$ denote the diffusion and the wave energies, respectively. Then the total energy $\mathcal{E}(t) = \mathcal{E}_u(t) + \mathcal{E}_d(t)$ is nonincreasing along the classical solutions of system (24).

Proof Differentiate $\mathcal{E}_i(t)$ with respect to time, use integration by parts and conditions (20)

$$\dot{\mathcal{E}}_i(t) = -h \partial_t \theta(1, t) \langle \delta^{(k)}, \varphi(\cdot, t) \rangle \quad (27)$$

Differentiate $\mathcal{E}_d(t)$ with respect to time, use integrations by parts and the fact that $(\theta, \partial_t \theta, \varphi)^T$, being a classical solution of system (24), φ must belong to $H^l(\mathbb{R})$

$$\dot{\mathcal{E}}_d(t) = -2 \|\partial_y^l \varphi\|_{L^2(\mathbb{R})}^2 + h \partial_t \theta(1, t) \langle \delta^{(k)}, \varphi(\cdot, t) \rangle \quad (28)$$

Now, by adding memberwise (27) and (28), we obtain the desired result

$$\dot{\mathcal{E}}(t) = -2 \|\partial_y^l \varphi\|_{L^2(\mathbb{R})}^2 \quad \square \quad (29)$$

Next we prove the following assertion for another useful estimate.

Proposition 3 Let $\Xi_d(t) = \|\partial_t \varphi\|_{L^2(\mathbb{R})}^2$ and $\Xi_u(t) = \|\partial_t \theta\|_{H_0^1(0, 1)}^2 + \|\partial_t^2 \theta\|_{L^2(0, 1)}^2$, then the sum $\Xi(t) = \Xi_d(t) + \Xi_u(t)$ is increasing along the solutions of (24) with initial conditions in $D(\Lambda)$.

Proof If $\Lambda_0 \in D(\Lambda)$ then $\Lambda(t) = T(t) \Lambda_0$ is a classical solution of (24). Hence we may proceed as in the proof of Proposition 2. We have

$$\dot{\Xi}_d(t) = -h \partial_t \theta(1, t) \langle \delta^{(k)}, \partial_t \varphi(\cdot, t) \rangle \quad (30)$$

and

$$\dot{\Xi}_u(t) = -2 \|\partial_t^l \partial_t \varphi\|_{L^2(\mathbb{R})}^2 + h \partial_t \theta(1, t) \langle \delta^{(k)}, \partial_t \varphi(\cdot, t) \rangle \quad (31)$$

Hence

$$\dot{\Xi}(t) = -2 \|\partial_t^l \partial_t \varphi\|_{L^2(\mathbb{R})}^2 \quad \square \quad (32)$$

We are now able to consider the following

Theorem 1 The operator Λ defined by (25)–(26) generates a C_0 semigroup $\{T(t) : t \geq 0\}$ in \mathcal{H} . For $\Lambda_0 \in D(\Lambda)$ the unique classical solution of (24) is given by $\Lambda(t) = T(t) \Lambda_0$, $\Lambda_0 \in D(\Lambda)$, $t \geq 0$.

Proof By the Lumer-Phillips theorem [11] it suffices to show that Λ is maximal dissipative. Since Proposition 2 already establishes the dissipativity of Λ on the space $D(\Lambda)$, it remains to prove that the operator $\lambda I - \Lambda$ is onto for some $\lambda > 0$. Let $\lambda = 1$. Hence our problem becomes the following

for any $(u, v, \varphi)^T \in \mathcal{H}$, find $(u, v, \varphi)^T \in D(\Lambda)$ such that these three equalities hold

$$\alpha(v) = u(v) - v(v) \quad (33)$$

$$f(v) = v(v) - \partial_x^2 u(v) \quad (34)$$

$$g(y) = \varphi(y) - \partial_t(1) \delta^{(k)}(y) + (-1)^l \partial_y^{2l} \varphi(y) \quad (35)$$

From (33) and (34) and using the fact that $u(0) = v(0) = 0$ it is fairly easily shown that

$$u(v - B) = B \sinh(v) - \int_0^v \{\alpha(\sigma) + f(\sigma)\} \sinh(v - \sigma) d\sigma \quad (36)$$

$$\begin{aligned} v(v - B) &= B \sinh(v) - \alpha(v) - \int_0^v \{\alpha(\sigma) \\ &\quad + f(\sigma)\} \sinh(v - \sigma) d\sigma, \end{aligned} \quad (37)$$

where B is a constant to be determined soon.

Now to show the existence of φ , we first note that

$$\hat{\chi}(\xi) = \frac{\hat{\gamma}(\xi) + (-i\xi)^k \hat{\nu}(1, B)}{1 + \xi^{2q}} \quad (38)$$

solves the Fourier transform of (35) when B is known. Therefore the inverse Fourier transform of $\hat{\chi}$ is the unique solution of (35) and belongs to the space $H^q(\mathbb{R})$. Substituting (36) and the inverse Fourier transform of (38) into the last boundary condition in (26) yields B :

$$\begin{aligned} 2B\pi \cosh(1) - \int_0^1 2\pi \{ \alpha(\sigma) + \beta(\sigma) \} \cosh(1 - \sigma) d\sigma \\ + Bh\nu \sinh(1) \int_{\mathbb{R}} \frac{\xi^{2k}}{1 + \xi^{2q}} d\xi \\ - h\nu \alpha(1) \int_{\mathbb{R}} \frac{\xi^{2k}}{1 + \xi^{2q}} d\xi \\ - h\nu \left\{ \int_0^1 \{ \alpha(\sigma) + \beta(\sigma) \} \sinh(1 - \sigma) d\sigma \right\} \\ \int_{\mathbb{R}} \frac{\xi^{2k}}{1 + \xi^{2q}} d\xi \\ + 2\pi(-1)^k h \int_{\mathbb{R}} \gamma(-y) \partial_y^k \rho(y) dy = 0 \end{aligned} \quad (39)$$

where $\rho(y)$ is the inverse Fourier transform of $[1 + \xi^{2q}]^{-1}$. This ends the proof. \square

IV. ASYMPTOTIC STABILITY

Now consider the subspace of \mathcal{H} defined by

$$\mathcal{S} = \{ z \in \mathcal{H} : \dot{\mathcal{E}}(t) = 0, \forall t \geq 0 \}. \quad (40)$$

Lemma 1: The only classical solution of (24) in the subspace \mathcal{S} is the zero solution.

Proof: Let $(\theta, \partial_t \theta, \varphi)^T \in \mathcal{S}$ be the classical solution of (24); then from (29) we have

$$\forall t \geq 0, \quad \int_{\mathbb{R}} [\partial_y^q \varphi(y, t)]^2 dy = 0 \quad (41)$$

which, together with the fact that $\varphi(\cdot, t) \in L^2(\mathbb{R})$, yields

$$\forall t \geq 0, \quad \varphi(\cdot, t) = 0 \quad \text{a.e. in } \mathbb{R}. \quad (42)$$

From (42) it is clear that system (18)–(20) reduces to the set of equations:

$$\partial_t^2 \theta(x, t) - \partial_x^2 \theta(x, t) = 0, \quad (43)$$

$$\theta(0, t) = 0, \quad \partial_x \theta(1, t) = 0, \quad \partial_t^3 \theta(1, t) = 0. \quad (44)$$

Using (5) and the last equality in (44), we have $\theta(1, t) \equiv \theta(1, 0)$. Combining this with (43)–(44) leads to the identity: $\theta(x, t) \equiv 0$ (In fact, this identity may be obtained by separation of variables). \square

Therefore, according to LaSalle's invariance principle [14], a solution will tend to zero provided its trajectory is precompact in \mathcal{H} . We shall prove the precompactness in Lemma 2 and Proposition 4.

Lemma 2: If $z_0 = (\theta_0, \theta_1, \varphi_0)^T \in D(\Lambda^2)$ then the trajectory of the pair $(\theta, \partial_t \theta)^T$ is compact in $H_0^1(0, 1) \times L^2(0, 1)$.

Proof: First, if $z_0 = (\theta_0, \theta_1, \varphi_0)^T \in D(\Lambda^2)$, then clearly: $(\theta, \partial_t \theta)^T \in H_0^1(0, 1) \times H_0^1(0, 1)$. Now using the differential equation (18) and the fact that $\mathcal{E}(t)$ and $\Xi(t)$ are bounded, we see that

$$\begin{aligned} \|(\theta, \partial_t \theta)^T\|_{H_0^1 \times H_0^1}^2 &\triangleq \int_0^1 |\partial_x \theta|^2 dx \\ &+ \int_0^1 |\partial_x^2 \theta|^2 dx + \int_0^1 |\partial_x \partial_t \theta|^2 dx < C, \quad \text{for some } C > 0. \end{aligned} \quad (45)$$

Hence we conclude by the compact embedding of $H_0^2(0, 1) \times H_0^1(0, 1)$ into $H_0^1(0, 1) \times L^2(0, 1)$. \square

Proposition 4: If $z_0 = (\theta_0, \theta_1, \varphi_0)^T \in D(\Lambda^2)$, then the trajectory of φ , the third component of the solution of (24), is precompact in $L^2(\mathbb{R})$.

Proof: Since for $z_0 \in D(\Lambda^2)$, $\varphi(t)$ is a continuous mapping from $[0, +\infty)$ into $L^2(\mathbb{R})$, it is therefore sufficient to show that $\|\varphi(t)\|_{L^2(\mathbb{R})} \rightarrow 0$ as $t \rightarrow \infty$ whenever $z_0 \in D(\Lambda^2)$.

From relations (29) and (32), we have

$$\int_0^\infty dt \int_{\mathbb{R}} [\partial_t \partial_y^q \varphi]^2 dy < \infty, \quad \int_0^\infty dt \int_{\mathbb{R}} [\partial_y^q \varphi]^2 dy < \infty. \quad (46)$$

Using the above relations together with the Cauchy-Schwartz inequality, we can easily show that

$$\lim_{t \rightarrow \infty} \int_{\mathbb{R}} [\partial_y^q \varphi(y, t)]^2 dy \quad \text{exists.} \quad (47)$$

Now, from the second equality in (46) and from (47), we have

$$\lim_{t \rightarrow \infty} \int_{\mathbb{R}} [\partial_y^q \varphi(y, t)]^2 dy = \lim_{t \rightarrow \infty} \int_{\mathbb{R}} \xi^{2q} |\hat{\varphi}(\xi, t)|^2 d\xi = 0. \quad (48)$$

Therefore, from (48), it is clear that $\|\varphi(t)\|_{L^2(\mathbb{R})}$ will tend to 0, as t approaches ∞ , if

$$\lim_{t \rightarrow \infty} \int_{|\xi| \leq 1} |\hat{\varphi}(\xi, t)|^2 d\xi = 0. \quad (49)$$

We shall now prove the above equality (49) by the dominated convergence theorem.

1) Applying both Parseval's equality and Fubini's theorem to both inequalities in (46), we have

$$\begin{aligned} \int_0^\infty |\partial_t \widehat{\partial_y^q \varphi}(\xi, t)|^2 dt &< \infty, \\ \int_0^\infty |\widehat{\partial_y^q \varphi}(\xi, t)|^2 dt &< \infty, \\ \text{a.e. in } \xi \in [-1, 1]. \end{aligned} \quad (50)$$

So that, by the same arguments that led to (49), we may conclude that

$$\begin{aligned} \lim_{t \rightarrow \infty} |\widehat{\partial_y^q \varphi}(\xi, t)|^2 &= \lim_{t \rightarrow \infty} \xi^{2q} |\hat{\varphi}(\xi, t)|^2 = 0, \\ \text{a.e. in } \xi \in [-1, 1]. \end{aligned} \quad (51)$$

Hence

$$\lim_{t \rightarrow \infty} |\hat{\varphi}(\xi, t)|^2 = 0, \quad \text{a.e. in } \xi \in [-1, 1]. \quad (52)$$

2) Now, taking the Fourier transform in (19), solving for $\hat{\varphi}$ and then using integration by parts with respect to time and the

fact that $\theta(1, t)$ is bounded (Proposition 2), it is not difficult to see that

$$|\varphi(\xi, t)|^2 \leq (|\varphi_0(\xi)|^2 + Q) \in I^1(0, 1) \quad \text{for some } Q > 0 \quad (53)$$

Finally from (52)–(53) and the dominated convergence theorem, we obtain $\lim_{t \rightarrow \infty} \|\varphi(t)\|_{L^2(\mathbb{R})} = 0$ \square

Corollary For $\varphi_0 \in \mathcal{H}$ $\|\varphi(t) - \varphi_0\|_{\mathcal{H}} \rightarrow 0$ as $t \rightarrow \infty$

Proof For $\varphi_0 \in D(\mathcal{A}^2)$ it is a direct consequence of proposition 4, Lemmata 1 and 2 and the LaSalle's invariance principle [14]. Since $D(\mathcal{A}^2)$ is dense in \mathcal{H} the result still holds for $\varphi_0 \in \mathcal{H}$ \square

V. CONCLUSION

The existence, uniqueness and asymptotic decay towards zero of the solution of the coupled wave-diffusion system (24) has been proved. Moreover, since the original system (7)–(9) is embedded in the "augmented" system (24), all the results obtained for the latter carry over to the original system. Also the approach presented here proves to be both simpler and very efficient.

Observer-Based Parameter Identifiers for Nonlinear Systems with Parameter Dependencies

Shahab Sheikholeslam

Abstract—The class of nonlinear dynamical systems whose dynamics depends linearly on the unknown parameter vector is considered. After reviewing a standard observer-based identifier for estimating the unknown parameters, we propose a family of new identifiers which exploit the *a priori* known parameter dependencies. Then we establish that, under mild assumptions on the dynamical system, 1) the proposed identifiers are stable, 2) the weighted norm of state-parameter errors using the proposed identifiers are less than the corresponding errors using the standard identifier for a length of time after $t = 0$. The main contribution of this paper is that it introduces a family of observer-based identifiers which exhibit better transient performance than the standard identifier.

I. INTRODUCTION

The subject of adaptive identification and control has been studied extensively in the literature. For the basic theory refer to [8]–[5], [11]–[9]. Adaptive parameter identifiers studied in the literature fall into two classes: 1) identification algorithms which use the input–output relations to continuously estimate the unknown parameters (see [8]–[5]) and 2) model reference identification algorithms [11]–[9] which use an observer to continuously estimate the unknown parameters. The algorithms in class 2) are useful for adaptive control. The identifiers in this paper belong to class 2).

In most engineering applications the unknown parameters in the system equations are known functions of the physical parameters of the model. In many such cases the unknown parameters are known functions of a strictly proper subset of all the unknown parameters. Our approach in designing new parameter identifiers for a class of nonlinear systems is to exploit such parameter dependencies while maintaining the stability of the identifier. Intuitively an identifier which exploits the *a priori* known parameter dependencies should yield smaller errors than a similar identifier which does not make use of such dependencies. In [3] and [1] the authors propose identification algorithms in class 1) that make use of parameter dependencies. The main contribution of this paper is that it introduces a family of identifiers in class 2) that exhibit better transient performance than a standard identifier. The method of proof used to show the superior transient performance can be used to prove that the parameter errors resulting from using the identifier in [3] in class 1) are smaller than the corresponding errors using a standard least squares identification algorithm.

Recently some authors have studied the problem of robust adaptive control of linear time invariant systems [6]–[4]. As pointed out in [6] one of the main limitations to the theory is the lack of a more convenient quantification of the transient performance. We believe that the results presented in this paper are preliminary attempts at such a quantification.

The paper is organized as follows. Section II proposes a new observer-based identifier for a class of nonlinear dynamical systems and states theorems regarding its stability and transient performance to compare the transient performance of the proposed identifier with

that of the standard identifier, Section III shows simulation results for adaptive identification of the longitudinal dynamics of a vehicle; Section IV outlines the main results and provides future directions for research; Section V contains the proofs of the theorems.

II. PARAMETER IDENTIFIERS

Throughout this paper, we use $|\cdot|$ to denote the Euclidean norm of a vector and $\|\cdot\|$ to denote the induced norm of a matrix.

A. Background

Consider the nonlinear time-invariant dynamical system

$$\begin{aligned}\dot{x} &= W^T(x, u)\theta^* \\ x(0) &= x_0\end{aligned}\quad (2.1)$$

where $x \in R^n$ denote the state of the system, $u \in R^m$ denotes the control input to the system, $\theta^* \in R^p$ is a constant vector of unknown parameters, and $W(\cdot, \cdot)$ is a $p \times n$ matrix of piecewise continuous functions. W^T denotes the transpose of the matrix W .

Parameter Structure: In (2.1), components of the unknown parameter vector θ^* are known functions of the physical parameters (e.g., engine time-lag (τ) and drag coefficient (K_d) in the vehicle dynamics (2.10) with θ^* defined in (2.13)). Previous papers [13], [14], [16], [2] have proposed observer-based identifiers, for (2.1), which do not exploit these parameter dependencies.

Identifier Structure (Not Using Parameter Dependencies) [13], [14], [16], [10]: Let $A \in R^{n \times n}$ be a Hurwitz matrix and $Q \in R^{n \times n}$ be a given symmetric positive definite matrix; let $P \in R^{n \times n}$ denote the unique symmetric positive-definite solution of the Lyapunov equation

$$A^T P + P A = -Q. \quad (2.2)$$

For the dynamical system in (2.1) the identifier is chosen to be

$$\dot{\hat{x}}'' = A(\hat{x}'' - x) + W^T(x, u)\hat{\theta}'' \quad (2.3)$$

$$\dot{\hat{\theta}}'' = -W(x, u)P(\hat{x}'' - x) \quad (2.4)$$

$$\hat{x}''(0) = \hat{x}_0 \quad (2.5)$$

$$\hat{\theta}''(0) = \hat{\theta}_0. \quad (2.6)$$

The superscript u in \hat{x}'' , $\hat{\theta}''$ indicates that the Lyapunov function, used to prove the stability of the above identifier, is unconstrained with respect to parameter dependencies in (2.1).

Assumption 1 (Boundedness of Regressor): We assume that $W: R^n \times R^m \rightarrow R^{p \times n}$ is bounded.

Stability of the Identifier: Define the state error and the parameter error by

$$e'' = \hat{x}'' - x \quad (2.7)$$

$$\phi'' = \hat{\theta}'' - \theta^*. \quad (2.8)$$

Theorem 1 (Stability of Identifier (2.3)–(2.4)): Consider the dynamical system (2.1) with the identifier (2.3)–(2.4). Let Assumption 1 hold; then $e'' \in L_2 \cap L_\infty$, $\dot{e}'' \in L_\infty$, and $\phi'' \in L_\infty$.

Proof of Theorem 1: See [16 (and references therein)], [11, sec. 2.4]. The proof of Theorem 1 uses a standard unconstrained Lyapunov function candidate

$$V''(e'', \phi'') = \frac{1}{2} e''^T P e'' + \frac{1}{2} \phi''^T \phi''. \quad (2.9)$$

B. New Identifier

In many engineering applications, the components of $\theta^* \in R^p$ are known functions of a strictly proper subset of θ_i^* for $i = 1, 2, \dots, p$. (θ_i^* denotes the i th component of θ^* .) This is illustrated in the following example.

Example: Consider the following nonlinear differential equation representing the longitudinal dynamics of a vehicle [15], [12]:

$$\ddot{x} = -2 \frac{K_d}{m} \dot{x} \ddot{x} - \frac{1}{\tau} \left[\dot{x} + \frac{K_d}{m} \dot{x}^2 + \frac{d_m}{m} \right] + \frac{u}{m\tau} \quad (2.10)$$

where x is the position of the vehicle with respect to a fixed reference point O on the road; K_d denotes the vehicle's aerodynamic drag coefficient; m denotes the mass of the vehicle; τ denotes the vehicle's engine time-constant; d_m denotes the mechanical drag of the vehicle; and u denotes the throttle-command input to the vehicle's engine.

Equation (2.10) can be put into the form

$$\ddot{x} = w^T(\dot{x}, \ddot{x}, u)\theta^* \quad (2.11)$$

where

$$w(\dot{x}, \ddot{x}, u) = \left[-\frac{2}{m} \dot{x} \ddot{x}, -\ddot{x} - \frac{d_m}{m} + \frac{u}{m}, -\frac{\dot{x}^2}{m} \right]^T \quad (2.12)$$

and

$$\theta^* = \left[K_d, \frac{1}{\tau}, \frac{K_d}{\tau} \right]^T \quad (2.13)$$

For the vehicle dynamics (2.11), $\theta_1^* = \theta_2^* \theta_3^*$.

Our approach in designing a new parameter identifier for (2.1) is to exploit such parameter dependencies while maintaining the stability of the identifier.

Parameter Dependencies:

Definition (Parameter Constraint Set): Consider the dynamical system (2.1) with $\theta^* \in R^p$. The parameter constraint set is an N -dimensional C^2 submanifold of R^p parameterized by $\theta_1^*, \dots, \theta_N^*$. Hence, the parameter constraint manifold is described by

$$\begin{aligned}C(\{\gamma_i, i = N+1, \dots, p\}) \\ = \{\theta \in R^p \mid \theta_i = \gamma_i(\theta_1, \dots, \theta_N) \text{ for } i = N+1, \dots, p\}\end{aligned} \quad (2.14)$$

where for $i = N+1, \dots, p$, $\gamma_i: R^N \rightarrow R$ is a known C^2 map (i.e., γ_i is at least twice continuously differentiable).

Penalty function: Consider the parameter constraint set in (2.14). We define a penalty function $\hat{P}: R^p \rightarrow R$ with

$$\hat{P}(\hat{\theta}) = \frac{1}{2} \sum_{i=N+1}^p \lambda_i [\hat{\theta}_i - \gamma_i(\hat{\theta}_1, \dots, \hat{\theta}_N)]^2 \quad (2.15)$$

where $\lambda_i > 0$ for all $i = N+1, \dots, p$.

For the vehicle dynamics (2.11), the parameter constraint set is $C(\{\gamma_3\}) = \{\theta \in R^3 \mid \theta_3 = \gamma_3(\theta_1, \theta_2) = \theta_1 \theta_2\}$. The penalty function (2.15) with respect to the parameter constraint set $C(\{\gamma_3\})$ is

$$\hat{P}(\hat{\theta}) = \frac{1}{2} \lambda_3 [\hat{\theta}_3 - \hat{\theta}_1 \hat{\theta}_2]^2 \quad (2.16)$$

where $\lambda_3 > 0$.

Identifier Structure (Using Parameter Dependencies): Let $A \in R^{n \times n}$, $Q \in R^{n \times n}$, and $P \in R^{n \times n}$ be the same matrices used in (2.2) and (2.3)–(2.4). Let \hat{P} be the penalty function in (2.15) for the parameter constraint set in (2.14).

The new identifier for the dynamical system (2.1) is

$$\dot{\hat{x}}^c = A(\hat{x}^c - x) + W^T(x, u)[\hat{\theta}^c + D\hat{P}(\hat{\theta}^c)] \quad (2.17)$$

$$\dot{\hat{\theta}}^c = -W(x, u)P(\hat{x}^c - x) \quad (2.18)$$

$$\hat{x}^c(0) = \hat{x}_0 \quad (2.19)$$

$$\hat{\theta}^c(0) = \hat{\theta}_0 \quad (2.20)$$

where $D\hat{P}(\cdot)$ denotes the differential of the penalty function.

We have used the superscript c in \hat{x}^c , $\hat{\theta}^c$ to indicate that the Lyapunov function candidate, used to prove the stability of the above identifier, is constrained with respect to parameter dependencies in (2.1). (See (2.23) below.)

Assumption 2 (Existence and Uniqueness): Throughout this paper, we assume that the solutions of the differential equations (2.17)–(2.18) with initial conditions (2.19)–(2.20) exist and are unique on $[0, \infty)$.

Stability of the Identifier: Denote

$$\epsilon' := \hat{x}' - x \quad (2.21)$$

$$\phi' := \hat{\theta}' - \theta^*. \quad (2.22)$$

Theorem 2 (Stability of Identifier (2.17)–(2.18)): Consider the dynamical system (2.1) with the identifier (2.17)–(2.18). Let ϵ' , ϕ' denote the identifier's state-error and parameter error vectors, respectively. Suppose Assumption 1 (Boundedness of Regressor) and Assumption 2 (Existence and Uniqueness) hold, then $\epsilon' \in L_2 \cap L_\infty$, $\dot{\epsilon}' \in L_\infty$, and $\phi' \in L_\infty$.

Proof (Theorem 2) See the Appendix.

Comments: a) Proof of Theorem 2 uses a Lyapunov function candidate of the form

$$V'(\epsilon', \phi') := \frac{1}{2} \epsilon'^T P \epsilon' + \frac{1}{2} \phi'^T \phi' + P(\phi' + \theta^*). \quad (2.23)$$

Comparing (2.9) with (2.23), we note that the penalty term $\hat{P}(\phi' + \theta^*)$ is the new addition to the standard Lyapunov function candidate. The design of the new identifier (2.17)–(2.18) is motivated by using the Lyapunov function candidate (2.23).

b) In [3, (2.14)], the authors propose a similar Lyapunov function for improving the robustness of a least squares type identification algorithm. The main differences between the identification algorithms presented in [3] and the observer-based identifier in (2.17)–(2.18) are: 1) the identifier in (2.17)–(2.18) belongs to the so-called model reference identification family of algorithms [11, p. 50]. The algorithms in this family are useful for adaptive control. The identification algorithms in [3] use the input-output relations to estimate the unknown parameters; 2) the dynamical systems in [3] are SISO, linear, time-invariant, whereas, we consider MIMO, nonlinear, time-invariant dynamical systems (see (2.1)); and 3) in [3], the parameters are multilinear functions of the unknowns (i.e., the γ_i , see (2.14), are multilinear functions); whereas, we allow more general parameter dependencies in the definition of the parameter constraint set (2.14).

Transient Performance We now compare the transient performance of the new identifier (2.17)–(2.18) with that of the standard identifier (2.3)–(2.4).

Consider the dynamic system represented by (2.1) with the parameter constraint set (2.14). Let $t \mapsto \theta''(t) := (\theta_1''(t), \dots, \theta_N''(t), \hat{\theta}_{N+1}''(t), \dots, \hat{\theta}_p''(t))^T \in R^n$ denote the solution of (2.4) with initial condition $\theta''(0)$.

Assumption 3 (Deviation from Constraint Set) We assume that there exists a $j \in \{N+1, \dots, p\}$ such that

$$\left. \frac{d}{dt} [\hat{\theta}_j''(0) - \gamma_j(\hat{\theta}_1''(0), \dots, \hat{\theta}_N''(0))] \right|_{t=0} \neq 0. \quad (2.24)$$

Remark. Intuitively, Assumption 3 indicates that the direction of the velocity vector of the parameter estimates at $t = 0$, using the update law (2.4), lies outside the tangent space of the parameter constraint set (2.14) at $\theta''(0)$. Hence, after $t = 0$, the parameter estimates may not lie on the parameter constraint set (2.14).

Theorem 3 (Transient Performance): Consider the dynamical system represented by (2.1). Let the proposed identifier (2.17)–(2.18) and the standard identifier (2.3)–(2.4) have the same initial conditions (2.5)–(2.6). Suppose the parameter estimates initially lie on the parameter constraint set (2.14). Suppose Assumption 1 (Boundedness of Regressor), Assumption 2 (Existence and Uniqueness), and Assumption 3 (Deviation from Constraint Set) hold. Let $\epsilon'' : R_+ \rightarrow R^n$, $\phi'' : R_+ \rightarrow R^n$ be defined as in (2.7), (2.8), respectively. Let

$\epsilon' : R_+ \rightarrow R^n$, $\phi' : R_+ \rightarrow R^n$ be defined as in (2.21), (2.22), respectively. Under these conditions, there exists an $\hat{\epsilon} > 0$ such that for all $\epsilon \in [0, \hat{\epsilon})$,

$$\epsilon'^T(\epsilon) P \epsilon'(\epsilon) + \phi'^T(\epsilon) \phi'(\epsilon) \leq \epsilon''^T(\epsilon) P \epsilon''(\epsilon) + \phi''^T(\epsilon) \phi''(\epsilon). \quad (2.25)$$

Proof (Theorem 3) See the Appendix.

Comments 1) Theorem 3 is the main result of this paper. It shows that initially the proposed identifier (2.17)–(2.18) results in smaller state and parameter errors than the standard identifier (2.3)–(2.4). In [3], the authors present simulation results to verify the improvement in the overall robustness characteristics of their proposed identifiers; they do not prove that their identifiers result in smaller parameter errors.

2) Theorem 3 does not make any assertions comparing the magnitude of the parameter errors between the two identifiers. Using the same steps in the proof of Theorem 3 for the least squares type identification algorithm in [3, eq. (2.18)], one can show that

there exists an $\hat{\epsilon} > 0$ such that for all $\epsilon \in [0, \hat{\epsilon})$,

$$\phi'^T(\epsilon) \phi'(\epsilon) \leq \phi''^T(\epsilon) \phi''(\epsilon). \quad (2.26)$$

Whether (2.26) remains valid for the identifier (2.17)–(2.18) remains an open question.

3) In general the largest value of ϵ , for which (2.25) holds, depends on the choice of the penalty function $\hat{P}(\cdot)$, the exogenous input vector u , and the dynamics of the system.

4) At the present time, there are no systematic procedures for selecting the values of λ_i in (2.15). Intuitively, the choice of the λ_i reflects a tradeoff between the weighted norm of the identifier's state-parameter error vectors and the deviation of the parameter estimates from the parameter constraint set.

III SIMULATION

To compare the transient performance of the proposed identifier (2.17)–(2.18) with that of the standard identifier (2.3)–(2.4), we ran simulations using the nonlinear differential equation (2.10) representing the longitudinal dynamics of a vehicle.

The standard identifier for (2.11) is

$$\frac{d}{dt} \dot{x}'' = -\sigma_x (\ddot{x}'' - \ddot{x}) + w^T(\dot{x}, \ddot{x}, u) \theta'' \quad (3.1)$$

$$\frac{d}{dt} \theta'' = -\sigma_\theta w(\dot{x}, \ddot{x}, u) (\dot{x}'' - \dot{x}) \quad (3.2)$$

where $\dot{x}''(0) = \dot{x}_0$, $\theta''(0) = \theta_0$, $\ddot{x}'' \in R$, $\theta'' \in R^1$, $\sigma_x > 0$, and $\sigma_\theta > 0$.

Using the penalty term $P(\cdot)$ in (2.16), the proposed identifier for (2.11) is

$$\frac{d}{dt} \dot{x}' = -\sigma_x (\dot{x}' - \dot{x}) + w^T(\dot{x}, \ddot{x}, u) [\hat{\theta}' + D \hat{P}(\theta')] \quad (3.3)$$

$$\frac{d}{dt} \theta' = -\sigma_\theta w(\dot{x}, \ddot{x}, u) (\dot{x}' - \dot{x}) \quad (3.4)$$

where $\dot{x}'(0) = \dot{x}_0$, $\theta'(0) = \hat{\theta}_0$, $\dot{x}' \in R$, and $\theta' \in R^1$.

Vehicle Parameters In all the simulations conducted, the vehicle parameters were as follows: $m = 1136$ kg, $d_m = 150.74$ N, $K_d = 0.396$ kg/m, and $\tau = 0.18$ s.

Identifier Parameters We chose $\sigma_x = 1$ and $\sigma_\theta = 2$. For the proposed identifier (3.3)–(3.4), $\lambda_1 = 2$ was used for the penalty term $P(\theta)$ in (2.16). The initial state and parameter estimates were $\dot{x}_0 = 1$, $\hat{\theta}_0 = [0.44, 5, 2.2]^T$, respectively.

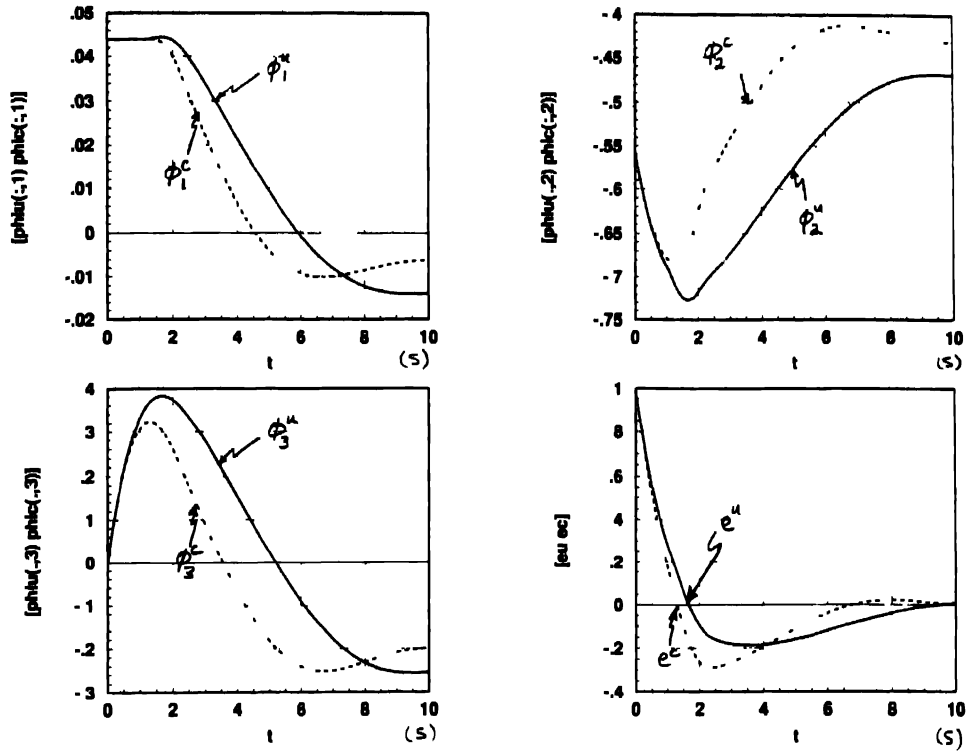

Fig. 1 $\phi_i(t)$, $\hat{\phi}_i(t)$ ($i = 1, 2, 3$), $e(t)$ and $\hat{e}(t)$ versus t

Simulation Setup Initially the vehicle was traveling at a constant speed of 17.9 m/s (i.e. $v(0) = 17.9$ m/s, $\dot{v}(0) = 0$ m/s², $\ddot{v}(0) = 0$ m/s³). Starting at time $t = 1$ s, the throttle command input increased linearly from its initial steady state value of 381 N at a rate of 1136 N/s until it reached its final value of 1517 N at $t = 2$ s.

Simulation Results Fig. 1 shows the state and the parameter errors for the standard identifier (3.1)–(3.2) and the proposed identifier (3.3)–(3.4). Note that the magnitude of the parameter errors using the proposed identifier (3.3)–(3.4) are smaller than the corresponding errors using the standard identifier (3.1)–(3.2) for a length of time after $t = 0$ s. Also note that in either case the parameter errors do not converge to zero.

Fig. 2 shows the weighted norm of the state parameter error vectors for the standard identifier (3.1)–(3.2) (i.e. $t \mapsto \sqrt{\epsilon'(t)\epsilon(t) + \phi'(t)\phi(t)}$) and the proposed identifier (3.3)–(3.4) (i.e. $t \mapsto \sqrt{\epsilon(t)\epsilon(t) + \phi(t)\phi(t)}$). Note that for all $t \in [0, 10]$, $\sqrt{\epsilon(t)\epsilon(t) + \phi(t)\phi(t)} \leq \sqrt{\epsilon'(t)\epsilon(t) + \phi'(t)\phi(t)}$.

These simulation results show that the proposed identifier (3.3)–(3.4) has better transient performance than the standard one (3.1)–(3.2). Thus, we expect that using the parameter estimates from the identifier (3.3)–(3.4) together with a certainty-equivalence control law will result in superior closed-loop adaptive-control performance of a vehicle's longitudinal dynamics. Simulations of indirect adaptive control laws for a platoon of vehicles support this conclusion.

IV. CONCLUSION

We have proposed a family of observer-based identifiers for a class of nonlinear dynamical systems which use the a priori known parameter dependencies. Under mild assumptions on the dynamical system, we have shown that 1) the proposed identifiers are stable (see Theorem 2), and 2) the weighted norm of state-parameter errors using the new identifier are less than the corresponding errors using the standard identifier, for a length of time after $t = 0$ (see Theorem 3).

There remain a number of open questions:

1) How can we select the coefficients λ_i for $i = \lambda + 1, \dots, p$ in the definition of the penalty function $P(\cdot)$ (see (2.15)) so as to attain the 'best' transient performance?

2) Is the proposed identifier more robust with respect to parameter variations and exogenous measurement noise?

3) Can we design stable identifiers which have the least number of states (e.g. the update law only updates the basic parameters; other parameter estimates are then computed using estimates of the basic parameters)?

We believe that satisfactory answers to the above questions will lead to systematic strategies for designing robust nonlinear adaptive control laws.

APPENDIX

Proof of Theorem 2

Consider the following Lyapunov function candidate

$$V(\epsilon, \phi) = \frac{1}{2}\epsilon^T P \epsilon + \frac{1}{2}\phi^T \phi + P(\phi + \theta^*) \quad (5.1)$$

Differentiating both sides of (5.1) with respect to time, and using (2.2), we get

$$\dot{V}(\epsilon(t), \phi(t)) = -\frac{1}{2}\epsilon^T(t)Q\epsilon(t) \leq 0 \quad (5.2)$$

Hence, by the standard reasoning, $\epsilon \in L_\infty$ and $\phi \in L_\infty$. Since V is bounded (i.e., Assumption 1), $DP(\cdot)$ is bounded ($DP(\cdot)$ is continuous and $\theta = \phi + \theta^* \in L_\infty$), $\epsilon \in L_\infty$ and $\phi \in L_\infty$, we get $\epsilon \in L_\infty$.

Integrating both sides of (5.2) from zero to t and noting that $Q = Q^T \geq \lambda_1^Q I_{n \times n} > 0$ (λ_1^Q is the smallest eigenvalue of Q), we get

$$V(\epsilon'(t), \phi(t)) - V(\epsilon(0), \phi(0)) \leq -\frac{1}{2}\lambda_1^Q \int_0^t \epsilon^T(\tau)\epsilon(\tau) d\tau \quad (5.3)$$

Dividing both sides of (5.3) by $-\frac{1}{2}\lambda_1^Q$, we get $\epsilon \in L_2$. \square

Fig. 2 $V(u(t), v(t)) - V(u(t), v'(t))$ versus t

Proof of Theorem 3

Consider the Lyapunov function candidates (2.9) and (5.1) for the error dynamics (2.3), (2.4) and (2.17), (2.18) respectively. Since the initial parameter estimate θ_0 lies on the parameter constraint set (2.14) (i.e., $P(\theta_0) = 0$) and both identifiers have the same initial conditions from (2.9) and (5.1) we get

$$V(u(t), v(t)) = V(u(t), v'(t)) \quad (5.4)$$

Differentiating both sides of (2.9) with respect to time we get

$$V_{(2.17)(2.18)}(u(t), v(t)) = -\frac{1}{2} \epsilon^{-1}(t) Q \epsilon(t) \quad (5.5)$$

Thus from (5.2), (5.5) and given $\epsilon(0) = \epsilon'(0)$ we get

$$V_{(2.17)(2.18)}(u(0), v(0)) = V_{(2.17)(2.18)}(u(0), v'(0)) \quad (5.6)$$

Since $\epsilon(0) = \epsilon'(0)$, $\epsilon(0) = \epsilon'(0)$, $DP(\epsilon(0) + \theta^*) = 0$

$$\epsilon(0) = \epsilon'(0) \quad (5.7)$$

Differentiating both sides of (5.5) and (5.2) with respect to time (5.7) and given $\epsilon(0) = \epsilon'(0)$ we get

$$V_{(2.17)(2.18)}(u(0), v(0)) = V_{(2.17)(2.18)}(u(0), v'(0)) \quad (5.8)$$

Writing the Taylor expansion of $V(u(\epsilon), v(\epsilon)) - V(u(\epsilon'), v(\epsilon'))$ about $t = 0$ and noting (5.4), (5.6) and (5.8) we get

$$V(u(\epsilon), v(\epsilon)) - V(u(\epsilon'), v(\epsilon')) = O(\epsilon^4) \quad (5.9)$$

where $\epsilon \mapsto O(\epsilon^4)$ denotes a function such that $\lim_{\epsilon \rightarrow 0} |O(\epsilon^4)/\epsilon^4| < \infty$

For $i = N+1, \dots, p$ let

$$q_i(t) = \theta_i(t) - \mu_i(\theta_1(t), \dots, \theta_N(t)) \quad (5.10)$$

Since $\theta(0)$ lies on the parameter constraint set (2.14), for $i = N+1, \dots, p$ we have

$$q_i(0) = 0 \quad (5.11)$$

Since $\epsilon(0) = \epsilon'(0)$, $\epsilon(0) = \epsilon'(0)$ (for $i = N+1, \dots, p$)

$$q_i(0) = \frac{d}{dt} [\theta_i(0) - \mu_i(\theta_1(0), \dots, \theta_N(0))] \quad (5.12)$$

Successively differentiating both sides of (2.15) with respect to time along the solution trajectories of (2.17), (2.18) we get

$$P_{(2.17)(2.18)}(\theta) = \sum_{j=N+1}^i \lambda_j q_j \quad (5.13)$$

$$P_{(2.17)(2.18)}(\theta) = \sum_{j=N+1}^i \lambda_j (q_j + q_j q_j) \quad (5.14)$$

Hence from (5.11), (2.15), (5.13) and (5.14) we get

$$P(\theta(0)) = 0 \quad (5.15)$$

$$P_{(2.17)(2.18)}(\theta(0)) = 0 \quad (5.16)$$

$$P_{(2.17)(2.18)}(\theta(0)) = \sum_{j=N+1}^i \lambda_j q_j(0) \quad (5.17)$$

From (5.12) and Assumption 3 (deviation from constraint set) we note that for some $j \in \{N+1, \dots, p\}$, $q_j(0) \neq 0$. Hence from (5.17) we note that

$$P_{(2.17)(2.18)}(\theta(0)) \geq \lambda_j q_j^*(0) > 0 \quad (5.18)$$

Writing the Taylor expansion of $P(\theta(\epsilon))$ about $t = 0$ and noting (5.15) and (5.16), we get

$$P(\theta(\epsilon)) = \frac{\epsilon^2}{2} P_{(2.17)(2.18)}(\theta(0)) + O(\epsilon^4) \quad (5.19)$$

From the definition of V' in (5.1) and V'' in (2.9) we note that

$$V(u(\epsilon), v(\epsilon)) - V(u(\epsilon'), v(\epsilon')) = V''(u(\epsilon), v(\epsilon)) + P(\epsilon(\epsilon) + \theta^*) \quad (5.20)$$

Substituting the expression for $V^c(e^c(\epsilon), \phi^c(\epsilon))$ from (5.20) into (5.9), we get

$$V^u(e^c(\epsilon), \phi^c(\epsilon)) + \tilde{P}(\hat{\theta}^c(\epsilon)) - V^u(e^u(\epsilon), \phi^u(\epsilon)) = O(\epsilon^3). \quad (5.21)$$

Substituting the expression for $\tilde{P}(\hat{\theta}^c(\epsilon))$ from (5.19) into (5.21), after algebraic manipulations, we get

$$\begin{aligned} V^u(e^c(\epsilon), \phi^c(\epsilon)) - V^u(e^u(\epsilon), \phi^u(\epsilon)) \\ = -\frac{\epsilon^2}{2} \ddot{P}_{(2,17)(2,18)}(\hat{\theta}^c(0)) + O(\epsilon^3). \end{aligned} \quad (5.22)$$

From (5.18) and (5.22) we get

$$\begin{aligned} V^u(e^c(\epsilon), \phi^c(\epsilon)) - V^u(e^u(\epsilon), \phi^u(\epsilon)) \\ \leq -\frac{\epsilon^2}{2} \lambda_j \dot{q}_j^2(0) + O(\epsilon^3). \end{aligned} \quad (5.23)$$

By definition, $\lim_{\epsilon \rightarrow 0} |O(\epsilon^3)/\epsilon^3| < \infty$; hence, there exists an $\bar{\epsilon} > 0$ such that for all $\epsilon \in [0, \bar{\epsilon}]$, the right hand side of (5.23) is negative, i.e.,

$$-\frac{\epsilon^2}{2} \lambda_j \dot{q}_j^2(0) + O(\epsilon^3) \leq 0. \quad (5.24)$$

Thus, from (5.23) and (5.24) we get, for all $\epsilon \in [0, \bar{\epsilon}]$,

$$V^u(e^c(\epsilon), \phi^c(\epsilon)) - V^u(e^u(\epsilon), \phi^u(\epsilon)) \leq 0. \quad (5.25)$$

Noting the definition of V^u in (2.9), from (5.25) we get, for all $\epsilon \in [0, \bar{\epsilon}]$,

$$e^{cT}(\epsilon) P e^c(\epsilon) + \phi^{cT}(\epsilon) \phi^c(\epsilon) \leq e^{uT}(\epsilon) P e^u(\epsilon) + \phi^{uT}(\epsilon) \phi^u(\epsilon). \quad (5.26)$$

Computation of Approximate Null Vectors of Sylvester and Lyapunov Operators

Ali R. Ghavimi and Alan J. Laub

Abstract—This paper describes an effective algorithm for computing approximate null vectors of certain matrix operators associated with Sylvester or Lyapunov equations. The singular value decomposition and rank-revealing QR methods are two widely used stable algorithms for numerical determination of the rank and nullity of a matrix A . These methods, however, are not readily applicable to Sylvester and Lyapunov operators since they require on the order of n^6 arithmetic operations on order n^2 data. For these problems, a variant of inverse power iteration is employed to compute orthonormal bases for singular subspaces associated with the small singular values. The method is practical since it relies only on the ability to solve a Sylvester or Lyapunov equation. Certain practical aspects are considered, and a direct refinement technique is proposed to enhance the convergence of the algorithm.

I. INTRODUCTION

The purpose of this paper is to describe an algorithm for computing approximate numerical null vectors of a matrix operator associated with the Sylvester equation $AX + XB = C$ or the symmetric Lyapunov equation $A^T X + X A^T = -Q = -Q^T$, where $X \in \mathbb{R}^{n \times m}$, $Y = Y^T \in \mathbb{R}^{n \times n}$, and the coefficient matrices are compatibly dimensioned. These equations arise in many applications in applied mathematics and control theory. For example, the solution of linear elliptic boundary value problems on rectangular domains can be written in the form of a Sylvester equation [22], [27]. The Sylvester equation also arises in connection with multi-input pole assignment problems [6], [16] and the design of reduced-order observers that achieve precise loop transfer recovery [3], [26]. The Sylvester equation also plays an essential role in many eigenproblems. Examples of such algorithms that require solution of a related Sylvester equation include invariant subspace problems, block diagonalization of a matrix [10], reordering the eigenvalues of a quasi-triangular matrix [1], and computing real square roots of a real matrix [13]. Important applications of the Lyapunov equation include stability analysis of linear systems [18], [19], model reduction

[5], [14], [21], and determination of covariance matrices in filtering and estimation.

In floating-point arithmetic with finite precision, it is quite possible that these equations are nearly singular. Equivalently, some of the small singular values of the matrix operator

$$S = I_m \otimes A + B^T \otimes I_n \in \mathbb{R}^{m \times m} \quad (1)$$

for the Sylvester equation, or

$$L = I_n \otimes A + A \otimes I_n \in \mathbb{R}^{n^2 \times n^2} \quad (2)$$

for the Lyapunov equation, are of the order of the relative machine precision (here \otimes denotes the Kronecker product [12]). In this situation, computed solutions of the matrix equations using general-purpose algorithms are usually of large norm and generally inaccurate.

Examples of ill-conditioned Sylvester and Lyapunov equations can be found in a variety of problems in control theory, especially in connection with the control of large-scale dynamical systems and problems subject to H_∞ constraints. For example, consider the deterministic optimal control problem whose quadratic performance index is of the form

$$\min_u \int_0^\infty [x^T(t)Gx(t) + u^T(t)Ru(t)]dt$$

subject to $\dot{x}(t) = Ax(t) + Bu(t)$ with $x(0) = x_0$, where $R = R^T > 0$ and $G = G^T \geq 0$ are symmetric matrices, B is an $n \times m$ input matrix, and $u(t)$ is the control law. Under the usual stabilizability and detectability assumptions for (A, B) and (A, G) , respectively, the optimal feedback control for this cost function is given by $u_{\text{opt}}(t) = -R^{-1}B^T Px(t)$ and the associated minimum cost is $J_{\text{min}} = x_0^T Px_0$, where P is the unique symmetric nonnegative definite stabilizing solution of the algebraic Riccati equation

$$PA + A^T P - PBR^{-1}B^T P + G = 0. \quad (3)$$

A reliable algorithm [20] for solving (3) involves a Schur decomposition of the related Hamiltonian matrix

$$\begin{bmatrix} A & -BR^{-1}B^T \\ -G & -A^T \end{bmatrix} = QSQ^T; \quad S = \begin{bmatrix} S_{11} & S_{12} \\ 0 & S_{22} \end{bmatrix}$$

where Q is orthogonal and S is quasi-upper triangular. The eigenvalues of S are ordered via additional orthogonal similarities if necessary so that S_{11} and S_{22} are quasi-upper triangular and S_{11} contains the stable eigenvalues. Reordering of a Schur form requires solutions of certain Sylvester equations where the coefficient matrices are related to the diagonal blocks of S . For the sake of illustration, let

$$\hat{A} = \begin{bmatrix} \hat{A}_{11} & \hat{A}_{12} \\ 0 & \hat{A}_{22} \end{bmatrix}$$

where $\hat{A}_{11} \in \mathbb{R}^{p \times p}$ and $\hat{A}_{22} \in \mathbb{R}^{q \times q}$, with $p, q = 1$, or 2 . The problem is to find an orthogonal matrix $N \in \mathbb{R}^{(p+q) \times (p+q)}$ such that

$$\hat{A} = \begin{bmatrix} \hat{A}_{22} & \hat{A}_{12} \\ 0 & \hat{A}_{11} \end{bmatrix} = N^T \hat{A} N$$

and \hat{A}_{11} and \hat{A}_{22} have the same eigenvalues. In other words, \hat{A} is similar to \hat{A} and the eigenvalues of the $(1, 1)$ and $(2, 2)$ subblocks have been interchanged. It can be shown that N is obtained from the QR factorization

$$\begin{bmatrix} -X \\ I_q \end{bmatrix} = N \begin{bmatrix} U \\ 0 \end{bmatrix}$$

where $X \in \mathbb{R}^{p \times q}$ solves the Sylvester equation $\hat{A}_{11}X - X\hat{A}_{22} = \hat{A}_{12}$. This Sylvester equation can be nearly singular for a number of reasons. A case of particular interest is when \hat{A}_{11} and \hat{A}_{22} contain

eigenvalues that are reflections of each other with respect to the imaginary axis and are close to the imaginary axis. That is, if $\alpha \pm \beta j$ are the eigenvalues of \hat{A}_{11} , then $-\alpha \pm \beta j$ are the eigenvalues of \hat{A}_{22} and $0 < \alpha \ll 1$. In this case, the associated Sylvester equation is ill conditioned, N can be computed only approximately, and the zero block in \hat{A} is actually nonzero. As a result, the computed solution of (3) may not have sufficient accuracy and, consequently, may induce instability in the computed closed-loop matrix.

Computed solutions of (3) may be refined via Newton's method [17]. This involves rewriting (3) as $P(A - FP) + (A - FP)^T P = -G - PFP$, where $F = BR^{-1}B^T$, and suggests the iteration

$$P_{k+1}(A - FP_k) + (A - FP_k)^T P_{k+1} = -G - P_k F P_k \quad (4)$$

which can be shown to be equivalent to Newton's method for solving (3). It can further be shown that if $A - FP_0$ is stable, the sequence generated by this iteration ensures the stability of the "closed-loop" matrices $A - FP_k$ at each step and $\lim_{k \rightarrow \infty} P_k = P$. Potential difficulty may arise, however, when the Lyapunov equations in (4) are ill conditioned. This occurs if, for example, $A - FP_k$ has an eigenvalue very close to the imaginary axis. In this case, the procedure can give inaccurate solutions which may cause the process to leave the region of convergence for Newton's method.

An alternative approach for solving ill-conditioned Sylvester and Lyapunov equations is to consider least-squares-type solutions. This then allows a computed solution to be expressed more accurately in terms of a part that is purged of the numerical or approximate null vectors (in a sense to be defined below) and a part that is spanned by the numerical null vectors. As in the case of linear systems, however, a knowledge of approximate null vectors is needed as a basic tool for any least-squares solver.

The numerical rank and nullity of a matrix are best understood in terms of its singular value decomposition (SVD). Many theorems and results in linear algebra depend explicitly or implicitly on knowing the rank of a matrix. Computational difficulties may arise, however, when working in finite precision. For example, a matrix that is known to be nonsingular may be nearly singular. It is therefore appropriate to define numerical ϵ -rank and ϵ -nullity for some small ϵ . In [8] and [10], these concepts are defined in terms of the SVD. Specifically, it is shown that the ϵ -nullity of a matrix is equal to the number of singular values that are less than a prespecified ϵ in magnitude. Moreover, the numerical null vectors are best characterized in terms of the associated singular vectors. In this respect, the remainder of the paper adopts this convention and we refer to ϵ -null vectors of a nearly singular matrix as the approximate or numerical null vectors of that matrix.

The organization of the paper is as follows. Section II describes a variant of the simultaneous iteration method for the dominant eigenvectors of a Hermitian matrix [23] to implement an algorithm for computing approximate null vectors of a matrix. A simple refinement technique is then proposed to enhance convergence. Section III specializes the method to nearly singular Sylvester and Lyapunov equations. Certain practical aspects also are considered to exploit efficiency. Section IV presents a numerical example to demonstrate further the effectiveness of the algorithm and concluding remarks are given in Section V.

II. SIMULTANEOUS INVERSE ITERATION METHOD

This section considers the subspace version of an inverse iteration algorithm for finding the smallest singular value of a matrix [28]. The method is analogous to the orthogonal iteration technique (a generalization of the power method) for finding a prescribed set of the dominant eigenvalues of a Hermitian matrix [23]. The differences can be resolved by first viewing the singular values of a matrix A in

ms of the eigenvalues of the Hermitian matrix $A^T A$, and secondly applying the orthogonal iteration to A^{-1} rather than A . Note that similar ideas can also be found in [15], [28] and other scattered work throughout the literature. An expository outline of the main ideas is presented here for the sake of completeness.

Suppose that $A \in \mathbb{R}^{n \times n}$ is nearly rank m -deficient. That is, A has small singular values that are of the order of the relative machine precision. Define an SVD of A by

$$A = U \Sigma V^T = [U_1 \quad U_2] \begin{bmatrix} \Sigma_{11} & 0 \\ 0 & \Sigma_{22} \end{bmatrix} [V_1 \quad V_2]^T \quad (5)$$

where $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_{n-m} \gg \sigma_{n-m+1} \geq \dots \geq \sigma_n > 0$ and the partitions are conformal. It then follows that the orthonormal columns of U_2 and V_2 are bases for the approximate left and right null vectors of A , respectively [10]. When the SVD of A is not available explicitly, the near-singular subspaces U_2 and V_2 can be approximated implicitly by U and V , respectively as follows.

Simultaneous Inverse Iteration Algorithm

- Choose $U_0 \in \mathbb{R}^{n \times m}$ with orthonormal columns (almost arbitrary)
- Loop until convergence
 - 1) Solve $U_{i+1} = U$
 - 2) $V_{i+1} = V_{i+1} T_{i+1}$ (QL factorization)
 - 3) Solve $U_{i+1}^T U_{i+1} = I$
 - 4) $U_{i+1} = U_{i+1} R_{i+1}$ (QL factorization)
- End loop
- $U \leftarrow$ converged U_{i+1} and $V \leftarrow$ converged V_{i+1}

The QL factorization in the above algorithm is a natural extension of the well known QR factorization. This decomposition is of the form $U = QI$ where $Q \in \mathbb{R}^{n \times m}$ has orthonormal columns and $I \in \mathbb{R}^{m \times m}$ is lower triangular. It is useful however to focus attention further on the unique choice of the QL factorization of $U \in \mathbb{R}^{n \times m}$ (or possibly square) by requiring $I \in \mathbb{R}^{m \times m}$ to be lower triangular with positive diagonal elements. The uniqueness of such a decomposition follows by similar analysis for the "skinny" QR factorization [10].

The convergence of the simultaneous inverse iteration algorithm parallels similar arguments for the convergence of the QR method in [28] or orthogonal iteration in [23]. A detailed convergence proof of the algorithm is also given in [9]. Several of the key points are summarized as follows. The above algorithm converges to a set of m singular vectors of A almost independent of the choice of U_0 . The convergence might be unstable however, in the sense that some of the converged singular vectors do not correspond to those associated with the small singular values. This happens when $\mathcal{R}(U_0)$ is orthogonal to at least one of the singular vectors in U_2 . In practice, this situation is somewhat unlikely to occur since rounding errors usually turn unstable convergence into a delayed stable one. In any case, a countermeasure should be taken to overcome this undesirable effect. It is easy to verify that the last column of U_{i+1} (i.e., Step 4 of the above loop) is most accurate in the sense that it has the most contributions from the singular vectors associated with the small singular values. On the other hand, the first column of U_{i+1} is the least accurate since it contains the components of singular vectors corresponding to singular values larger than σ_{n-m+1} . This suggests that the first column of U_{i+1} can be replaced by a random vector that is orthogonal to the last $m-1$ columns. This process can be terminated once the convergence of the first column vector is ascertained.

If the singular values satisfy the condition stated after (5), the columns of U_k and V_k converge to vectors that are linear combina-

tions of the left and right singular vectors, respectively. In the span of the same subspaces. Furthermore, when the small singular values are all distinct and well separated from each other, then the limiting values of U_k and V_k converge to the individual singular vectors denoted by the columns of U_2 and V_2 , respectively. The convergence rate in this case is quadratic with a ratio of $\max \left\{ \frac{\sigma_{n-m+1}}{\sigma_{n-m}}, \frac{\sigma_{n-m}}{\sigma_{n-m+1}} \right\}$ with $i > j$. Even if the small singular values are poorly separated, U_k and V_k converge to a linear span of the singular vectors in U_2 and V_2 at a rate of $(\sigma_{n-m+1}/\sigma_{n-m})^2$, a rapid convergence rate by assumption. Note that for singular values of nearly equal magnitude additional iterations for convergence to the individual singular vectors is generally slow and computationally not tractable. In other words, while the individual singular vectors associated with a set of clustered singular values are poorly determined, the singular subspaces spanned by them are well determined. Moreover, a direct refinement procedure may also be utilized to both enhance the convergence and reduce the computational cost.

The following refinement scheme is somewhat similar to a procedure used by Stewart for accelerating the convergence of the approximate dominant eigenvectors of a matrix via the orthogonal iteration method [23]. Similar techniques have also been used in connection with finding complex conjugate eigenvalues of a real matrix [28], diagonalization of a real symmetric matrix [10], and calculation of the dominant invariant subspace of a nonsymmetric matrix [2]. These methods are generally known as Ritz acceleration techniques.

Suppose that the orthonormal columns of U and V are approximations to the left and right singular vectors, respectively, corresponding to the set of small singular values of A whose SVD is given by (5). Define $P, Q \in \mathbb{R}^{n \times m}$ and $B \in \mathbb{R}^{m \times m}$ by

$$P = U^T U = \begin{bmatrix} U_1^T U \\ U_2^T U \end{bmatrix} = \begin{bmatrix} P_1 \\ P_2 \end{bmatrix}$$

and

$$Q = V^T V = \begin{bmatrix} V_1^T V \\ V_2^T V \end{bmatrix} = \begin{bmatrix} Q_1 \\ Q_2 \end{bmatrix} \quad (6)$$

$$B = U^T A V = U^T U \Sigma V^T V = P^T \Sigma Q = P_1^T \Sigma_{11} Q_1 + P_2^T \Sigma_{22} Q_2 \quad (7)$$

Moreover, denote the SVD of B by $B = M \Lambda \Lambda^T$ where M and Λ are orthogonal and $\Lambda = \text{diag}(\lambda_1, \lambda_2, \dots, \lambda_m)$ whose entries satisfy $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_m$. When $P_1 = Q_1 = 0$, P_2 and Q_2 are orthogonal. Thus $\Sigma_{22} = \Lambda$. Furthermore, if the singular values are distinct, then corresponding singular vectors can be recovered by choosing $M = P_2^T$ and $\Lambda = Q_2^T$ since $U M = U P M = U P_2 P_2^T = U_2$. Similarly, $V \Lambda = V$. The above suggests that when the column spaces of U and V are good approximations of the spans of the singular subspaces associated with the small singular values, P_1 and Q_1 are nearly zero, P_2 and Q_2 are nearly orthogonal and $\Sigma_{22} \approx \Lambda$. In addition, $U M$ and $V \Lambda$ are better approximations to U_2 and V_2 than U and V , respectively. The following states the algorithm in a formal manner.

A Refinement Method for Approximate Singular Vectors

- Start with U and V as approximations to U_2 and V_2 in (5) respectively
- Form $B = U^T A V$
- Compute the SVD of $B = M \Lambda \Lambda^T$
- $U \leftarrow U M$ and $V \leftarrow V \Lambda$

Details of the above procedure parallel similar results in [23] and has been examined closely in [9]. Thus, only certain highlights of the method are summarized here. Let $\Delta \Sigma = \Lambda - \Sigma_{22}$ denote the deviation of the refined singular values from the actual ones.

Then $|\Delta\Sigma| = |\Lambda - \Sigma_{22}| \leq \sigma_1 \|P_1\| \|Q_1\| + \sigma_{n-m+1} (\|P_1\|^2 + \|P_1\|^2 \|Q_1\|^2 + \|Q_1\|^2)$, where the absolute value of a matrix is in the componentwise sense. This bound implies that for small values of P_1 and Q_1 , the refined singular values are therefore good approximations of their actual values. As far as the accuracy of the refined singular vectors is concerned, it is seen that $U(V)$ and $UM(VN)$ span the same space. Therefore, the refined singular vectors are just as good approximations of the singular subspaces of interest as U and V are. Furthermore, UM and VN are better enhancements of the individual singular vectors than U and V , respectively. This can be seen from $(UM)^T A(VN) = M^T U^T A V N = M^T B N = \Lambda \approx \Sigma_{22}$, whereas $B = U^T A V$ is generally a dense matrix. Moreover, the refined singular vectors tend to converge at a faster rate than the original ones. This suggests that the refinement algorithm can be employed after a few steps of simultaneous iteration to further enhance the convergence rate of the iterates. The next section incorporates the above results to construct bases for the approximate null vectors of nearly singular Sylvester and Lyapunov equations.

III. INVERSE ITERATION FOR SYLVESTER AND LYAPUNOV EQUATIONS

This section extends the simultaneous inverse iteration method to compute orthonormal bases for approximate null spaces of matrix operators associated with nearly singular Sylvester and Lyapunov equations. The extension follows by viewing the Sylvester or Lyapunov equation as the linear system $Sx = c$ or $Ly = q$, respectively, where S and L are as specified in (1) and (2), and $x = \text{vec}(X)$, $c = \text{vec}(C)$, $y = \text{vec}(Y)$, and $q = \text{vec}(Q)$. Note that vec of an $m \times n$ matrix M is the mn -vector formed by successively stacking the n columns of M on top of each other. Since the Lyapunov equation is a special case of the Sylvester equation, the results are presented for the Sylvester equation. The method applies to the Lyapunov equation with only a slight and obvious modification.

Suppose that $A \in \mathbb{R}^{n \times n}$ and $B \in \mathbb{R}^{m \times m}$ are given and that the associated matrix operator S in (1) is nearly singular. Algorithms for deflated solutions of nearly singular linear systems are given in [7], [25]. Note, however, that while the extension of the simultaneous inverse iteration method to a nearly singular Sylvester equation seems natural, certain steps are crucial. Potential difficulties in using the method derive from the fact that numerical nullities are not known *a priori* and that the matrix S in (1) generally should not be formed explicitly. It is therefore logical to construct bases for the numerical null spaces one vector at a time. Successive formation of the approximate null vectors involves normalizations with respect to the Frobenius norm, and orthogonalizations with respect to the inner product $\langle w, z \rangle = w^T z = \text{tr}(W^T Z)$, where $w = \text{vec}(W)$ and $z = \text{vec}(Z)$.

Let the orthonormal columns of $P \in \mathbb{R}^{m \times n}$ and $Q \in \mathbb{R}^{n \times m}$ denote the left and right singular vectors of S , respectively, associated with the ν small singular values. The following algorithm constructs approximations to P and Q by U and V , respectively.

Simultaneous Inverse Iteration for Nearly Singular Sylvester Equations

- For nullity $\nu \geq 1$, choose $U_0 \in \mathbb{R}^{m \times \nu}$ with orthonormal columns.
- Loop until convergence
 - 1) Solve $S\tilde{V} = U_0$ for \tilde{V}
 - 2) $\tilde{V} = \tilde{V}T$ (QL factorization)
 - 3) Solve $S^T \tilde{U} = \tilde{V}$ for \tilde{U}
 - 4) $\tilde{U} = \tilde{U}R$ (QL factorization)
 - 5) $G = \tilde{U}^T S \tilde{V}$
 - 6) $G = M \Lambda N^T$ (SVD)

- 7) $U \leftarrow UM$ and $V \leftarrow VN$
- 8) If $\lambda_j > \text{tol}$, a user-specified tolerance, for $1 \leq j \leq \nu$,
 - a) $U \leftarrow U(:, j+1 : \nu)$ (truncate the first j columns)
 - b) $V \leftarrow V(:, j+1 : \nu)$ (truncate the first j columns)
 - c) $\nu = j$
 - d) Stop
 - Else
 - e) $\nu = \nu + 1$
 - f) $U_0 = [\tilde{U}^T U]$ such that $U_0^T U_0 = I_\nu$
 - g) Return to Innerstep 1).

The following provides certain key details of the actual implementation of the algorithm. As was mentioned above, the large structured matrix S is generally not available explicitly. Therefore, appropriate manipulations are necessary for operations involving S . Let x_k and y_k be the corresponding left and right singular vectors of S associated with the singular value σ_k . That is, $Sy_k = \sigma_k x_k$ and $S^T x_k = \sigma_k y_k$. It then follows that $A Y_k + Y_k B = \sigma_k X_k$ and $A^T X_k + X_k B^T = \sigma_k Y_k$, where $X_k = \text{unvec}(x_k) \in \mathbb{R}^{n \times m}$, $Y_k = \text{unvec}(y_k) \in \mathbb{R}^{m \times m}$, and $\text{unvec}(\cdot)$ is the operator that "undoes" the vec operator, i.e., forms a matrix from a column vector stack. Furthermore, Innerstep 1) is a linear system with multiple right-hand sides. The equation is of the form $SW = Z$, where $W = (w_1, \dots, w_\nu)$ and $Z = (z_1, \dots, z_\nu) \in \mathbb{R}^{m \times \nu}$. The k th column of W is found by solving $Sw_k = z_k$. This can be written as $A W_k + W_k B = Z_k$, where $W_k = \text{unvec}(w_k) \in \mathbb{R}^{n \times m}$ and $Z_k = \text{unvec}(z_k) \in \mathbb{R}^{m \times m}$. Thus, the columns of W are obtained by successively solving the associated Sylvester equations and setting $w_k = \text{vec}(W_k)$. Moreover, Innerstep 3) is also a linear system of the form $S^T W = Z$. Hence, W can be solved by rewriting the Sylvester equation of the above loop as $A^T W_k + W_k B^T = Z_k$. If the Bartels–Stewart algorithm [4] or the Hessenberg–Schur method [11] is used, these equations can be solved fairly inexpensively with the aid of previously computed factorizations of A and B . Innerstep 5) is of the form $G = (g_{ij}) = W^T S Z \in \mathbb{R}^{\nu \times \nu}$. Let e_i denote the k th elementary unit vector. Then the entries of G are given by

$$g_{ij} = e_i^T W^T S Z e_j = w_i^T S z_j = (\text{vec}(W_i))^T \text{vec}(AZ_j + Z_j B) \\ = \text{tr}(W_i^T (AZ_j + Z_j B)).$$

Innersteps 8a) and 8b) are MATLAB notations for overwriting U and V by deleting their first j columns. Innerstep 8c) indicates that the numerical rank of S is ν . Innerstep 8f) is realized by letting $w = z - U U^T z$, where $z \in \mathbb{R}^{m \times m}$ is a random vector. Then $\bar{w} = \frac{w}{\|w\|}$ and $\bar{U} = \text{unvec}(\bar{w})$.

IV. NUMERICAL RESULTS

The following example is presented to illustrate the effectiveness of the results. All of the computations were performed using MATLAB implemented on a Sparc 2 workstation. The relative machine precision reported by MATLAB is about 2.22×10^{-16} .

Let A and B be of the form $A = W \Lambda W^T$ and $B = Z \Gamma Z^T$, where $W \in \mathbb{R}^{n \times n}$ and $Z \in \mathbb{R}^{m \times m}$ are random orthogonal matrices. Moreover, $\Lambda = \text{diag}(n, n-1, \dots, 3, \alpha_2, \alpha_1)$ and $\Gamma = \text{diag}(m, m-1, \dots, 3, \beta_2, \beta_1)$, where $\alpha_1, \alpha_2, \beta_1$, and β_2 are between 3.0×10^{-14} and 1.0×10^{-15} . Note that W and Z in this example are formed via the QR factorization of random matrices. A thorough discussion of computing random orthogonal matrices can be found in [24]. Since W and Z are orthogonal, the eigenvalues of A and B are given by the diagonal entries of Λ and Γ , respectively. Furthermore, $S = M D M^T$ where $M = (Z^T W)$ is orthogonal and $D = I_m - \Lambda + \Gamma - I_n$ is diagonal. Hence, the eigenvalues of S are given by the sum of any two diagonal elements of Λ and Γ . Moreover, the singular

values of S are the absolute values of its eigenvalues, i.e., S is normal. This implies that S has four small singular values, namely, $(\alpha_1 + \beta_1)$, $(\alpha_1 + \beta_2)$, $(\alpha_2 + \beta_1)$, and $(\alpha_2 + \beta_2)$ for any $m, n \geq 3$. Thus the Sylvester equation $AX + XB = C$ is nearly singular. For the sake of illustration, the dimension m was kept constant at 10 while n was varied from 3 to 100 in increments of one, and vice versa. Approximate null vectors of S were found directly by computing an SVD of S and selecting the singular vectors associated with the small singular values. Next, the proposed inverse iteration algorithm was used to compute the singular subspaces of interest. In each case, only one or two iterations at most was necessary to achieve convergence. The results were compared numerically by measuring the angles between subspaces [10] obtained directly (via SVD) and those by the inverse iteration algorithm. It was observed that null vectors obtained by the two methods were essentially the same and were good approximations of each other. The computational advantage of the inverse iteration algorithm over the SVD method was apparent as the dimensions m and n increased. This results from the fact that the direct method requires the SVD of an $nm \times nm$ matrix, whereas the inverse iteration algorithm requires solving only a few $n \times m$ Sylvester equations. In terms of floating-point operations, the SVD method and the inverse iteration algorithm therefore require on the order of $\alpha m^3 n^3$ flops and $\beta(m^3 + n^3) + \gamma(m^2 n + mn^2)$, respectively, where α , β , and γ are some modest constants. For example, if $m = n = 10$, the number of flops needed by the SVD method is on the order of 10^6 compared to 10^3 for the inverse iteration algorithm. Even greater efficiencies can be realized when the computed factorizations of A and B in the first step are used in succeeding steps.

V. CONCLUDING REMARKS

An analysis has been given of computation of approximate numerical null vectors for matrix operators associated with Sylvester equations. The method is reliable, efficient, and requires nothing but the ability to solve linear matrix equations. Computational complexity can be reduced by saving computed decompositions of the coefficient matrices. The method becomes relatively more expensive, however, as the number of small singular values increases.

One advantage of the inverse iteration algorithm lies in its modularity. Note that the linear systems in the innersteps 1) and 3) of the algorithm are independent processes. This means that the method can be easily extended to the Lyapunov equation $AX + XA^T = Q$ or the discrete-time Sylvester equation $AXB + X = C$ and the discrete-time Lyapunov equation $AXA^T - X = Q$. In fact, it can be applied to any matrix equation that can be formulated as a standard linear system. Another important factor is that the choice of linear solvers is also an independent step in the algorithm. This is significant since specialized solvers can be employed in place of conventional ones when appropriate.

THE 34TH IEEE CONFERENCE ON DECISION AND CONTROL

New Orleans Hilton Riverside and Towers
New Orleans, Louisiana
December 13-15, 1995

The IEEE CSS Conference on Decision and Control (CDC) is the annual meeting of the IEEE Control Systems Society (CSS), conducted in cooperation with the Society for Industrial and Applied Mathematics (SIAM) and the Operations Research Society of America (ORSA). The thirty-fourth CDC will be held December 13-15, 1995, with tutorial workshops preceding the conference on Monday and Tuesday, December 11-12. The Conference General Chairman is Panos Antsaklis of the University of Notre Dame, and the Program Chairman is Edward Kamen of the Georgia Institute of Technology. The venue is the New Orleans Hilton Riverside and Towers, located on the Mississippi River immediately west of Canal Street. A short walk through a landscaped Riverwalk brings one to the French Quarter, scene of New Orleans nightlife and musical history.

CALL FOR CONTRIBUTED PAPERS AND INVITED SESSIONS

The IEEE CDC will include both contributed and invited sessions and a full Proceedings will be published. Contributed papers are hereby solicited in all aspects of the theory and applications of systems, including decision-making, control, adaptation, optimization, industrial automation, and manufacturing. Invited sessions are also solicited in new developments in these and related areas. All submissions are due 1 MARCH 1995.

CONTRIBUTED PAPERS:

The Program Committee is soliciting both regular and short contributed papers for presentation at the conference and publication in the Proceedings. All submissions must follow the guidelines below.

REGULAR PAPERS. Regular papers describe completed work in some detail. Authors should submit five (5) copies of the full paper for review to the Conference Publications Editor at the address below.

SHORT PAPERS. Short papers describe important recent or preliminary results which require limited length for their development. Authors should submit four (4) copies of a 4-6 page detailed summary, including references, for review to the Program Vice-Chair for Short Papers at the address below.

INVITED SESSIONS:

The Program Committee is soliciting proposals for invited sessions. Cohesive sessions focusing on new or emerging topics in the above-listed areas are particularly encouraged, and will have priority over those of a classical or mainstream flavor. Session organizers should submit four (4) copies of proposals for invited sessions for review to the Program Vice-Chair for Invited Sessions at the address below. Organizers should contact the Vice-Chair by 1 FEBRUARY 1995 stating their intent to submit a proposal.

Proposals for invited sessions should contain the names, affiliations, and complete mailing addresses of the session organizer(s), chairperson, co-chairperson, and all authors (with corresponding authors identified) along with a list of paper titles. The organizers must include in the proposal: (1) a clear statement of the topic and purpose of the session and (2) a description of how the papers form a cohesive, well-integrated exploration of the session topic. Detailed extended summaries, following the submission guidelines below and consisting of a minimum of 2000 words, covering all contributions of the paper in sufficient depth to permit an informed review, must be included for each paper. The initial paper may be a tutorial or survey which can be allotted twice the usual time for presentation. The usual number of papers in a session is six. Organizers will be contacted near 1 June 1995 concerning the tentative disposition of their session.

SUBMISSION GUIDELINES AND ACCEPTANCE INFORMATION

Each submitted regular paper, short paper extended summary, or invited session proposal must be headed with a title, the names, affiliations and complete mailing addresses of all authors (or organizers for invited sessions), a list of three keywords, and the statement "34th CDC". The first named author of each paper will be used for all correspondence unless otherwise requested, if possible an electronic mail address and fax number of the corresponding author should be included. Incomplete submissions or submissions by fax or electronic mail cannot be accepted.

Final selection of papers and invited sessions will be announced in mid-July 1995. Authors of all accepted papers will be provided with instructions for preparation of manuscripts for the Proceedings. Authors should limit their manuscripts to six Proceedings pages (approx. 6000 words) for regular papers or two Proceedings pages (approx. 2000 words) for short papers. There will be a mandatory page charge for each additional page. Authors of accepted papers are expected to attend the CDC to present their work.

ADDRESSES FOR SUBMISSIONS

Regular Papers:

Prof. M. Peshkin, 34th CDC
Editor, Conference Publications
Mechanical Engr. Dept.
Northwestern University
2145 Sheridan Road
Evanston, Ill 60208-3111
Tel: (708) 467-2666
Fax: (708) 491-3915
email: cdc@nwu.edu

Short Papers:

Prof. J. Jim Zhu, 34th CDC
VC for Short Papers
3221 CEBA Bldg.
Rem. Sens./Image Proc. Lab.
Louisiana State University
Baton Rouge, LA 70803
Tel: (504) 388-6826
email: zhu@sun-ra.rsp.lsu.edu

Invited Sessions:

Prof. W. J. Rugh, 34th CDC
VC for Invited Sessions
Elect. & Computer Engr. Dept.
Johns Hopkins University
Baltimore, MD 21218
Tel: (410) 516-7004
email: wjr@jhuunix.hcf.jhu.edu

General Information:

Panos J. Antsaklis, 34th CDC
General Chair
Dept. of Electrical Engineering
University of Notre Dame
Notre Dame, IN 46556
Tel: (219) 631-5792
Fax: (219) 631-4393
Panos.J.Antsaklis@nd.edu

SCHEDULE SUMMARY:

1 Feb. 1995	Deadline for statement of intent to submit invited session proposals
1 March 1995	Deadline for submission of contributed papers and invited session proposals
1 June 1995	Tentative notification of invited session organizers
Mid-July 1995	Notification regarding acceptance of papers and invited sessions
Early Aug. 1995	Instructions for manuscript preparation sent to authors
Mid-Sept. 1995	Camera-ready papers due at the printer

Observer Design for Nonlinear Systems with Discrete-Time Measurements, *Moraal and Grizzle*.

Observer Design for Nonlinear Systems has been a hot topic in nonlinear control theory since the early 1980's when Krener and Isidori published their seminal paper of linearization of nonlinear systems by output injection and the relevance of this concept to nonlinear observer design. Much effort has been devoted to finding a nonlinear analog of the now standard observer construction procedures in linear systems theory. Predominantly, the method of attack has been to try out some nonlinear generalizations of linear techniques. Even though there have been sporadic successes, these attempts have not led to a rich theory.

The work of Moraal and Grizzle is aimed at moving away from this approach and focussing more on techniques that have to do with inverting nonlinear maps. The notion of uniform γ observability essentially says that there are a fixed number of inputs and a system of equations the solution of which yields the initial state of the system uniquely. Now the problem of solving the equation can be approached as any numerical analyst would do by resorting to numerical map inversion techniques such as the Newton-Raphson method. A suitable generalization leads to a system which the authors call a Newton Observer. This procedure is described in great detail in the paper and mild conditions that guarantee convergence are given. It is shown that Newton Observers are closely related to Kalman filters. An example to illustrate the concept is given in the form of an application to a bioreactor system.

A Probabilistic Approach to Multivariable Robust Filtering and Open-Loop Control, *Ohlin Ahlen and Sternad*.

A new approach to robust filtering, prediction and smoothing of discrete time signal output of modeling errors is presented. A simple design based on the minimization of the squared estimation error averaged both with respect to model errors and noise is obtained. An optimal robust filter is calculated by means of an averaged spectral factorization and an unilateral diophantine equation.

The robust estimator is referred to as a cautious Wiener filter. It turns out to be only slightly more complicated to design than an ordinary Wiener filter. The methodology can be applied to any open loop filtering or control problem. This paper illustrates this for the design of robust multivariable feedforward regulators, decoupling, and model matching filters.

A New Model for Control of Systems with Friction, *anudas de Wit, Olsson Astrom, and Lischinsky*.

The modeling of friction is an important concern in the design of control systems for high quality servo mechanisms. Friction can lead to tracking errors, limit cycles and undesired stick-slip motion. A high gain control loop can sometimes be used to compensate for friction, but in other circumstances it is necessary to compensate for the effects of friction based on a suitable friction model. Friction models based in static maps, such as Coulomb and viscous friction, may not be satisfactory for applications such as high precision pointing or low velocity tracking. Dynamic friction models are

generally better for such applications and a number of such models have been developed. In this paper the authors introduce a new dynamic model for friction which is consistent with experimentally observed effects. The model properties relevant to control systems are investigated and discussed. The authors show that the model predicts the limit cycle behavior sometimes observed in servos with PID controls. They also use the model in the design of a friction observer to compensate for friction in position and velocity tracking control.

Adaptive Nonlinear Design with Controller-Identifier Separation and Swapping, *Krstic and Kokotovic*.

This paper introduces a modular approach to adaptive control design for a class of nonlinear systems in parametric-strict feedback form. By achieving a separation between the designs of the adaptive controller and the parameter identifier, it is shown that the stability properties of the certainty equivalence laws can be enhanced thereby enabling a wide variety of adaptive update laws to tune the control. The former is designed such that the states of the nonadaptive system are bounded if the parameter errors and their derivatives are bounded, the latter guarantees the boundedness of the parameter errors and their derivatives. A nonlinear version of the swapping lemma is used to facilitate the proofs.

Approximate Decoupling and Asymptotic Tracking for MIMO Systems, *Godbole and Sastry*.

This paper proposes an algorithm for approximate input-output decoupling of nonlinear MIMO systems where the standard decoupling algorithm produces poor results. The systems considered are regular, but are numerically ill posed in that application of the exact decoupling algorithm requires inversion of an ill conditioned matrix. The algorithm is numerically robust and also avoids pole-zero cancellations thus providing controllers with reasonable gain even when the system has far off zeros. The general algorithm here is motivated by the work of various authors on physical examples such as flight control, reaction kinetics, and electric motors.

A Generalized Orthonormal Basis for Linear Dynamical Systems, *Heuberger Van den Hof, and Bosgra*.

In many areas of signal, system, and control theory, orthogonal functions play an important role in analysis and design. In this paper, it is shown that there exist orthogonal functions that are generated by stable linear dynamical systems and that constitute an orthonormal basis for the signal space l_2 . The orthogonal functions can be considered as generalizations of, e.g., the pulse functions, Laguerre functions, and Kautz functions, and give rise to an alternative series expansion of rational transfer functions. It is shown how these generalized basis functions can be used to increase the speed of convergence in a series expansion, i.e., to obtain a good approximation by retaining only a finite number of expansion coefficients. Consequences for identification of expansion coefficients are analyzed, and a bound is formulated on the error that is made when approximating a system by a finite number of expansion coefficients.

H_∞ Control Via Measurement Feedback for General Nonlinear Systems, Isidori and Kang.

The H_∞ control problem is a well-motivated problem for a wide variety of engineering applications. The problem is very well studied for linear systems. A comprehensive and elegant solution is available for linear systems and is well documented in various recent papers. The generalization of these results to nonlinear systems is an

important problem. The authors provide a solution to the nonlinear version of the H_∞ control problem with measurement feedback (i.e., the partial observations case), by investigating solutions of Hamilton-Jacobi inequalities. In their analysis, the authors follow the lines of the H_∞ optimal control results for linear systems. A certainty equivalence argument is applied to treat a nonlinear version of the H_∞ control problem with imperfect observations. The results of this paper extend a number of recent achievements in this area.

Observer Design for Nonlinear Systems with Discrete-Time Measurements

P. E. Moraal and J. W. Grizzle, *Senior Member, IEEE*

Abstract—This paper focuses on the development of asymptotic observers for nonlinear discrete-time systems. It is argued that instead of trying to imitate the linear observer theory, the problem of constructing a nonlinear observer can be more fruitfully studied in the context of solving simultaneous nonlinear equations. In particular, it is shown that the discrete Newton method, properly interpreted, yields an asymptotic observer for a large class of discrete-time systems, while the continuous Newton method may be employed to obtain a global observer. Furthermore, it is analyzed how the use of Broyden's method in the observer structure affects the observer's performance and its computational complexity. An example illustrates some aspects of the proposed methods; moreover, it serves to show that these methods apply equally well to discrete-time systems and to continuous-time systems with sampled outputs.

I. INTRODUCTION

A. General

THE need to study state estimators (observers) for dynamical systems is, from a control point of view, well understood by now. For the class of finite-dimensional, time-invariant linear systems, a solution to the observer problem has been known since the mid 1960's: the observer incorporates a copy of the system and uses output injection to achieve an exponentially decaying error dynamics. For the class of continuous-time nonlinear systems, the reader is referred to [38], [39] and the references therein for a summary of the theory up to 1986. More recent developments include the work of Krener *et al.* [23] on higher-order approximations for achieving a linearizable error dynamics. Tsinias in [37] has proposed (nonconstructive) existence theorems on nonlinear observers via Lyapunov techniques. Gauthier *et al.* [12] and Deza *et al.* [9] show how to construct high-gain, extended Luenberger- and Kalman-type observers for a class of nonlinear continuous-time systems. Tomambè [36] and Nicosia *et al.* [31] have proposed a continuous-time version of Newton's algorithm as a method for computing the inverse kinematics of robots; moreover, the latter paper also presents a symbiotic relationship in general between asymptotic observers and

nonlinear map inversion. Finally, Michalska and Mayne [27] have used a dual form of moving horizon control to construct observers for nonlinear systems.

Less attention has been focused on the observer problem for discrete-time systems. It was shown in [6] that certain properties, like observer error linearizability [22], are not inherited from the underlying continuous-time system. Moreover, the class of continuous-time systems that admit approximate solutions to the observer error linearization problem for their exact discretizations with sampling time T in an open interval is limited to the class of nonlinear systems that are approximately state-equivalent to a linear system and hence is very restricted [5]. These results motivated the search for a structurally more robust approach to the observer problem. In Section II, it is argued that instead of trying to imitate the linear observer theory, the nonlinear observer problem should be studied in the context of solving sets of simultaneous nonlinear equations. This viewpoint is supported by showing in Section III that the discrete Newton method, properly interpreted, yields an asymptotic observer for a large class of discrete-time systems. In Section IV, a relationship between this observer and the well-known extended Kalman filter is established. As an extension to the result from Section III, it is shown in Section V, that the continuous Newton method may be used to obtain a global exponential observer. Section VI addresses an alternative to using Newton's method in the observer design—namely, Broyden's method—in the case that computational efficiency is an important issue. Finally, an example will illustrate the theory presented herein.

Some of the results reported here have previously appeared in [16], [17], and [28]. Extensions to the case of singularly perturbed discrete-time systems have been presented by Shouse and Taylor [33].

B. Notation and Terminology

Consider a continuous-time system

$$\Sigma_c: \begin{aligned} \dot{x} &= f(x, u) \\ y &= h(x, u) \end{aligned} \quad (1)$$

where $x \in \mathbb{R}^n$, $u \in \mathbb{R}^m$, and $y \in \mathbb{R}^p$. Its sampled-data representation, obtained by holding the input constant over half open intervals $[kT, (k+1)T]$ and measuring the output at times kT , will be denoted

$$\Sigma(T): \begin{aligned} x_{k+1} &= F_T(x_k, u_k) \\ y_k &= h(x_k, u_k) \end{aligned} \quad (2)$$

Manuscript received April 23, 1993; revised May 15, 1994. Recommended by Associate Editor, W. P. Dayawansa. This work was supported in part by National Science Foundation Contract NSF ECS-88-96136.

IEEE Log Number 9408270.

where $x_k := x(kT)$, $y_k := y(kT)$, and $u_k := u(kT)$. The symbol " $:=$ " means that the object on the left is defined to be equal to the object on the right; the reverse holds for " $=$."

It is worth noting that if (A, B, C, D) are the matrices describing the Jacobian linearization of (1) around a given equilibrium point, then $(\exp(AT), \int_0^T \exp(A\tau) B d\tau, C, D)$ are the corresponding matrices for (2) about the same equilibrium point [14]. Consequently, if the linearization of (1) is controllable and/or observable, the same will be true of the linearization of (2) for "almost all" T [35].

A discrete-time system will be denoted as

$$\Sigma: \begin{aligned} x_{k+1} &= F(x_k, u_k) \\ y_k &= h(x_k, u_k) \end{aligned} \quad (3)$$

where $x \in \mathbb{R}^n$, $u \in \mathbb{R}^m$, and $y \in \mathbb{R}^p$. It is convenient to let $F^u(x) := F(x, u)$ and $h^u(x) := h(x, u)$ so that things like $F(F(x, u_1), u_2)$ and $h(F(x, u_1), u_2)$ can be written as $F^{u_2} \circ F^{u_1}(x)$ and $h^{u_2} \circ F^{u_1}(x)$ respectively, where " \circ " denotes composition.

In the sequel, we will often be dealing with a set of N consecutive measurements or controls; these will be denoted as

$$Y_{[k-N+1, k]} := \begin{bmatrix} y_{k-N+1} \\ \vdots \\ y_k \end{bmatrix}, \quad U_{[k-N+1, k]} := \begin{bmatrix} u_{k-N+1} \\ \vdots \\ u_k \end{bmatrix}. \quad (4)$$

If N is fixed and clearly understood, then the abbreviations Y_k and U_k will be employed, so that certain formulas will be easier to read.

To a discrete-time system Σ , we associate an N -lifted system (see [11]), Σ^N , by block processing the measurements and controls over a window of N sampling instances. Specifically, fix N and let $\tilde{Y}_j := Y_{Nj} = Y_{[N(j-1)+1, Nj]}$, $\tilde{U}_j := U_{Nj} = U_{[N(j-1)+1, Nj]}$, and $\tilde{x}_j := x_{Nj}$. Write out \tilde{U}_j in terms of its vector components as $\tilde{U}_j = \text{col}(\tilde{u}_j^1, \dots, \tilde{u}_j^N)$ where $\tilde{u}_j^i := u_{N(j-1)+i}$. Let

$$\Phi(\tilde{x}, \tilde{U}) := F^{\tilde{u}^N} \circ \dots \circ F^{\tilde{u}^1}(\tilde{x}) \quad (5)$$

and

$$H(\tilde{x}, \tilde{U}) = \begin{bmatrix} h^{\tilde{u}^1}(\tilde{x}) \\ \vdots \\ h^{\tilde{u}^N} \circ F^{\tilde{u}^{N-1}} \circ \dots \circ F^{\tilde{u}^1}(\tilde{x}) \end{bmatrix}. \quad (6)$$

The N -lifted system is defined to be

$$\begin{aligned} \tilde{x}_{j+1} &= \Phi(\tilde{x}_j, \tilde{U}_j) \\ \Sigma^N: \quad \tilde{Y}_j &= H(\tilde{x}_j, \tilde{U}_j) \end{aligned} \quad (7)$$

Note that its dynamics is nothing more than the dynamics of (3) iterated N -times. The state of (7) is the state of (3) at the beginning of each "window" of length N , and Φ simply describes how the state evolves from window to window. The representation (7) can be termed "multirate" because, if (3)

arises from a continuous-time system (1), (7) can be obtained directly from (1) by sampling the inputs and outputs N -times faster than the state; in other words, $\tilde{x}_j := x(jNT)$, $\tilde{u}_j^i = u((j-1)NT + iT)$, etc. More generally, one could sample the inputs and outputs at different rates, or even some input components at faster rates than others, but we will not pursue this here. Throughout this paper, the notation $\|\cdot\|$ will be used to denote both a vector norm and the corresponding induced operator norm. Finally, we recall that if $g: \mathbb{R}^{r_1} \rightarrow \mathbb{R}^{r_2}$ is at least once continuously differentiable, its rank at a point $x_0 \in \mathbb{R}^{r_1}$ is the rank of its Jacobian matrix at x_0 , [4] that is, $\text{rank} [\frac{\partial g}{\partial x}(x_0)]$.

II. OBSERVERS FOR SMOOTH DISCRETE-TIME NONLINEAR SYSTEMS

A. General

Consider a discrete-time system on \mathbb{R}^n

$$\Sigma: \begin{aligned} x_{k+1} &= F(x_k, u_k) \\ y_k &= h(x_k, u_k) \end{aligned} \quad (8)$$

A second system

$$\begin{aligned} z_{k+1} &= \Gamma(z_k, y_k, u_k) \\ \hat{x}_k &= \eta(z_k, y_k, u_k) \end{aligned} \quad (9)$$

with $z_k \in \mathbb{R}^l$, some $l \geq 0$, is an asymptotic observer [25] for (8) if it satisfies: A) $\forall x_1 \in \mathbb{R}^n, \forall u_k \in \mathbb{R}^m, \exists z_1 \in \mathbb{R}^l$ such that $\hat{x}_k = x_k$ for all $k \geq 2$, and B) $\forall x_1 \in \mathbb{R}^n, \forall u_k \in \mathbb{R}^m, z_1 \in \mathbb{R}^l, \lim_{k \rightarrow \infty} \|\hat{x}_k - x_k\| = 0$. If the read-out map η in (9) is the identity, $\hat{x}_k = z_k$, then (9) is called an identity observer [25]; if the convergence of \hat{x} to x is exponential, then (9) is called an exponential observer.

For later use, the observer (9) will be said to be dead-beat of order d , if, upon writing $\Gamma(z_k, y_k, u_k) =: \Gamma^{y_k, u_k}(z_k)$ and $\eta(z_k, y_k, u_k) =: \eta^{y_k, u_k}(z_k)$, then

$$\eta^{y_d, u_d} \circ \Gamma^{y_{d-1}, u_{d-1}} \circ \dots \circ \Gamma^{y_1, u_1}(z_1) = x_d \quad (10)$$

independently of the particular observer initial condition z_1 , where x_d is the state of (8) at time d . It is remarked that dead-beat observers are of interest for stabilization problems, because, if $u_k = \alpha(x_k)$ is a stabilizing feedback for (8), then $u_k = \alpha(\hat{x}_k)$ will always result in an internally stable closed-loop system whenever the observer (9) has the dead-beat property. This is one of the rare instances of a nonlinear separation principle.

All the above has been stated in a global fashion. Let us note that there are at least two ways of localizing the concept of an observer. The first is essentially infinitesimal: one guarantees the existence of open neighborhoods \mathcal{O}_x and \mathcal{O}_z of the origin of (8) and (9), respectively, and an open neighborhood of controls \mathcal{O}_u such that A) and B) hold as long as $z \in \mathcal{O}_z$ and $\forall k \geq 1, u_k \in \mathcal{O}_u$ and $x_k \in \mathcal{O}_x$. The work on observers with linearizable error dynamics [6], [20]–[24], for instance, falls into this category. A second way to localize the concept

ould be called (S, \mathcal{V}) -quasilocal: one is given subsets S and \mathcal{V} , of the state space of (8) and of its controls, respectively, having the property that, for every initial point $x_1 \in S$, there exists an open subset $\mathcal{O}_z(x_1)$ of the state space of (9), such that A) and B) hold as long as $z_1 \in \mathcal{O}_z(x_1)$ and $\forall k \geq 1$, $r_k \in S$, and $u_k \in \mathcal{V}$. In other words, for the case of identity observers, instead of guaranteeing the existence of an open set about the origin of the product state space $\mathbb{R}^n \times \mathbb{R}^n$ where everything works, one is assuring the existence of an open set about the diagonal of $\mathbb{R}^n \times \mathbb{R}^n$, whose projection onto the r -coordinate contains S .

In the following, an approach to the construction of observers for discrete-time systems is developed. The authors' perspective was influenced by the work of Aeyels [1], [2], Fitts [10], Glad [13], and the multi-rate time sampling results of [14].

B Dead-Beat Observers

Consider once again the system Σ (8) and let $Y_{[1,N]}$ denote a vector of N consecutive measurements

$$Y_{[1,N]} = \begin{pmatrix} h^{u_1}(x) \\ h^{u_2} \circ F^{u_1}(x) \\ \vdots \\ h^{u_N} \circ F^{u_{N-1}} \circ \dots \circ F^{u_1}(x) \end{pmatrix} =: H(x, U_{[1,N]}) \quad (11)$$

Σ is said to be N -observable¹ [1], [32], [35] at a point $x \in \mathbb{R}^n$, $N \geq 1$, if there exists an N -tuple of controls $U_{[1,N]} = \text{col}(u_1, \dots, u_N) \in (\mathbb{R}^m)^N$ such that x is the unique solution of the set of equations

$$\bar{Y}_{[1,N]} = H(x, U_{[1,N]}) \quad (12)$$

where

$$\bar{Y}_{[1,N]} = H(\bar{x}, U_{[1,N]}). \quad (13)$$

The system is uniformly N -observable if the mapping

$$H^*: \mathbb{R}^n \times (\mathbb{R}^m)^N \rightarrow (\mathbb{R}^p)^N \times (\mathbb{R}^m)^N \quad (14)$$

by $(x, U_{[1,N]}) \mapsto (H(x, U_{[1,N]}), U_{[1,N]})$ is injective; it is locally uniformly N -observable with respect to $\mathcal{O} \subset \mathbb{R}^n$ and $\mathcal{U} \subset (\mathbb{R}^m)^N$ if H^* restricted to $\mathcal{O} \times \mathcal{U}$ is injective.

Whenever Σ is uniformly N -observable, the system of equations

$$Y_{[k-N+1,k]} = H(x_{k-N+1}, U_{[k-N+1,k]}) \quad (15)$$

can be, for each N applied inputs $U_{[k-N+1,k]}$, uniquely solved for x_{k-N+1} , and the current state x_k obtained by

$$x_k = \Phi^{U_{[k-N,k-1]}}(x_{k-N+1}). \quad (16)$$

¹ N refers to the minimum number of measurements needed to recover the state. In [2], Aeyels shows that, "generically," N can be taken to be $2n + 1$.

This constitutes an order N dead-beat observer for Σ , [14]. Conversely, suppose that (9) is a dead-beat observer of order N . Then

$$\eta^{y_N, u_N} \circ \Gamma^{y_{N-1}, u_{N-1}} \circ \dots \circ \Gamma^{y_1, u_1}(z) = r_N \quad (17)$$

for all $z \in \mathbb{R}^l$; thus the left-hand side of (17) does not depend on z and is a solution to (15)–(16). This shows that constructing a dead-beat observer of order N is equivalent to left-inverting (15) and composing the result with the right-hand side of (16). In a similar vein, an asymptotic (nondead-beat) observer can be thought of as constructing a solution to (15)–(16) as $N \rightarrow \infty$. Clearly, for nonlinear systems, insisting that this can be done in closed-form is very restrictive. It is therefore natural to formulate an extended concept of an observer as a possibly implicitly defined dynamical system, involving successive approximation routines, logical variables and/or lookup tables to dynamically "estimate" the state of a deterministic nonlinear system [16]. This perspective will be further pursued in the next section where Newton's algorithm is interpreted as a nonlinear observer (9).

Before doing so, however, let us first tie in the notion of a dead-beat observer with the observer error linearization approach [6], [20]–[24]. For simplicity of exposition, suppose that (8) does not have any inputs. One seeks a (locally defined) coordinate transformation $x = T(\bar{x})$ in which (8) takes the form

$$\begin{aligned} x_{k+1} &= Ax_k + \psi(y_k) \\ y_k &= C\bar{x}_k \end{aligned} \quad (18)$$

where the pair (A, C) is observable. This gives a family of infinitesimally-local observers

$$\begin{aligned} \hat{z}_{k+1} &= (A - KC)\hat{z}_k + \psi(y_k) + Ky_k \\ \hat{x}_k &= T^{-1}(\hat{z}_k). \end{aligned} \quad (19)$$

Letting $e_k := x_k - \hat{x}_k$ yields

$$e_{k+1} = (A - KC)e_k. \quad (20)$$

Choosing K to place the eigenvalues of $(A - KC)$ at zero makes $\hat{\Sigma}$ into a dead-beat observer of order n . In other words, the ability to achieve a linear error dynamics (20) implies the explicit knowledge of a left-inverse to (12).

III. NEWTON'S ALGORITHM AS AN OBSERVER

Consider again the system Σ , (8). It is said to satisfy the N -observability rank condition with respect to $\mathcal{O} \subset \mathbb{R}^n$ and $\mathcal{U} \subset (\mathbb{R}^m)^N$ if $H^*: \mathcal{O} \times \mathcal{U} \rightarrow (\mathbb{R}^p)^N \times (\mathbb{R}^m)^N$ is an immersion [35]; that is, it has rank $n + Nm$ at each point of $\mathcal{O} \times \mathcal{U}$ (recall that H^* was defined in (14)). Note that Σ is N -observable and satisfies the N -observability rank condition with respect to \mathcal{O} and \mathcal{U} if, and only if, $H^*: \mathcal{O} \times \mathcal{U} \rightarrow (\mathbb{R}^p)^N \times (\mathbb{R}^m)^N$ is an injective immersion;² this is in turn equivalent to: for each $U_{[1,N]} \in \mathcal{U}$, $H(\cdot, U_{[1,N]}): \mathcal{O} \rightarrow (\mathbb{R}^p)^N$ is an injective immersion.

²That is, an embedding [4].

Newton's algorithm for

$$Y_{[k-N+1,k]} - H(x_{k-N+1}, U_{[k-N+1,k]}) = 0 \quad (21)$$

is

$$\xi^{i+1} = \xi^i + \left[\frac{\partial H}{\partial x}(\xi^i, U_{[k-N+1,k]}) \right]^{-1} \cdot (Y_{[k-N+1,k]} - H(\xi^i, U_{[k-N+1,k]})) \quad (22)$$

where, for simplicity, it has been assumed that the set of (21) is square; in the case that there are more equations than states, the inverse in (22) should be replaced by a pseudo-inverse [26, p. 309], [8, pp. 222–224]. The standard convergence theorem for this algorithm can be found in [26]. For the moment, assume that $U_{[k-N+1,k]}$ is fixed, and let $H(x) = H(x, U_{[k-N+1,k]})$ for this fixed value of U .

Theorem 3.1 [26]: Suppose that H is twice differentiable and that $\|\frac{\partial^2 H}{\partial x^2}(x)\| \leq K$ for $x \in \mathbb{R}^n$; suppose there is a point $\xi^0 \in \mathbb{R}^n$ such that $P_0 := \frac{\partial H}{\partial x}(\xi^0)$ is invertible with $\|P_0^{-1}\| \leq \beta_0$ and $\|P_0^{-1}(Y_k - H(\xi_0))\| \leq \eta_0$. Under these conditions, if the constant $h_0 = \beta_0 \eta_0 K < 1/2$, then the sequence ξ^i generated by (22) exists for all $i \geq 0$ and converges to a solution of (21). If instead $\|\frac{\partial^2 H}{\partial x^2}(x)\| \leq K$ only in a neighborhood B of ξ_0 with radius

$$r \geq \frac{1}{h_0} (1 - \sqrt{1 - 2h_0}) \eta_0 \quad (23)$$

then the successive approximations generated by Newton's algorithm remain within this neighborhood and converge to a solution of (21).

The most interesting point is that Theorem 3.1 gives an estimate of how good the initial estimate of x_k should be before a few iterations of (22) will generate better estimates. In this regard, the quantity $\|\frac{\partial^2 H}{\partial x^2}(x)\|$, which measures the degree of nonlinearity of (21), is seen to be of central importance. For a linear system, $\|\frac{\partial^2 H}{\partial x^2}(x)\| \equiv 0$, and the initial estimate can be arbitrarily poor; when $\|\frac{\partial^2 H}{\partial x^2}(x)\|$ is large, the initial estimate should, in general, be better.

Newton's algorithm is now interpreted as a quasilocal exponential observer. Suppose that N has been fixed; for notational ease, let $Y_k = Y_{[k-N+1,k]}$ be the vector of the last N measurements and similarly let $U_k = U_{[k-N+1,k]}$ be $\text{col}(u_{k-N+1}, \dots, u_k)$ be the vector of the last N controls. Define

$$\Theta^{Y_k, U_k}(\zeta) = \zeta + \left[\frac{\partial H}{\partial x}(\zeta, U_k) \right]^{-1} (Y_k - H(\zeta, U_k)) \quad (24)$$

and let $(\Theta^{Y_k, U_k})^{(d)}(\xi)$ represent $\Theta^{Y_k, U_k}(\xi)$ composed with itself d -times.

Let \mathcal{O} be a subset of \mathbb{R}^n , \mathcal{V} a subset of \mathbb{R}^m , $N \geq 1$ a given integer and $\epsilon > 0$ a positive constant. Denote the complement of \mathcal{O} by $\sim \mathcal{O}$ and define $\text{dist}(x, \sim \mathcal{O}) = \inf\{\|x - y\| : y \in \sim \mathcal{O}\}$, and $\mathcal{O}_{\epsilon/2} = \{x \in \mathcal{O} : \text{dist}(x, \sim \mathcal{O}) \geq \epsilon/2\}$. Finally, define

constants α , β , γ , L , and C by

$$\begin{aligned} \alpha &= \sup \left\{ \left\| \left[\frac{\partial H}{\partial x}(x, U) \right]^{-1} \right\| : x \in \mathcal{O}_{\epsilon/2}, U \in \mathcal{V}^N \right\} \\ \beta &= \sup \left\{ \left\| \frac{\partial H}{\partial x}(x, U) \right\| : x \in \mathcal{O}_{\epsilon/2}, U \in \mathcal{V}^N \right\} \\ \gamma &= \sup \left\{ \left\| \frac{\partial^2 H}{\partial x^2}(x, U) \right\| : x \in \mathcal{O}_{\epsilon/2}, U \in \mathcal{V}^N \right\} \\ L &= \sup \left\{ \left\| \frac{\partial F}{\partial x}(x, u) \right\| : x \in \mathcal{O}_{\epsilon/2}, u \in \mathcal{V} \right\} \\ C &= \frac{1}{2} \sup \left\{ \left\| \frac{\partial^2 \Theta^{Y, U}}{\partial x^2}(x) \right\| : Y = H(x, U), \right. \\ &\quad \left. x \in \mathcal{O}_{\epsilon/2}, U \in \mathcal{V}^N \right\}. \end{aligned}$$

Theorem 3.2: Suppose that the following conditions hold:

- 1) F and h in (8) are at least three times differentiable with respect to x ;
- 2) there exist a bounded subset $\mathcal{O} \subset \mathbb{R}^n$ and a compact subset $\mathcal{V} \subset \mathbb{R}^m$ such that for each $x \in \mathcal{O}$ there exists $u \in \mathcal{V}$ such that $F(x, u) \in \mathcal{O}$ (i.e., \mathcal{O} is controlled-invariant with respect to \mathcal{V}); moreover, the controls are always applied so that $F(x, u) \in \mathcal{O}$;
- 3) there exists an integer $1 \leq N \leq n$ such that the set of equations (11) is
 - a) square,
 - b) uniformly N -observable with respect to \mathcal{O} and \mathcal{V}^N ,
 - c) satisfies the N -observability rank condition with respect to \mathcal{O} and \mathcal{V}^N .

Then, for every $\epsilon > 0$, the constants α , β , γ , L , and C are finite; moreover, whenever

$$\delta \leq \min \left\{ \frac{\epsilon}{4L}, \frac{1}{4\gamma\beta(\alpha)^2 L}, \frac{\epsilon}{8\beta\alpha L}, \frac{1}{2CL} \right\} \quad (25)$$

and

$$d \geq \max\{1, \log_2 \log_2 4L\}, \quad d \in \mathbb{N} \quad (26)$$

then

$$z_{k+1} = (\Theta^{Y_k, U_k})^{(d)}(F(z_k, u_{k-N})) \quad (27)$$

$$\hat{x}_k = F^{u_{k-1}} \circ F^{u_{k-2}} \circ \dots \circ F^{u_{k-N}}(z_k) \quad (28)$$

is a quasilocal, exponential observer for (8) in the sense that. A) if $x_1 \in \mathcal{O}$ and $z_{N+1} = x_1$, then $\hat{x}_k = x_k$ for all $k \geq N+1$ and B), if $x_1 \in \mathcal{O}$, $\|z_{N+1} - x_1\| < \delta$ and for all $k \geq 0$, $\text{dist}(x_k, \sim \mathcal{O}) \geq \epsilon$, then $\|\hat{x}_{k+1} - x_{k+1}\| \leq \frac{1}{2} \|\hat{x}_k - x_k\|$.

The proof may be found in [17]; the basic idea is to view the observer problem as one of solving a sequence of nonlinear inversion problems, each described by (12). Since the set \mathcal{O} is relatively compact and controlled invariant with a compact set of controls, Newton's algorithm can be shown to have a uniform rate of convergence over the entire sequence of problems. The idea then is to iterate long enough on each problem (the parameter d) so that F applied to the solution of the k th problem is a very good initial guess for the $(k+1)$ st problem.

The set \mathcal{O} is assumed to be bounded, but not necessarily small; if it is not controlled-invariant, then only finite time estimates are possible; the same is true of the observer error linearization approach of [20]–[24] (for discrete-time systems, see [6]).

The observer (27)–(28) is coordinate dependent. It is interesting to note that the coordinate transformation approaches, in general, would only favor convergence of (21) if they reduce $\| \frac{\partial^2 H}{\partial x^2}(x, U) \|$. In particular, eliminating low-order polynomial terms in favor of high-order terms will not always accomplish this task.

Remark 3.3:

- In Theorem 3.2, one may take $d = 1$ if, in (25), $\frac{1}{2CL}$ is replaced by $\frac{1}{2CL^2}$.
- Once again, assumption 3-a), that (11) is square, is NOT essential. One could try eliminating certain rows of (11) while still preserving the rank condition 3-c), but this would, more-than-likely, invalidate 3-b). The better alternative is to replace the inverse in (24) with a pseudo-inverse, as in [26, p. 309] or [8, pp. 222–224].
- The observer (27)–(28) bears some resemblance to the iterated extended Kalman filter of [7]. This will formally be established in the next section.
- By modifying the step-size in Newton's algorithm, "globally convergent" versions of the algorithm can be shown to exist. Chapter 6 of [8] presents this very nicely from a numerical analytic viewpoint. A different way of "globalizing" the algorithm is to systematically produce a good point at which to initialize it. This is discussed in [15], [16]. In Section V, the continuous Newton method will be shown to yield a global version of the above observer.
- It is often pointed out, and in [29] shown to be a valid practical concern, that the evaluation of the Jacobian $\frac{\partial H}{\partial x}$, be it explicitly or using finite difference approximations, may be computationally very expensive or even prohibitive. Modified Newton methods have been proposed, in which the Jacobian is not explicitly evaluated at every step, but updated iteratively without requiring additional function evaluations. Section VI explores the consequences of using Broyden's method instead of Newton's in the observer (27)–(28).

IV. RELATION BETWEEN KALMAN FILTERS AND NEWTON OBSERVERS

To show how the Newton observer is related to the extended Kalman filter, we will consider an invertible, autonomous discrete-time system

$$\begin{aligned} x_{k+1} &= F(x_k), & x_k &\in \mathbb{R}^n \\ y_k &= h(x_k), & y_k &\in \mathbb{R}^p \end{aligned} \quad (29)$$

in which we replace the output map h by the extended output map H , defined in the following manner

$$Y_k = \begin{pmatrix} y_{k-N+1} \\ \vdots \\ y_{k-1} \\ y_k \end{pmatrix} = \begin{pmatrix} h \circ F^{-(N-1)}(x_k) \\ \vdots \\ h \circ F^{-1}(x_k) \\ h(x_k) \end{pmatrix} =: H(x_k). \quad (30)$$

Assume that the above system satisfies the N -observability rank condition and is N -observable; furthermore, assume that H is a square map, i.e., $H: \mathbb{R}^n \rightarrow \mathbb{R}^n$. A common way

to construct an observer for system (29)–(30) is to apply the extended Kalman filter to the associated noisy system, i.e., the system with added artificial noise processes

$$\begin{aligned} z_{k+1} &= F(z_k) + Nw_k \\ \xi_k &= H(z_k) + Rv_k \end{aligned} \quad (31)$$

where v_k and w_k are assumed to be jointly Gaussian and mutually independent random processes with zero mean and unit variance. The extended Kalman filter for this system is given by the following equations:

measurement update

$$\begin{aligned} \hat{x}_k &= \hat{x}_k^- + K_k(\xi_k - H(\hat{x}_k^-)), \\ Q_k^{-1} &= (Q_k^-)^{-1} + H_k^T(RR^T)^{-1}H_k \end{aligned}$$

time update

$$\begin{aligned} \hat{x}_{k+1}^- &= F(\hat{x}_k), \\ Q_{k+1}^- &= A_k Q_k A_k^T + NN^T \end{aligned}$$

where

$$\begin{aligned} K_k &= Q_k^- H_k^T (H_k Q_k^- H_k^T + RR^T)^{-1}, \\ A_k &= \frac{\partial F}{\partial x}(\hat{x}_k), \\ H_k &= \frac{\partial H}{\partial x}(\hat{x}_k^-) \end{aligned}$$

and N , R , and Q_0 are the design parameters. Let us choose $N = \mu I$ and $R = \varepsilon I$, and consider the equations for the error covariance Q_k^- and the observer gain K_k

$$\begin{aligned} Q_{k+1}^- &= A_k \left((Q_k^-)^{-1} + \frac{1}{\varepsilon^2} H_k^T H_k \right)^{-1} A_k^T + \mu^2 I \\ &= \varepsilon^2 A_k (\varepsilon^2 (Q_k^-)^{-1} + H_k^T H_k)^{-1} A_k^T + \mu^2 I \\ K_k &= Q_k^- H_k^T (H_k Q_k^- H_k^T + \varepsilon^2 I)^{-1}. \end{aligned}$$

Given any positive definite Q_0^- , the update equation for Q_k^- in the limit as $\varepsilon \rightarrow 0$ is given by

$$Q_{k+1}^- = \mu^2 I.$$

Substituting this in the equation for K_k and letting $\varepsilon \rightarrow 0$ gives

$$\begin{aligned} K_k &= \mu^2 H_k^T (H_k \mu^2 H_k^T)^{-1} \\ &= H_k^T (H_k H_k^T)^{-1} \\ &= H_k^{-1} \end{aligned}$$

which is valid since, given the observability conditions, H_k is invertible. The extended Kalman filter equations are then given by

$$\hat{x}_k = \hat{x}_k^- + H_k^{-1}(Y_k - H(\hat{x}_k^-)) \quad (32)$$

$$\hat{x}_{k+1}^- = F(\hat{x}_k) \quad (33)$$

which is exactly the Newton observer for system (29) with one Newton iteration per time step.

In [3], it was recently shown that the measurement update equations for \hat{x}_k in the iterated extended Kalman filter are exactly those arising from the minimization problem

$$\min_{x_k} \left((Y_k - H(\hat{x}_k^-))^T R^{-1} (Y_k - H(\hat{x}_k^-)) + (x_k - \hat{x}_k^-)^T (Q_k^-)^{-1} (x_k - \hat{x}_k^-) \right) \quad (34)$$

when a Gauss-Newton method (an approximate Newton method) is used with \hat{x}_k^- as initial guess. This shows that the covariance matrices R and Q_k^- may be interpreted as weights on the norms in the output space and state space, respectively. It remains presently unclear, however, how the update equations for the covariance matrix Q_k^- in the Kalman filter can be given a meaningful interpretation in terms of updating the weighting matrix in the above minimization problem after every iteration.

It must be pointed out that the extended Kalman filter, although commonly used as a nonlinear observer, had not been actually proven to be a convergent asymptotic nonlinear observer until recently. In [34], it is shown that, under suitable observability conditions, if the state evolves in a compact set and the Kalman filter is initialized close enough to the true state, then the error covariance matrices Q_k^- and $(Q_k^-)^{-1}$ remain bounded, and the observer error goes to zero exponentially. A proof of convergence for the continuous Kalman filter with a special choice for the initial error covariance matrix is given in [9].

V. CONTINUOUS NEWTON METHOD AS A GLOBAL OBSERVER

In the remaining sections, we will, for notational simplicity and without loss of generality, restrict ourselves to invertible and autonomous systems. The results that are obtained can without any difficulty be extended to noninvertible systems and/or systems with inputs (see example section). Consider once again the discrete-time system

$$\begin{aligned} \hat{x}_{k+1} &= F(x_k), \quad x_k \in \mathbb{R}^n \\ y_k &= h(x_k), \quad y_k \in \mathbb{R}^p \end{aligned} \quad (35)$$

with the extended output map H , defined in the following manner

$$Y_k = \begin{pmatrix} y_{k-N+1} \\ \vdots \\ y_{k-1} \\ y_k \end{pmatrix} = \begin{pmatrix} h \circ F^{-(N-1)}(x_k) \\ \vdots \\ h \circ F^{-1}(x_k) \\ h(x_k) \end{pmatrix} =: H(x_k). \quad (36)$$

Assume that H is a square map.³ The discrete Newton method with step size h_1 for solving $Y_k - H(x) = 0$ is

$$z_k^{i+1} = z_k^i + h_1 J(z_k^i)^{-1} (Y_k - H(z_k^i)) \quad (37)$$

where $J(z) := \frac{\partial H}{\partial x}(z)$. If we consider this equation with an infinitesimally small step size, we obtain the following differential equation

$$\dot{z}_k = J(z_k)^{-1} (Y_k - H(z_k)), \quad z_k(0) = z_k^0 \quad (38)$$

which is referred to as the continuous Newton method; the right hand side of (38) is commonly referred to as (gradient) Newton flow [19]. The stability of Newton flows has been studied extensively (see [19], [40] and references therein).

We now construct a global asymptotic high-gain hybrid observer for the system (35), by interpreting (38) as an observer

for that system. Assume that the time interval between x_k and x_{k+1} is T , i.e., $x_k = x(kT)$. We thus obtain the following hybrid system-observer

$$x_{k+1} = F(x_k) \quad (39)$$

$$Y_k = H(x_k)$$

$$\begin{aligned} \dot{z}_k &= K J(z_k)^{-1} [Y_k - H(z_k)]; \quad z_k(kT) = F(z_{k-1}(kT)) \\ \hat{x}_k &= z_k((k+1)T) \end{aligned} \quad (40)$$

where K is a positive scalar, to be determined later.

Theorem 5.1. Assume that (35) is uniformly N -observable and satisfies the N -observability rank condition with respect to \mathbb{R}^n . Suppose that

$$\begin{aligned} L &:= \sup_{r \in \mathbb{R}^n} \left\| \frac{\partial F}{\partial r}(r) \right\| < \infty; \\ \beta &:= \sup_{r \in \mathbb{R}^n} \left\| \frac{\partial F}{\partial r}(r) \right\| < \infty; \\ \alpha &:= \sup_{x \in \mathbb{R}^n} \left\| \left(\frac{\partial H}{\partial x}(x) \right)^{-1} \right\| < \infty \end{aligned} \quad (41)$$

If $K \geq \frac{1}{T} \log(2L\alpha/\beta)$, then (39) is a global asymptotic observer for (35).

The proof for this and the next result can be found in [28]. In general, the quantities $\|\frac{\partial F}{\partial r}\|$, $\|\frac{\partial H}{\partial x}\|$, and $\|\frac{\partial F}{\partial x}\|$ will not be uniformly bounded on \mathbb{R}^n , nor will the system (35) be globally observable. For these cases, we can still obtain a nonlocal convergence result for the observer (40).

Proposition 5.2. Suppose the following conditions hold:

- 1) F and h are at least once continuously differentiable;
- 2) \exists compact $\mathcal{O} \subset \mathbb{R}^n$ such that:
 - a) (35) is N -observable with respect to \mathcal{O} ;
 - b) (35) satisfies the N -observability rank condition with respect to \mathcal{O} ;
- 3) $\exists \mu > 0$ such that $\mathcal{O}_\mu := \{x \in \mathcal{O} \mid \inf_{y \in \mathbb{R}^n \setminus \mathcal{O}} \|x - y\| > \mu\}$ is F -invariant and nonempty.

Then, if $K \geq \frac{1}{T} \log(2L\alpha/\beta)$, if $x_0 \in \mathcal{O}_\mu$ and if $\|z_0(0) - x_0\| < \frac{\mu}{\beta\alpha}$, it follows that $\lim_{k \rightarrow \infty} \|\hat{x}_k - x_k\| = 0$.

Remark 5.3 If no *a priori* information is known about the initial state of the system, one may, for lack of a better alternative, initialize the observer at the origin. Suppose \mathcal{O} contains the closed ball centered at the origin, with radius R $B(0, R)$. Then the previous analysis showed that convergence can be guaranteed if $\|\hat{x}_0 - x_0\| = \|x_0\| \leq \frac{R}{1+\beta\alpha}$ or, what may provide a more practical estimate, if $\|H(0) - Y_{N-1}\| \leq \frac{\beta R}{1+\beta\alpha}$. Most global modifications of the discrete Newton method are based on choosing a proper stepsize (e.g., Armijo stepsize procedures) and/or search direction (e.g., trust region updates) [8], [30], such as to assure a decrease in the term $\|Y_k - H(z^i)\|$ in the i th step of the algorithm. Obviously, in terms of a connected region of convergence, one cannot do better than allowing an infinite number of iterations, each taking infinitesimally small steps in a guaranteed descent direction, i.e., the continuous Newton method.

³This seems to be a crucial assumption

VI. BROYDEN'S METHOD

In the previous section, it was seen that a large region of convergence of the Newton-observer could be guaranteed if one used the hybrid form presented in (39). To implement the hybrid Newton-observer, however, a closed-form expression for the inverse of the Jacobian matrix would be necessary; this does not seem very realistic. Moreover—as mentioned in Section III—even in the discrete Newton algorithm, the computational complexity of repeated Jacobian evaluations might prove prohibitive in practice. This provides sufficient motivation to pursue methods for approximating the Jacobian and the investigation of the associated convergence properties. Here, we will look at Broyden's method, as it is among the most popular of such approximation schemes [8], [30].

Broyden's method for solving a system of nonlinear equations $P(x) = 0$ is a modified Newton method in which the Jacobian is not calculated exactly at each step, but rather iteratively approximated using secant updates. In contrast to, for example, finite difference approximations, no additional function evaluations are required. Define $J(x) = \frac{\partial P}{\partial x}(x)$. Broyden's method for solving $P(x) = 0$ is [8]: Given x^0 , the initial guess for \bar{x} , where $P(\bar{x}) = 0$, and A^0 , the initial approximation for the Jacobian of P at x^0

$$\text{solve } A' s' = -P(x') \text{ for } s' \quad (42a)$$

$$x'^{+1} := x' + s' \quad (42b)$$

$$v' := P(x'^{+1}) - P(x') \quad (42c)$$

$$A'^{+1} := A' + \frac{(v' - A' s')(s')^T}{(s')^T s'}. \quad (42d)$$

The update A' for the Jacobian has the property of bounded deterioration: even though it may not converge to $J(x)$, it deteriorates slowly enough for one to still be able to prove convergence of $\{x^i\}$ to \bar{x} .

Conditions for convergence are the same as those of Newton's method, with the additional requirement that, with $P(\bar{x}) = 0$, not only the initial guess x^0 be sufficiently close to \bar{x} , but that also A^0 be sufficiently close to $J(x)$. For Broyden's method, local superlinear convergence can be proven. Newton's method, on the other hand, exhibits local quadratic convergence.

In the following we will show that, in general, Broyden's method alone cannot successfully be used in the Newton-observer; occasional recalculation of the exact Jacobian seems to remain necessary, basically because the property of bounded deterioration no longer holds when Broyden's method is applied to a sequence of problems: $P_k(x) = 0$. For the class of slow-varying or weakly nonlinear systems, however, this approach can substantially reduce the computational complexity.

In the observer problem, at each step k we want to solve

$$P_k(x_k) := H(x_k) - Y_k = 0. \quad (43)$$

Note that this sequence of equations has a special structure: $\frac{\partial P_{k+1}}{\partial x} \equiv \frac{\partial P_k}{\partial x}$ and their solutions are related by $x_{k+1} = F(x_k)$. Assume for simplicity of exposition that $H: \mathbb{R}^n \rightarrow \mathbb{R}^n$. Let

\mathcal{O} be a subset of \mathbb{R}^n such that the following quantities are finite

$$L := \sup_{x \in \mathcal{O}} \left\| \frac{\partial F}{\partial x}(x) \right\| < \infty$$

$$\beta := \sup_{x \in \mathcal{O}} \left\| \frac{\partial H}{\partial x}(x) \right\| < \infty$$

$$\alpha := \sup_{x \in \mathcal{O}} \left\| \left(\frac{\partial H}{\partial x}(x) \right)^{-1} \right\| < \infty$$

$$\gamma := \sup_{x \in \mathcal{O}} \left\| \frac{\partial^2 H}{\partial x^2}(x) \right\| < \infty.$$

Given the d th iterate in the k th problem, x_k^d and A_k^d , being approximations for x_k and $J(x_k)$, respectively, the initial guess for the $(k+1)$ st problem is taken as $x_{k+1}^0 = F(x_k^d)$. In terms of (42a)–(42d), this defines \bar{s}_k and \bar{v}_k , and hence A_{k+1}^0 , the initial approximation for the Jacobian at x_{k+1}^0 as

$$A_{k+1}^0 = A_k^d + \frac{(\bar{v}_k - A_k^d \bar{s}_k) \bar{s}_k^T}{\bar{s}_k^T \bar{s}_k} \quad (44a)$$

where

$$\bar{s}_k = F(x_k^d) - x_k^d \quad (44b)$$

$$\bar{v}_k = P_{k+1}(x_{k+1}^0) - P_{k+1}(x_k^d) \quad (44c)$$

$$x_{k+1}^0 = F(x_k^d). \quad (44d)$$

Note that this update is the same as in Broyden's method, (42d), except that s_k is determined by (44b), which is a consequence of switching from the k th to the $(k+1)$ -st problem in the sequence $\{P_k(x) = 0\}$.

To develop bounds on the approximation error, we will need the following lemma from [8].

Lemma 6.1 (Bounded Deterioration): Let $D \subseteq \mathbb{R}^n$ be open and convex; $x^i, x^{i+1} \in D, x^i \neq \bar{x}$. Let $A^i \in \mathbb{R}^{n \times n}$ and let A^{i+1} be defined by (42a)–(42d). Assume that J is such that $\exists \gamma < \infty$ verifying

$$\|J(x) - J(\bar{x})\| \leq \gamma \|x - \bar{x}\| \quad \forall x \in D. \quad (45)$$

Then, for either the Frobenius or the l_2 -matrix norm

$$\|A^{i+1} - J(\bar{x})\| \leq \|A^i - J(\bar{x})\| + \frac{1}{2} \gamma (\|x^{i+1} - \bar{x}\|_2 + \|x^i - \bar{x}\|_2). \quad (46)$$

To begin with, let x_k and x_{k+1} be such that $P_k(x_k) = H(x_k) - Y_k = 0$ and $P_{k+1}(x_{k+1}) = H(x_{k+1}) - Y_{k+1} = 0$. Let A_k^d and x_k^d be given and determine A_{k+1}^0 and x_{k+1}^0 by (44a)–(44d). Furthermore, define $E_k^i := A_k^i - J(x_k)$ and $e_k^i := x_k^i - x_k$. A bound on the error $\|E_{k+1}^0\|$ can then be derived to be

$$\begin{aligned} \|E_{k+1}^0\| &\leq \|E_k^d\| + \gamma \|x_k - x_{k+1}\| \\ &\quad + \frac{1}{2} \gamma (\|e_k^d\| + \|e_{k+1}^0\| + \|x_{k+1} - x_k\|) \\ &\leq \|E_k^d\| + \frac{1}{2} \gamma (1 + L) \|e_k^d\| + \frac{3}{2} \gamma \|x_k - x_{k+1}\|. \end{aligned} \quad (47)$$

From Lemma 6.1 we get the following

$$\|E_k^d\| \leq \|E_k^0\| + \frac{1}{2} \gamma \left(\|e_k^0\| + 2 \sum_{i=1}^d \|e_k^i\| \right). \quad (48)$$

From the superlinear convergence of Broyden's method, it follows that, with $\|E_k^0\|$ sufficiently small, for any $0 < c < 1$, the following holds: provided that $\|e_k^0\|$ is sufficiently small

$$\|e_k^{i+1}\| \leq c\|e_k^i\| \quad \forall i \geq 0. \quad (49)$$

Now we can write (48) as

$$\begin{aligned} \|E_k^d\| &\leq \|E_k^0\| + \frac{1}{2}\gamma \left(\|e_k^0\| + 2 \left(\frac{1-c^{d+1}}{1-c} - 1 \right) \|e_k^0\| \right) \\ &\leq \|E_k^0\| + \frac{1}{2}\gamma \|e_k^0\| \left(\frac{1+c-2c^{d+1}}{1-c} \right) \end{aligned} \quad (50)$$

and (47) becomes

$$\begin{aligned} \|E_{k+1}^0\| &\leq \|E_k^0\| + \frac{3}{2}\gamma \|x_k - x_{k+1}\| \\ &\quad + \frac{1}{2}\gamma \left(\frac{1+c-2c^{d+1}}{1-c} + (1+L)c^d \right) \|e_k^0\|. \end{aligned} \quad (51)$$

The above inequality actually provides an upper bound on the worst-case deterioration of the approximation to the Jacobian after d iterates and a switch from the k th to the $(k+1)$ st problem. There are two special cases of interest:

- 1) H is linear, hence $\gamma = 0$, and we then obtain uniform superlinear convergence of the sequence of problems $\{P_k(x_k) = 0\}$, which is essentially reduced to one single problem to which Broyden's method is applied. This yields an asymptotic observer different from the classical Luenberger observer.
- 2) The system is operated near an equilibrium point, in which case the term $\|x_{k+1} - x_k\|$ is small, or H is weakly nonlinear, in which case γ is small. In either case, $\|E_k^0\|$ will remain sufficiently small over a number of problems.

In general, due to the last two terms in (51), the sequence $\{\|A_k^0 - J(x_k)\|\}$ will not be uniformly bounded from above. Hence, for some k , A_k^0 will no longer be sufficiently close to $J(x^k)$, which, in practice, may be indicated by slow decrease, or even increase, of the term $\|Y_k - H(x_k^i)\|$, or by ill-conditioning of the matrix A_k^i . In an actual implementation of Broyden's method, one will, for reasons of computational complexity, typically update the QR -factorization of A_k^i , rather than A_k^i itself, and ill-conditioning will be checked for to avoid numerical instabilities [8]. For the iterates to converge throughout the sequence of problems, $J(x_k^0)$ will have to be recalculated occasionally. Although one might be able to obtain a tighter bound than (51), the term $\|x_{k+1} - x_k\|$ will remain. This term represents in a sense the "distance" between two subsequent problems, which is prescribed by the system's dynamics and, in general, cannot be made smaller such as to coerce uniform convergence of $\{x_k^0\}$, unless the observer is being used in a closed-loop situation and the state is being regulated to a fixed value, for example.

Suppose the discrete-time system (35) is the exact discretization with sampling time T of an underlying continuous-time system: $\dot{x} = f(x)$. Then the term $\|x_{k+1} - x_k\|$ in (51) can be estimated by

$$\|x_{k+1} - x_k\| = \|x((k+1)T) - x(kT)\| \leq \beta_f T \quad (52)$$

where β_f is the Lipschitz constant for f on some given set. Slower sampling means more time in between samples for calculating x_k given Y_k . However, (52) indicates also that the error in $\|A_{k+1}^0 - J(x_{k+1})\|$ grows faster as T increases, hence the Jacobian has to be recalculated more often too. On the other hand, as $T \rightarrow 0$, the approximation to the Jacobian will deteriorate more and more slowly. It should be pointed out though, that for very small T , the problem of solving $Y_k - H(x_k) = 0$ becomes ill-conditioned, since consecutive measurements will differ only slightly from each other. From a numerical analytic point of view, the system becomes practically unobservable. Thus, as is usual, there are trade-offs to be made.

VII. EXAMPLE: MIXED-CULTURE BIO REACTOR WITH COMPETITION AND EXTERNAL INHIBITION

In this section, we will illustrate the Newton observer and the continuous Newton observer by means of an example concerning a mixed-culture bioreactor. An application of the Broyden observer to an automotive problem can be found in [29].

The system under consideration describes the growth of two species in a continuously stirred bioreactor, which compete for a single rate-limiting substrate. In addition, an external agent is added which inhibits the growth of one species, while being deactivated by the second species. The measured quantity is the total cell mass of the two species. The example is taken from [18], where the system was shown to be globally feedback linearizable, provided that full state information is available.

Here, it will be shown first that, assuming noise-free measurements and dynamics, a discrete Newton observer may fail to converge if not properly initialized. The (global) continuous Newton observer is then implemented and shown to converge for a wide range of operating conditions irrespective of the observer initialization, i.e., even when large initial observer errors are present.

The system dynamics are given by

$$\begin{aligned} \dot{x}_1 &= \frac{0.4S(x_1, x_2)}{0.05 + S(x_1, x_2)} x_1 - u_1 x_1 \\ \dot{x}_2 &= \frac{0.01S(x_1, x_2)}{(0.05 + S(x_1, x_2))(0.02 + x_3)} x_2 - u_1 x_2 \\ \dot{x}_3 &= -0.5x_1 x_3 - u_1 x_3 + u_1 u_2 \end{aligned} \quad (53)$$

where $S(x_1, x_2) = 2 - 5x_1 - 6.667x_2$, time is expressed in hours.

- x_1 : cell density of inhibitor resistant species
- x_2 : cell density of inhibitor sensitive species
- x_3 : inhibitor concentration in fermentation medium
- u_1 : dilution rate
- u_2 : inlet concentration of the inhibitor.

Following the notation of the previous section, let $x_k := (x_k^1, x_k^2, x_k^3)^T$, $u_k := (u_k^1, u_k^2)^T$, and y_k denote the states, inputs, and outputs, respectively, evaluated at time kT , with T being the sampling time with which the system (53) is discretized. Furthermore, let $Y_k := (y_{k-2}, y_{k-1}, y_k)^T$ and $U_k := (u_{k-1}^1, u_k^1)^T$.

Fig. 1. Discrete Newton observer: relative observer error $e = (e_1, e_2, e_3)$, where $e_i = \frac{x_i - \hat{x}_i}{x_i}$, for $x = (0.2, 0.02, 0.005)$ and $\hat{x} = (0.02, 0.2, 0.015)$ when $u_1(t) = 0.3$ and $u_2(t) = 0.0067$.

A discretization of the above system with sampling time T may then be expressed as

$$\begin{aligned} x_{k+1} &= F_T^{u_k}(x_k) \\ y_k &= h(x_k) \end{aligned} \quad (54)$$

and the state-to-measurement map is given by

$$H(x_{k-2}, U_{k-1}) := \begin{pmatrix} h(x_{k-2}) \\ h \circ F^{u_{k-2}}(x_{k-2}) \\ h \circ F^{u_{k-1}} \circ F^{u_{k-2}}(x_{k-2}) \end{pmatrix} = Y_k. \quad (55)$$

Computing the rank of $\frac{\partial H}{\partial x}$ at a number of different points in the state space showed that the N -observability rank condition is indeed satisfied for $N = 3$. It was also found, however, that system (54) is poorly observable, indicated by ill-conditioning of $\frac{\partial H}{\partial x}$: ratio of its largest to smallest singular value for a sampling time of $T = 1$ (i.e., one hour) is on the order of 500. A typical response for the Newton observer is shown in Fig. 1, simulations showed however, that the Newton observer fails to converge if it is not initialized closely enough to the actual states, e.g., when

$$x = \begin{pmatrix} 0.2 \\ 0.02 \\ 0.005 \end{pmatrix} \text{ and } \hat{x} = \begin{pmatrix} 0.02 \\ 0.2 \\ 0.015 \end{pmatrix}.$$

Given the time scale—sampling times in the order of minutes or even hours—there is virtually no restriction to available CPU time in the observer design. We therefore simulated the continuous Newton observer as well. It is given by

$$\begin{aligned} \dot{z}_k^- &= K \left(\frac{\partial H}{\partial z}(z_k^-, U_{k-1}) \right)^{-1} [Y_k - H(z_k^-, U_{k-1})], \\ z_k^- &= F^{u_{k-2}}(z_k^-(kT)) \\ \hat{x}_k &= F^{u_{k-1}}(z_k^-). \end{aligned}$$

As expected, this observer did converge for all physically feasible initial values. Responses are shown in Fig. 2 for four values of the observer gain K . The plot confirms our finding that the observer may fail to converge if K is too small.

Fig. 2. Continuous Newton observer with different observer gains K : shown is the relative observer error for x_2 , when $u_1(t) \equiv 0.3$ and $u_2(t) \equiv 0.0067$.

VIII. CONCLUDING REMARKS

In this paper, we have provided a new observer design method for nonlinear systems with discrete measurements. The method relies on asymptotically inverting the state-to-measurement map, which is constructed by relating the system's state at a given time to a (predetermined) number of consecutive measurements. By using a continuous Newton method for the map inversion, the observer error was shown to converge to zero, globally and exponentially. If, instead, a computationally less expensive discrete Newton method is used, the observer shows quasilocal exponential convergence. Even more computational advantage may be gained by employing Broyden's method, whose effect on the observer performance was also investigated. The theory was illustrated on an example. Results on using this observer in a closed-loop setting have been reported in [17].

ACKNOWLEDGMENT

The authors wish to thank A. Tornambè for his insightful comments on the continuous Newton method.

Paul E. Moraal was born in Drachten, The Netherlands in 1965. He received the engineering degree in applied mathematics from Twente University Enschede, The Netherlands in 1990 and the Ph.D. degree in electrical engineering systems from the University of Michigan Ann Arbor in 1994.

Dr. Moraal is currently an Engineering Specialist at Ford Motor Company's Research Laboratory in Dearborn, MI. His current research interests include nonlinear control theory and applications of modern control theory to automotive powertrain control.

Jessy W. Grizzle (S 79-M 83-SM 90) received the Ph.D. in electrical engineering from the University of Texas at Austin in 1983.

In 1984, he was at the Laboratoire des Signaux et Systèmes, Gif sur Yvette, France, as a PostDoc. From January 1984 to August 1987, he was an Assistant Professor in the Department of Electrical Engineering at the University of Illinois at Urbana-Champaign. Since September 1987, he has been with the Department of Electrical and Computer Science at the University of Michigan Ann Arbor.

where he is currently a Professor. He has held visiting appointments at the Dipartimento di Informatica e Sistemistica at the University of Rome and the Laboratoire des Signaux et Systèmes SUPELEC CNRS-SE Gif sur Yvette, France. He has served as a consultant on engine control systems to Ford Motor Company for seven years. His research interests include nonlinear system theory, geometric methods, multirate digital systems, automotive applications, and electronics manufacturing.

Dr. Grizzle was a Fulbright Grant awardee and a NATO Postdoctoral Fellow from January-December 1984. He received a Presidential Young Investigator Award in 1987 and the Henry Russell Award in 1993. In 1992, he received a Best Paper Award with K. L. Dobbins and J. A. Cook from the IEEE VEHICULAR TECHNOLOGY SOCIETY. In 1993, he received a College of Engineering teaching award. He was Past Associate Editor of TRANSACTIONS ON AUTOMATIC CONTROL and *System & Control Letters*.

A Probabilistic Approach to Multivariable Robust Filtering and Open-Loop Control

Kentth Öhrn, Anders Ahlén, *Senior Member, IEEE*, and Mikael Sternad, *Senior Member, IEEE*

Abstract—A new approach to robust filtering, prediction, and smoothing of discrete-time signal vectors is presented. Linear time-invariant filters are designed to be insensitive to spectral uncertainty in signal models. The goal is to obtain a simple design method, leading to filters which are not overly conservative. Modeling errors are described by sets of models, parameterized by random variables with known covariances. These covariances could either be estimated from data or be used as robustness “tuning knobs.” A robust design is obtained by minimizing the \mathcal{H}_2 -norm or, equivalently, the mean square estimation error, averaged with respect to the assumed model errors. A polynomial solution, based on an averaged spectral factorization and a unilateral Diophantine equation, is derived. The robust estimator is referred to as a cautious Wiener filter. It turns out to be only slightly more complicated to design than an ordinary Wiener filter. The methodology can be applied to any open-loop filtering or control problem. In particular, we illustrate this for the design of robust multivariable feedforward regulators, decoupling and model matching filters.

I. INTRODUCTION

FOR any model-based filter, modeling errors are a potential source of performance degradation. Here, we will propose a cautious Wiener filter for the prediction, filtering, or smoothing of discrete-time signal vectors. As in the scalar case, discussed in [36], it constitutes a generalization of the polynomial equations methodology pioneered by Kučera [21]. The design is based on a stochastic description of model errors, with relations to e.g., the stochastic embedding concept of Goodwin and coworkers [11], [12]. To be more specific, our problem formulation is as follows:

- A set of (true) dynamic systems is assumed to be well described by a set of discrete-time, stable, linear and time-invariant transfer function matrices

$$\mathcal{F} = \mathcal{F}_o + \Delta\mathcal{F}. \quad (1.1)$$

We call such a set an extended design model, in which \mathcal{F}_o represents a stable nominal model, while an error model $\Delta\mathcal{F}$ describes a set of stable transfer functions, parameterized by stochastic variables. The random variables enter linearly into $\Delta\mathcal{F}$, and they are assumed independent of the noise.

- A single robust linear filter is to be designed for the whole class of possible systems. Robust performance is obtained by minimizing the averaged mean square estimation error criterion

$$J = \text{trace} E E(\varepsilon(k) \varepsilon(k)^*). \quad (1.2)$$

Here, $\varepsilon(k)$ is the estimation error vector, E denotes expectation over noise and E is an expectation over the stochastic variables parameterizing the error model $\Delta\mathcal{F}$.

The averaged mean square error has been used previously in the literature by e.g., Chung and Bélanger [9], Speyer and Gustafson [32], and by Grimble [13]. These works were based on assumptions of small parametric uncertainties and on series expansions of uncertain parameters. We suggest the use of the criterion (1.2), together with a particular description of the set (1.1): transfer function elements in $\Delta\mathcal{F}$ have stochastic numerators and fixed denominators. Such models can describe nonparametric uncertainty and undermodeling as well as parametric uncertainty. A discussion of the utility, and versatility, of linearly parameterized stochastic error models can be found in [36].

Most previous suggestions for obtaining robust filters have been based on some type of minimax approach [10], [24]. A paper [26] by Martin and Mintz takes both spectral uncertainty and uncertainty in the noise distribution into account. The resulting filter will, however, be of very high order. Minimax design of a filter \mathcal{R} becomes very complex, unless there exists either a saddle point or a boundary point solution. A crucial condition here is that $\min_{\mathcal{R}} \max_{\mathcal{F}}$ equals $\max_{\mathcal{F}} \min_{\mathcal{R}}$. If so, one can search for models whose optimal filter gives the worst (nominal) performance and use the corresponding filter. As compared to finding the worst case with respect to a set of models, this is a much simpler task. It can still, however, be computationally demanding. See [19], [28], [31], [38], and the survey paper by Kassam and Poor [20]. The condition $\min_{\mathcal{R}} \max_{\mathcal{F}} = \max_{\mathcal{F}} \min_{\mathcal{R}}$ is not fulfilled in numerous problems, which makes them very difficult to solve. See, e.g., Example 5 in [36] and the example in Section IV.

Kalman filter-like estimators have recently been developed for systems with structured and possibly time-varying parametric uncertainty of the type

$$x(k+1) = (\mathbf{A} + \mathbf{D}\Delta(k)\mathbf{E})x(k) + w(k)$$

where the matrix $\Delta(k)$ contains norm-bounded uncertain parameters. See [30], [7], and [39] for continuous-time results and [40] for the discrete-time one-step predictor. See also [16]

Manuscript received July 2, 1993; revised May 20, 1994. Recommended by Associate Editor, B. Pasik-Duncan. The work was supported in part by Swedish Research Council for Engineering Sciences (TFR) under Grant 775.

IEEE Log Number 9408271

for a related method. For systems which are stable for all $\Delta(k)$, an upper bound on the estimation error covariance matrix can be minimized by solving two coupled Riccati equations, combined with a one-dimensional numerical search. This represents a computational simplification, as compared to previous minimax designs. Still, the resulting estimators are quite conservative, partly because they rest on worst case design. This conservatism is illustrated and discussed in [29] and [37].

The method suggested in the present paper is computationally simpler than any of the minimax schemes referred to above. It also avoids two drawbacks of worst case designs. First, the stochastic variables in $\Delta\mathcal{F}$ need not have compact support. Thus, the descriptions of model uncertainties may have "soft" bounds. These are more readily obtainable in a noisy environment than the hard bounds required for minimax design. Second, not only the range of the uncertainties, but also their likelihood is taken into account by using the expectation $\bar{E}(\cdot)$ of the MSE. Highly probable model errors will affect the estimator design more than do very rare "worst cases." Therefore, the performance loss in the nominal case, the price paid for robustness, becomes smaller than for a minimax design. In other words, conservativeness is reduced. There do exist applications where a worst-case design is mandatory, e.g., for safety reasons. We believe, however, that the average performance of estimators is often a more appropriate measure of performance robustness.

In the present paper, one of our goals will be to present transparent design equations and to hold their number to a minimum without sacrificing numerical accuracy. We use matrix fraction descriptions with diagonal denominators and common denominator forms. This leads to a solution which is, in fact, significantly simpler and numerically better behaved than the corresponding nominal \mathcal{H}_2 -designs (without uncertainty) presented in [1] or [14]. Somewhat surprisingly, taking model uncertainty into account does not require any new types of design equations. We end up with just two equations for robust estimator design: a polynomial matrix spectral factorization and a unilateral Diophantine equation. The solution provides structural insight; important properties of a robust estimator are evident by direct inspection of the filter expression.

This paper is organized as follows. The filtering problem, model structure (1.1), and criterion (1.2) are discussed in more detail in Section II. Section III presents the design equations and some tools for performance evaluation. The design procedure is illustrated by a thorough numerical example in Section IV. The resulting estimator reduces the impact of model uncertainty and limited signal energy by using multiple sensors in an efficient way. In Section V the design of robust feedforward regulators, servos, and model matching filters is discussed.

Remarks on the Notation: Signals and polynomial coefficients may, in the following, be complex valued. (This is required in, e.g., communications applications.) Let p_j^* denote the complex conjugate (and transpose for matrices) of a polynomial coefficient p_j . For any polynomial

$$P(q^{-1}) = p_0 + p_1 q^{-1} + \dots + p_{np} q^{-np}$$

in the backward shift operator q^{-1} , define the conjugate polynomial

$$P_*(q) \triangleq p_0^* + p_1^* q + \dots + p_{np}^* q^{np}$$

where q is the forward shift operator. A polynomial $P(q, q^{-1})$ having coefficients of both q and q^{-1} will be called double-sided. Rational matrices, or transfer functions, are denoted by boldface calligraphic symbols, e.g., $\mathcal{R}(q^{-1})$. Polynomial matrices are denoted by boldface symbols, such as $\mathbf{P}(q^{-1})$, while constant matrices are denoted as \mathbf{P} . For example, the identity matrix of dimension n is denoted \mathbf{I}_n . We denote the trace of \mathbf{P} by $\text{tr} \mathbf{P}$. For polynomial or rational matrices, $P_*(q)$ and $\mathcal{R}_*(q)$ means complex conjugate, transpose, and substitution of q for q^{-1} . When appropriate, the complex variable z or $e^{j\omega}$ is substituted for the forward shift operator q . Arguments of polynomials and matrices are often omitted, when there is no risk of misunderstanding. The degree of a polynomial matrix is the highest degree of any of its polynomial elements. Square polynomial matrices $\mathbf{P}(q^{-1})$ are called stable if all zeros of $\det \mathbf{P}(z^{-1})$ are located in $|z| < 1$. A rational matrix is defined as stable if all its elements are stable. Causality is defined in the same way.

A rational matrix $\mathcal{G}(q^{-1})$ may be represented by polynomial matrices as a matrix fraction description (MFD), either left $\mathcal{G} = \mathbf{A}_1^{-1} \mathbf{B}_1$ or right $\mathcal{G} = \mathbf{B}_2 \mathbf{A}_2^{-1}$. It may also be represented in a common denominator form $\mathcal{G} = \mathbf{B}/\mathbf{A}$, where \mathbf{B} is a polynomial matrix. The scalar and monic polynomial A is then the least common denominator of all elements in \mathcal{G} . Denominator matrices in MFD's are assumed to have identity matrices as leading coefficients of their matrix polynomial representations, thus $\mathbf{A}_i(0) = \mathbf{I}$ above.

II. THE ROBUST ESTIMATION PROBLEM

Consider the following extended design model

$$\begin{aligned} y(k) &= \mathcal{G}(q^{-1})u(k) + \mathcal{H}(q^{-1})v(k) \\ u(k) &= \mathcal{F}(q^{-1})e(k) \\ f(k) &= \mathcal{D}(q^{-1})u(k) \end{aligned} \quad (2.1)$$

where \mathcal{G} , \mathcal{H} , \mathcal{F} , and \mathcal{D} are stable and causal, but possibly uncertain, transfer functions of dimension $p|s$, $p|r$, $s|n$, and $\ell|s$, respectively. The noise sequences $\{e(k)\}$ and $\{v(k)\}$ are mutually uncorrelated and zero mean stochastic sequences. To obtain a simple notation they are assumed to have unit covariance matrices, so scaling and uncertainty of the covariance are included in \mathcal{F} and \mathcal{H} , respectively. The signal $y(k)$ is assumed measurable, while $f(k)$ is the signal to be estimated

A. Multisignal Estimation

From data $y(k)$ up to time $k + m$, an estimator

$$\hat{f}(k|k+m) = \mathcal{R}(q^{-1})y(k+m) \quad (2.2)$$

of $f(k)$ is sought. See Fig. 1. The estimator may be a predictor ($m < 0$), a filter ($m = 0$), or a fixed lag smoother ($m > 0$). Here \mathcal{R} , of dimension $\ell|p$, is required to be stable and causal.

Fig. 1 A general linear filtering problem formulation. Based on noisy measurements $y(k+m)$, the signal $f(k)$ is to be estimated. Model errors in transfer functions are described by stochastic error models

The transfer function \mathcal{R} is designed to minimize the averaged mean square error (MSE) criterion (1.2)

$$J = \text{tr} \bar{E} E(\varepsilon(k) \varepsilon(k)^*) = \bar{E} E(\varepsilon(k)^* \varepsilon(k)) = \sum_{i=1}^l \bar{E} E|\varepsilon_i(k)|^2 \quad (2.3)$$

where

$$\varepsilon(k) = (\varepsilon_1(k) \cdots \varepsilon_l(k))^T \triangleq \mathcal{W}(q^{-1})(f(k) - \hat{f}(k|m)).$$

Above, \mathcal{W} is a stable and causal ℓ/ℓ rational weighting matrix, with a stable and causal inverse. It may be used by the designer to emphasize filtering performance in particular frequency bands. In filtering problems, \mathcal{W} is not assumed uncertain.

Model (2.1) offers considerable flexibility. For example, when estimating a signal $u(k)$ in colored noise, we set $\mathcal{G} = \mathcal{D} = \mathbf{I}_n$, giving $f(k) = u(k)$. In deconvolution, or input estimation problems, \mathcal{G} is a dynamic system and $\mathcal{D} = \mathbf{I}_n$. In a state estimation problem, $u(k)$ is the state vector, \mathcal{G} and \mathcal{D} are constant matrices while $\mathcal{H}v(k)$ represents (colored) measurement noise. Other special cases are discussed in [2], [3], and [8].

Example. An application where uncertain dynamics in \mathcal{G} is of interest is equalizer design for digital mobile radio communications [23]. A signal $u(k)$ then propagates along multiple paths, with different time delays, represented by delays in \mathcal{G} . The receiving antenna may have $p > 1$ elements (diversity design). See, e.g., [4]. Thus, an appropriate model of \mathcal{G} is a column vector of FIR channels, i.e., a vector of polynomials. The polynomials coefficients are estimated from short and noisy training sequences, with a known input $\{u(k)\}$. Estimation errors are inevitable. The task of a (robust) equalizer is to estimate $u(k)$, based on noisy measurements $y(k+m)$, a nominal model \mathcal{G}_o , and an estimate of the amount of model uncertainty \square

3 Parameterization of the Model

We choose to parameterize \mathcal{G} and \mathcal{H} as left MFD's having diagonal denominators,¹ while \mathcal{F} , \mathcal{D} , and \mathcal{W} are parameterized in common denominator form

$$\mathcal{G} = \mathbf{A}^{-1} \mathbf{B}; \quad \mathcal{H} = \mathbf{N}^{-1} \mathbf{M} \quad (2.4)$$

$$\mathcal{F} = \frac{1}{D} \mathbf{C}; \quad \mathcal{D} = \frac{1}{T} \mathbf{S}; \quad \mathcal{W} = \frac{1}{U} \mathbf{V}.$$

¹Note that this is a natural choice, if transfer functions are obtained by means of identification.

We have made these choices to obtain tidy and transparent design equations and to avoid coprime factorizations, which are known to be numerically sensitive. In (2.4), it is assumed that \mathcal{G} , \mathcal{H} , and \mathcal{F} may be uncertain. Introduction of uncertainty in the weighting matrix \mathcal{W} is not motivated in filtering problems. Its role in open-loop control will be discussed in Section III-B below. It is shown in Appendix C that uncertainty in \mathcal{D} does not affect the optimal filter design, provided it is uncorrelated to uncertainties in other blocks. Therefore, uncertainty in \mathcal{D} is not introduced.

The extended design models, cf. (1.1) and (2.1)

$$\mathcal{G} = \mathcal{G}_o + \Delta \mathcal{G}, \quad \mathcal{H} = \mathcal{H}_o + \Delta \mathcal{H}, \quad \mathcal{F} = \mathcal{F}_o + \Delta \mathcal{F}$$

are now expressed in polynomial matrix form. Using $\hat{\mathbf{B}}_o = \mathbf{A}_1 \mathbf{B}_o$, $\hat{\mathbf{B}}_1 = \mathbf{A}_o \mathbf{B}_1$ etc. we introduce

$$\begin{aligned} \mathcal{G} &= \mathbf{A}_o^{-1} \mathbf{B}_o + \mathbf{A}_1^{-1} \mathbf{B}_1 \Delta \mathbf{B} \\ &= \mathbf{A}_o^{-1} \mathbf{A}_1^{-1} (\hat{\mathbf{B}}_o + \hat{\mathbf{B}}_1 \Delta \mathbf{B}) \triangleq \mathbf{A}^{-1} \mathbf{B} \\ \mathcal{H} &= \mathbf{N}_o^{-1} \mathbf{M}_o + \mathbf{N}_1^{-1} \mathbf{M}_1 \Delta \mathbf{M} \\ &= \mathbf{N}_o^{-1} \mathbf{N}_1^{-1} (\hat{\mathbf{M}}_o + \hat{\mathbf{M}}_1 \Delta \mathbf{M}) \triangleq \mathbf{N}^{-1} \mathbf{M} \quad (2.5) \\ \mathcal{F} &= \frac{1}{D_o} \mathbf{C}_o + \frac{1}{D_1} \mathbf{C}_1 \Delta \mathbf{C} \\ &= \frac{1}{D_o D_1} (\hat{\mathbf{C}}_o + \hat{\mathbf{C}}_1 \Delta \mathbf{C}) \triangleq \frac{1}{D} \mathbf{C}. \end{aligned}$$

Above, $\mathcal{G}_o = \mathbf{A}_o^{-1} \mathbf{B}_o$ represents the nominal model and $\Delta \mathcal{G} = \mathbf{A}_1^{-1} \mathbf{B}_1 \Delta \mathbf{B}$ the error model. The same holds for \mathcal{H} and \mathcal{F} . The diagonal polynomial matrices $\mathbf{A} = \mathbf{A}_o \mathbf{A}_1$, $\mathbf{N} = \mathbf{N}_o \mathbf{N}_1$, and the polynomials $D = D_o D_1$, T and U are all assumed to be stable, with causal inverses. Denominator polynomials are assumed monic. In the error models, the polynomial D_1 , the diagonal matrices \mathbf{A}_1 and \mathbf{N}_1 , and the matrices \mathbf{C}_1 , \mathbf{B}_1 and \mathbf{M}_1 are fixed. They can be used to tailor the error models for specific needs. For example, if multiplicative error models are deemed appropriate, we use $\mathbf{A}_1 = \mathbf{A}_o$, $\mathbf{B}_1 = \mathbf{B}_o \mathbf{B}_m$ etc., with \mathbf{B}_m to be specified.

The matrices $\Delta \mathbf{B}$, $\Delta \mathbf{C}$, and $\Delta \mathbf{M}$ contain polynomials, with jointly distributed random variables as coefficients. These coefficients parameterize the class of assumed true systems. One particular modeling error is represented by one particular realization of the random coefficients.² Element ij of a stochastic polynomial matrix $\Delta \mathbf{P}$ is denoted

$$\Delta P^{ij} \triangleq [\Delta \mathbf{P}]_{ij} = \Delta p_o^{ij} + \Delta p_1^{ij} q^{-1} + \cdots + \Delta p_{h_p}^{ij} q^{-h_p} \quad (2.6)$$

where h_p is the degree of $\Delta \mathbf{P}$, i.e., the highest degree appearing in any polynomial ΔP^{ij} . All coefficients have zero means, so the nominal model is the average model in the set. Only the second-order moments of the random coefficients need to be specified, since the type of distribution, and higher order moments, will not affect the filter design. The parameter

²For a given system realization, the coefficients are assumed time-invariant and independent of the time-series $u(k)$ and $v(k)$. This is in contrast to the approach of Haddad and Bernstein in [15], who represent the effect of uncertainties by multiplicative noises. For a given uncertainty variance, a noise representation would underestimate the true effect of (time-invariant) parameter deviations in the dynamics.

covariances are denoted $\bar{E}(\Delta p_o^{ij})(\Delta p_o^{\ell k})^*$ and are collected in covariance matrices $\mathbf{P}_{\Delta P}^{(ij, \ell k)}$; see Section II-C.

We now introduce the assumption

- A1. The coefficients of all polynomial elements in ΔC are independent of those in ΔB .

It is possible to exclude Assumption A1, but it does simplify the solution, and it is also reasonable in most practical cases.

Error models can be obtained from ordinary identification experiments, provided the model structures match. For SISO systems, error models can be estimated in presence of under-modeling, using a maximum likelihood approach [11]. Even if the statistics is hard to obtain, one could still use the elements of covariance matrices pragmatically, as robustness "tuning knobs." They are then used similarly as when weighting matrices are adjusted in LQG controller design. An objective could be to obtain reasonable performance for the uncertainty set, for a prespecified acceptable degradation of performance in the nominal case. The error models may also be used to account for a slowly time-varying dynamics [25].

One way of obtaining the models (2.5)–(2.6) is by series expansion of state-space models with parametric uncertainty [37]. Parameter deviations are represented by stochastic variables. For small uncertainties, a first-order expansion can be used, which will directly lead to models of type (2.5). For larger uncertainties, a second-order Taylor expansion is usually sufficient; see [29]. Error models for nonparametric uncertainties can be adjusted directly to frequency domain data. In that context, a very useful concept is provided by the stochastic frequency domain theory of Goodwin and Salgado; see [12].

C. Covariance Matrices for the Stochastic Coefficients

To represent the uncertainties of the system in a natural way, covariance matrices will be organized as follows. The ij th element of a stochastic polynomial matrix ΔP can be expressed as

$$\Delta P^{ij}(q^{-1}) = \varphi^T(q^{-1}) \bar{p}_{ij} \quad (2.7)$$

where

$$\varphi^T(q^{-1}) = (1 \ q^{-1} \ \dots \ q^{-\delta p}) ; \quad \bar{p}_{ij} = (\Delta p_o^{ij} \Delta p_1^{ij} \ \dots \ \Delta p_{\delta p}^{ij})^T. \quad (2.8)$$

The cross covariance matrix $\mathbf{P}_{\Delta P}^{(ij, \ell k)}$, of dimension $\delta p + 1 | \delta p + 1$, between coefficients of $\Delta P^{ij}(q^{-1})$ and $\Delta P^{\ell k}(q^{-1})$, is given by

$$\begin{aligned} \mathbf{P}_{\Delta P}^{(ij, \ell k)} &= \bar{E} \bar{p}_{ij} \bar{p}_{\ell k}^* \\ &= \begin{bmatrix} \bar{E}(\Delta p_o^{ij})(\Delta p_o^{\ell k})^* & \dots & \bar{E}(\Delta p_o^{ij})(\Delta p_{\delta p}^{\ell k})^* \\ \vdots & \ddots & \vdots \\ \bar{E}(\Delta p_{\delta p}^{ij})(\Delta p_o^{\ell k})^* & \dots & \bar{E}(\Delta p_{\delta p}^{ij})(\Delta p_{\delta p}^{\ell k})^* \end{bmatrix} \end{aligned} \quad (2.9)$$

where $\mathbf{P}_{\Delta P}^{(ij, ij)}$ is Hermitian and positive semidefinite, while $\mathbf{P}_{\Delta P}^{(ij, \ell k)} = (\mathbf{P}_{\Delta P}^{(\ell k, ij)})^*$. Thus

$$\bar{E}(\Delta P^{ij} \Delta P^{\ell k}) = \bar{E}(\varphi^T(q^{-1}) \bar{p}_{ij} \bar{p}_{\ell k}^* \varphi(q)) = \varphi^T \mathbf{P}_{\Delta P}^{(ij, \ell k)} \varphi \quad (2.10)$$

With autocovariances, $(ij) = (\ell k)$, we model the uncertainty within each input–output pair. Cross-dependencies between different transfer functions may also be known. For example, uncertainty in one single physical parameter may very well enter into several transfer functions between inputs and outputs. Such effects are captured by cross covariances, $(ij) \neq (\ell k)$.

We collect all matrices of type (2.9) into one large covariance matrix, organized as shown by (2.11) at the bottom of the page. If ΔP has dimension $n|m$, then $\mathbf{P}_{\Delta P}$ is composed of nm by nm covariance matrices $\mathbf{P}_{\Delta P}^{(ij, \ell k)}$. The structure of (2.11) is useful from a design point of view. If, for example, a multivariable moving average model, or FIR model, is to be identified, then (2.11) is the natural way of representing the covariance matrix. If we instead prefer to use the blocks $\mathbf{P}_{\Delta P}^{(ij, \ell k)}$ of (2.11) as multivariable "tuning knobs," a given amount of uncertainty can be assigned to a specific input–output pair

III. DESIGN OF ROBUST FILTERS

A. An Averaged Spectral Factorization

We define an averaged spectral factor $\beta(q^{-1})$ as the numerator polynomial matrix of an averaged innovations model. It constitutes a key element of the robust filter. The average over the set of models, of the spectral density matrix $\Phi_y(e^{j\omega})$ of the measurement $y(k)$ is given by

$$\bar{E}\{\Phi_y(e^{j\omega})\} = \frac{1}{DD_*} A^{-1} N^{-1} \beta \beta_* N_*^{-1} A_*^{-1}.$$

$$\mathbf{P}_{\Delta P} = \begin{pmatrix} \begin{bmatrix} \mathbf{P}_{\Delta P}^{(11,11)} & \dots & \mathbf{P}_{\Delta P}^{(11,1m)} \\ \vdots & \ddots & \vdots \\ \mathbf{P}_{\Delta P}^{(1m,11)} & \dots & \mathbf{P}_{\Delta P}^{(1m,1m)} \end{bmatrix} & \dots & \begin{bmatrix} \mathbf{P}_{\Delta P}^{(11,n1)} & \dots & \mathbf{P}_{\Delta P}^{(11,nm)} \\ \vdots & \ddots & \vdots \\ \mathbf{P}_{\Delta P}^{(1m,n1)} & \dots & \mathbf{P}_{\Delta P}^{(1m,nm)} \end{bmatrix} \\ \vdots & \ddots & \vdots \\ \begin{bmatrix} \mathbf{P}_{\Delta P}^{(n1,11)} & \dots & \mathbf{P}_{\Delta P}^{(n1,1m)} \\ \vdots & \ddots & \vdots \\ \mathbf{P}_{\Delta P}^{(nm,11)} & \dots & \mathbf{P}_{\Delta P}^{(nm,1m)} \end{bmatrix} & \dots & \begin{bmatrix} \mathbf{P}_{\Delta P}^{(n1,n1)} & \dots & \mathbf{P}_{\Delta P}^{(n1,nm)} \\ \vdots & \ddots & \vdots \\ \mathbf{P}_{\Delta P}^{(nm,n1)} & \dots & \mathbf{P}_{\Delta P}^{(nm,nm)} \end{bmatrix} \end{pmatrix} \quad (2.11)$$

square polynomial matrix $\beta(z^{-1})$ is given by the stable solution to

$$\beta\beta_* = E\{NBCC_*B_*N_* + DAMM_*A_*D_*\} \quad (3.1)$$

Since that N^{-1} and A^{-1} are diagonal and will thus commute with the averaged second-order statistics of $y(k)$ is thus described by the same spectral density as for a vector-ARMA model

$$y(k) = \frac{1}{D} A^{-1} N^{-1} \beta \epsilon(k) \quad (3.2)$$

where $\epsilon(k)$ is white with a unit covariance matrix. This model is denoted as the averaged innovations model. (Note that $y(k) \neq y(k)$, but $\Phi_y(\epsilon^{i\omega}) = E\{\Phi_y(\epsilon^{i\omega})\}$.) When constructing the right-hand side of (3.1), the following results are useful.

Lemma 1 Let $H(q, q^{-1})$ be an $m|m$ polynomial matrix with double-sided polynomial elements having stochastic coefficients. Also, let $G(q, q^{-1})$ be an $n|m$ polynomial matrix with polynomial elements having stochastic coefficients, independent of all those of H . Then

$$E[GHG_*] = E[GE(H)G_*] \quad (3.3)$$

□

Proof. See Appendix A.

Now, introduce the double-sided polynomial matrices

$$\begin{aligned} CC_* &\triangleq L(CC_*) & B_\epsilon B_{\epsilon*} &\triangleq E(BCC_*B_*), \\ MM_* &\triangleq E(MM_*) \end{aligned} \quad (3.4)$$

Invoking (2.5) and using the fact that the stochastic coefficients are assumed to be zero mean, gives

$$\begin{aligned} CC_* &= C_o C_{o*} + C_1 E(\Delta C \Delta C_*) C_{1*} \\ B_\epsilon B_{\epsilon*} &= B_o CC_* B_{o*} + B_1 E(\Delta B CC_* \Delta B_*) B_{1*} \\ MM_* &= M_o M_{o*} + M_1 E(\Delta M \Delta M_*) M_{1*} \end{aligned} \quad (3.5)$$

Factorizations to obtain C , B_ϵ , etc. need not be performed. The double-sided polynomial matrices are expressed as CC_* , etc. merely to simplify the notation.

Lemma 2 Let Assumption A1 hold. By using (3.4), (3.5) and invoking Lemma 1, the averaged spectral factorization (3.1) can be expressed as

$$\beta\beta_* = NB_\epsilon B_{\epsilon*} N_* + DAMM_* A_* D_* \quad (3.6)$$

□

Proof. See Appendix A.

With a given right-hand side, (3.6) is just an ordinary polynomial matrix left spectral factorization. It is solvable under the following mild assumption

- **A2.** The averaged spectral density matrix $E\{\Phi_y(\epsilon^{i\omega})\}$ is nonsingular for all ω .

This assumption is equivalent to the right-hand side of (3.6) being nonsingular on $|z| = 1$. Then, the solution to (3.6) is unique, up to a right unitary factor (If $HH_* = I$, then $\beta\beta_* = (\beta H)(H_*\beta_*)$.) Under Assumption A2, a solution exists, with β having nonsingular leading coefficient matrix

$\beta(0)$. Its degree, n/β , will be determined by the maximal degree of the two right-hand side terms of (3.6).¹

To obtain the right-hand side of (3.6), averaged polynomial matrices $\bar{E}(\Delta PH \Delta P_*)$ have to be computed, where $H(q, q^{-1}) = \bar{C}C_*$ or I . It is shown in Appendix B that the ij th element of $\bar{E}(\Delta PH \Delta P_*)$ is given by

$$E[\Delta PH \Delta P_*]_{ij} = \text{tr} H \begin{bmatrix} \varphi^I & 0 \\ 0 & \varphi^J \end{bmatrix} \times \begin{bmatrix} P_{\Delta P}^{(i1,j1)} & P_{\Delta P}^{(im,j1)} \\ P_{\Delta P}^{(i1,jm)} & P_{\Delta P}^{(im,jm)} \end{bmatrix} \begin{bmatrix} \varphi_*^T & 0 \\ 0 & \varphi_*^J \end{bmatrix} \quad (3.7)$$

where φ^T was defined in (2.8). The block covariance matrix in (3.7) constitutes the block-transpose of the ij th block $\begin{bmatrix} & \\ & \end{bmatrix}$ of $P_{\Delta P}$ in (2.11). Average factors in (3.5) are readily obtained by substituting ΔC , ΔB , and ΔM for ΔP in (3.7).

B A Second Spectral Factorization

In the feedforward control problems discussed in Section V, we shall allow for \mathcal{W} being uncertain. Using a common denominator form, \mathcal{W} is parameterized in a similar way as \mathcal{F} in (2.5))

$$\mathcal{W} = V_o \frac{1}{U_o} + \Delta V V_1 \frac{1}{U_1} = \frac{1}{U_o U_1} (V_o + \Delta V V_1) \triangleq \frac{1}{U} V \quad (3.8)$$

A stable square matrix V , with $V(0)$ nonsingular, is introduced as a solution of the right spectral factorization

$$V_* V = E(V_* V) = V_{o*} V_o + V_{1*} E(\Delta V_* \Delta V) V_1 \quad (3.9)$$

Also, introduce the following assumptions

- **A3.** The coefficients of ΔV are independent of all other stochastic coefficients.
- **A4.** The right-hand side of (3.9) is nonsingular on the unit circle.

Whenever \mathcal{W} is known, ($\mathcal{W} = V_o/U_o = V/U$), (3.9) need not be solved, and $V = V_o = V$. This will be the case in filtering problems.

C The Cautious Multivariable Wiener filter

Theorem 1 Assume an extended design model (2.1), (2.4), (2.5), (3.8) to be given, with known covariance matrices (2.11). Assume A1–A4 to hold. A realizable estimator of $f(k)$ then minimizes the averaged MSE (2.3), among all linear time-invariant estimators based on $y(k+m)$, if and only if it has the same coprime factors as

$$f(k|k+m) = \mathcal{R} y(k+m) = \frac{1}{T} V^{-1} Q \beta^{-1} N A y(k+m) \quad (3.10)$$

¹When solving (3.6), we have utilized an algorithm by Ježek and Kučera, presented in [18]. It provides a solution with an upper triangular full rank leading coefficient matrix. For an overview of spectral factorization algorithms, see [22].

Here, $\beta(q^{-1})$ is obtained from (3.6), $\tilde{V}(q^{-1})$ from (3.9) while $Q(q^{-1})$ together with $L_*(q)$, both of dimensions $\ell|p$, is the unique solution to the unilateral Diophantine equation

$$q^{-m}\tilde{V}S\tilde{C}\tilde{C}_*\hat{B}_{o*}N_* = Q\beta_* + qL_*UTDI_p \quad (3.11)$$

with generic⁴ degrees

$$\begin{aligned} nQ &= \max(n\tilde{v} + n\pi + n\tilde{c} + m, nu + nt + nd - 1) \\ nL_* &= \max(n\tilde{c} + n\hat{b}_o + nn - m, n\beta) - 1 \end{aligned} \quad (3.12)$$

where $n\pi = \deg S$ etc. When applying the estimator (3.10) on an ensemble of systems, the minimal criterion value becomes

$$\begin{aligned} \text{tr} \tilde{E}E(\varepsilon(k)\varepsilon(k)^*)_{\min} &= \frac{1}{2\pi j} \oint_{|z|=1} \left\{ L_*\beta_*^{-1}\beta^{-1}L + \frac{1}{UTDD_*T_*U_*} \right. \\ &\quad \times \tilde{V}S\tilde{C} \left[I_n - \tilde{C}_*\hat{B}_{o*}N_*\beta_*^{-1}\beta^{-1}N\hat{B}_o\tilde{C} \right] \\ &\quad \left. \times \tilde{C}_*S_*\tilde{V}_* \right\} \frac{dz}{z}. \end{aligned} \quad (3.13)$$

□

Proof: See Appendix C.

Remarks: The only new type of computation, as compared to the nominal case described in [1]–[3], is the calculation of averaged polynomials using (3.7).

Since both \tilde{V} and β are stable, the estimator \mathcal{R} will be stable.⁵ If Assumptions A2 and A4 hold, $\tilde{V}(0)$ and $\beta(0)$ are nonsingular, so \mathcal{R} will be causal.

Note that the diagonal matrix $NA = N_oN_1A_oA_1$ appears explicitly in the filter (3.10). Thus, important properties of the robust estimator are evident by direct inspection. For example, assume some diagonal elements of N_1^{-1} or A_1^{-1} in the error models to have resonance peaks, indicating large uncertainty at the corresponding frequencies. Then, the filter will have notches, so the filter gain from the uncertain components of $y(k+m)$ will be low at the relevant frequencies.

The nominal Wiener filter has as a component a whitening filter. The robust estimator has a similar structure. By multiplying \mathcal{R} by the stable common factor D/D , the filter in (3.10) will contain $\beta^{-1}NAD$ as right factor. This averaged counterpart of a whitening filter is the inverse of the averaged innovations model (3.2).

The model structure (2.4)–(2.5) was selected to obtain a few simple design equations. Other choices are possible, but lead to various complications. For example, if stochastic polynomials had been introduced in the denominators, no exact analytical solution could have been obtained. Also stability would have been a problem. The use of general left MFD representations, instead of forms with diagonal denominators or common denominators, would have led to a solution involving seven coprime factorizations. Such a solution is presented in [29], but it provides less physical insight. It does also exhibit worse numerical behavior, since algorithms for coprime factorization are numerically sensitive.

⁴In special cases, the degrees may be lower.

⁵Stable common factors may exist in (3.10). They could be detected by calculating invariant polynomials of the involved matrices. If such factors have zeros close to the unit circle, it is advisable to cancel them before the filter is implemented. Otherwise, slowly decaying (initial) transients may deteriorate the filtering performance.

Furthermore, (3.11) is a unilateral Diophantine equation since Q and L_* appear on the same side of the terms in which they are involved. (When the unknowns appear on opposite sides, the equation is bilateral.) This property is a consequence of our choice of U, T , and D as scalar polynomials. Unilateral equations can easily be transformed into a system of linear equations, $AX = B$, where A is a block-Toeplitz matrix. For an example, see Section IV.

Robust design also makes the solution less numerically sensitive. Almost common factors of $\det \beta_*$ and UTD with zeros close to $|z| = 1$ would make the solution of (3.11) numerically sensitive. In the presence of model uncertainty, the risk for this is less than in the nominal case, due to the presence of averaged factors in (3.5). The averaged spectral factor β will, in general, have its zeros more distant from the unit circle than the nominal spectral factor, given by (3.20) below. This reduces the numerical difficulty of solving both (3.6) and (3.11).

For every cautious Wiener filter, there exists a system (without uncertainty) for which this estimator is the optimal Wiener filter (see [29]). It is therefore possible to represent model uncertainties by colored noises and then design a Wiener filter for the corresponding system. This correspondence provides a way of understanding the structure of the above design equations. We do not recommend such an equivalent noise-approach in the actual design, however, for two reasons:

- It is far from trivial to obtain a noise spectrum having similar effect on the filter design as do uncertainties in the block \mathcal{G} in Fig. 1. This is true in particular if the block \mathcal{F} is also uncertain, and if the problem is multivariable.
- It is advantageous from a design point of view to have separate tools which handle different aspects. Error models should represent the effect of modeling uncertainty; noise models should represent disturbances; criterion weighting functions should reflect the priorities of the user. A method which does not distinguish between these aspects will tend to confuse the designer.

The attainable performance improves monotonically with an increasing smoothing lag m . The following result gives the lower bound of the averaged estimation error. This bound can be approached pointwise in the frequency domain for $m < \infty$ by using a criterion filter \mathcal{W} with a high resonance peak.

Corollary 1: The limiting estimator for $m \rightarrow \infty$, the nonrealizable cautious Wiener filter, can be expressed as

$$\lim_{m \rightarrow \infty} q^m \mathcal{R} = \frac{1}{T} S\tilde{C}\tilde{C}_*\hat{B}_{o*}N_*\beta_*^{-1}\beta^{-1}NA. \quad (3.14)$$

Its average performance is given by (3.13) with $L = 0$. If $\mathcal{W} = I_\ell$, the spectral distribution of the lower bound of the estimation error $f(k) - \hat{f}(k|k+m)$ is

$$\begin{aligned} \lim_{m \rightarrow \infty} \text{tr} \tilde{E} \Phi_{f-f}(e^{j\omega}) &= \frac{1}{TDD_*T_*} \text{tr} \{ S\tilde{C} \\ &\quad [I_n - \tilde{C}_*\hat{B}_{o*}N_*\beta_*^{-1}\beta^{-1}N\hat{B}_o\tilde{C}] \tilde{C}_*S_* \}. \end{aligned} \quad (3.15)$$

The bound can be attained at a frequency ω_1 by an estimator with finite smoothing lag, if it is designed using a weighted criterion where

$$U(e^{-i\omega_1}) \approx 0. \quad (3.16)$$

□

Proof: In a similar way as in Appendix A.3 of [8], it is straightforward to show that $L \rightarrow 0$ as $m \rightarrow \infty$ in (3.11). Thus, (3.11) gives

$$\lim_{m \rightarrow \infty} q^m Q = \tilde{V} \tilde{S} \tilde{C} \tilde{C}^* \tilde{B}_{o*} N_* \beta_*^{-1}. \quad (3.17)$$

The substitution of this expression into (3.10) gives (3.14). The use of $L = 0$, $\tilde{V} = I_r$ and $U = 1$ in the integrand of (3.13) gives (3.15). When $U(e^{-i\omega_1}) \approx 0$, we obtain the same effect on the Diophantine equation (3.11) at the frequency ω_1 as if $L \rightarrow 0$: the rightmost term vanishes. Thus, at ω_1 , the gain and the phase of the elements of the polynomial matrix $q^m Q$ are approximately equal to those of (3.17) and the estimation error approaches the lower bound (3.15). ■

Remarks: Note that for realizable estimators (m finite), the lower bound (3.15) is only attainable at distinct frequencies ω_i by means of frequency weighting. For frequencies outside the bandwidth of \mathcal{W} , the estimate may be severely degraded. The results of Corollary 1 are illustrated at the end of the example in Section IV.

D. Analytical Expressions for Performance Evaluation

Theorem 2: Let a nominal estimator \mathcal{R}_n be designed based on a nominal model, with no uncertainties. Applying it, instead of (3.10), on an ensemble of systems results in an increase, as compared to (3.13), of the averaged MSE. The increase is given by

$$\text{tr} \tilde{E} E(\varepsilon(k) \varepsilon(k)^*) - \text{tr} \tilde{E} E(\varepsilon(k) \varepsilon(k)^*)_{\min} = \|\mathcal{W}(\mathcal{R}_n - \mathcal{R}) z^m D^{-1} A^{-1} N^{-1} \beta\|_2^2 \quad (3.18)$$

where β is defined by (3.1)–(3.6) and \mathcal{R} is the robust estimator (3.10). □

Proof: To obtain (3.18), the nominal filter \mathcal{R}_n is expressed as $\mathcal{R} + (\mathcal{R}_n - \mathcal{R})$. The optimality of \mathcal{R} implies that any modification gives an orthogonal contribution to the criterion. This, and the use of the averaged innovations model (3.2), gives (3.18). Mixed terms vanish, due to the orthogonality. ■

Theorem 3: Let a robust estimator \mathcal{R} be designed by (3.6)–(3.11). When applying it on a system equal to the nominal model, the increased MSE, as compared to the minimum obtainable with a nominal estimator \mathcal{R}_n , is

$$\text{tr} E(\varepsilon(k) \varepsilon(k)^*) - \text{tr} E(\varepsilon(k) \varepsilon(k)^*)_n = \|\mathcal{W}(\mathcal{R} - \mathcal{R}_n) z^m D_o^{-1} A_o^{-1} N_o^{-1} \beta_o\|_2^2. \quad (3.19)$$

Here, $D_o^{-1} A_o^{-1} N_o^{-1} \beta_o$ is the nominal innovations model and β_o is obtained from the nominal spectral factorization

$$\beta_o \beta_{o*} = N_o B_o C_o C_{o*} B_{o*} N_{o*} + D_o A_o M_o M_{o*} A_{o*} D_{o*}. \quad (3.20)$$

□

Fig. 2. Model and filter structure in the design example.

Proof: Analogous to that of Theorem 2, by expressing \mathcal{R} as $\mathcal{R}_n + (\mathcal{R} - \mathcal{R}_n)$. ■

Remarks: Expression (3.18) can be used for arbitrary linear estimators \mathcal{R}_n , for example, minimax-designs. Expression (3.19) quantifies the price paid in nominal performance for obtaining a robust design. The averaged innovations model in (3.18), and the nominal innovations model in (3.19), together with the filter \mathcal{W} , can be seen as weighting functions.

The largest effect of robust filtering is obtained at moderate and high signal-to-noise ratios. If the variance of broad-band measurement noise is increased, the gains of both the nominal and the robust filters decrease. If the noise level is high, performance differences between nominal and robust solutions tend to be small.

IV. A DESIGN EXAMPLE

Assume that a scalar signal $u(k)$ is to be estimated. It is described by a first order AR-process without uncertainty

$$u(k) = \frac{1}{1 - 0.5q^{-1}} c(k) \quad ; \quad E c(k)^2 = 1.$$

Thus, $\mathcal{D} = \mathcal{S}/T = 1$, $D_1 = 1$, $D = D_o = 1 - 0.5q^{-1}$, $\hat{C}_o = 1$, and $\hat{C}_1 = 0$. This signal is measured by two transducers ($p = 2$), with nominal models being second order FIR filters. The transducers are modeled by

$$y(k) = (B_o + A_1^{-1} \Delta B) u(k) + w(k)$$

with

$$B_o = \begin{pmatrix} B_o^{11} \\ B_o^{21} \end{pmatrix} = \begin{pmatrix} 0.100 + 0.080q^{-2} \\ 1 - 1.4q^{-1} + 0.92q^{-2} \end{pmatrix} \quad (4.1)$$

$$A_1 = \begin{pmatrix} 1 & 0 \\ 0 & 1 - 0.6q^{-1} \end{pmatrix};$$

$$\Delta B = \begin{pmatrix} \Delta B^{11} \\ \Delta B^{21} \end{pmatrix} = \begin{pmatrix} \Delta b_o^{11} + \Delta b_2^{11} q^{-2} \\ \Delta b_o^{21} + \Delta b_1^{21} q^{-1} + \Delta b_2^{21} q^{-2} \end{pmatrix}.$$

Thus, $B_1 = A_o = I_2$ and $A = A_1$ are used in (2.5). See Fig. 2.

In the first transducer B^{11} , there is only a single uncertain parameter. It affects the coefficients Δb_o^{11} and Δb_2^{11} with opposite signs, so they have zero mean, variance r_1^2 and cross-covariance $-r_1^2$. In the second transducer, the stochastic coefficients are assumed mutually uncorrelated, with zero

means and equal variance r_2^2 . Thus, the auto-covariance matrices are

$$\mathbf{P}_{\Delta\mathbf{B}}^{(11\ 11)} = r_1^2 \begin{pmatrix} 1 & 0 & -1 \\ 0 & 0 & 0 \\ -1 & 0 & 1 \end{pmatrix} \quad \mathbf{P}_{\Delta\mathbf{B}}^{(21\ 21)} = r_2^2 \mathbf{I}_3 \quad (4.2)$$

The scale factors (standard deviations) of the uncertainties are set to

$$r_1 = 0.02 \quad r_2 = 0.10 \quad (4.3)$$

Coefficients of ΔB^{11} and ΔB^{21} are assumed mutually uncorrelated. The complete covariance matrix (2.11) then becomes

$$\mathbf{P}_{\Delta\mathbf{B}} = \begin{pmatrix} \mathbf{P}_{\Delta\mathbf{B}}^{(11\ 11)} & \mathbf{0} \\ \mathbf{0} & \mathbf{P}_{\Delta\mathbf{B}}^{(21\ 21)} \end{pmatrix} \quad (4.4)$$

The measurement noises $w_i(k)$ have variance 0.01. They are white and mutually uncorrelated. Thus, $w(k) = \mathbf{M}v(k)$, with

$$\mathbf{M} = \mathbf{M}_o = 0.1 \mathbf{I}_2 \quad (4.5)$$

The goal is now to design a filter ($m = 0$), which estimates $u(k)$ based on the two measurements $y_1(k)$ and $y_2(k)$. Frequency weighting is not used here ($\mathbf{W} = 1$), but its influence will be illustrated at the end of the example. In (3.4)–(3.5), we obtain

$$\mathbf{C}\mathbf{C}_* = E(\mathbf{C}\mathbf{C}_*) = 1$$

$$\mathbf{M}\mathbf{M}_* = E(\mathbf{M}\mathbf{M}_*) = 0.01 \mathbf{I}_2 \quad (4.6)$$

$$\mathbf{B}_c \mathbf{B}_{c*} = E(\mathbf{B}\mathbf{C}\mathbf{C}_* \mathbf{B}_*) = \mathbf{B}_o \mathbf{B}_{o*} + L(\Delta\mathbf{B}\Delta\mathbf{B}_*)$$

Expression (3.7) or (2.10) gives

$$\begin{aligned} E(\Delta\mathbf{B}^{11}\Delta\mathbf{B}_*^{11}) &= \varphi^T \mathbf{P}_{\Delta\mathbf{B}}^{(11\ 11)} \varphi_*^T \\ &= (1 - q^{-1}q^{-2})r_1^2 \begin{pmatrix} 1 & 0 & -1 \\ 0 & 0 & 0 \\ -1 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1 \\ q \\ q^2 \end{pmatrix} \\ &= r_1^2(-q^2 + 2 - q^{-2}) \end{aligned} \quad (4.7)$$

Note that $E(\Delta\mathbf{B}^{11}\Delta\mathbf{B}_*^{11})$ has zeros at $z = 1$ and at $z = -1$. Thus, the static gain and the high-frequency gain are assumed to be exactly known. Furthermore

$$E(\Delta\mathbf{B}^{21}\Delta\mathbf{B}_*^{21}) = \varphi^T \mathbf{P}_{\Delta\mathbf{B}}^{(21\ 21)} \varphi_*^T = 3r_2^2 \quad (4.8)$$

The spectral factorization (3.6) has dimension $p|p = 2|$. Using (4.6), it reduces to

$$\beta\beta_* = \mathbf{B}_c \mathbf{B}_{c*} + D\mathbf{A}\tilde{\mathbf{M}}\tilde{\mathbf{M}}_*\mathbf{A}_*D_*$$

$$= \mathbf{A}_1\mathbf{B}_o\mathbf{B}_{o*}\mathbf{A}_{1*} + E(\Delta\mathbf{B}\Delta\mathbf{B}_*) + 0.01D\mathbf{A}_1\mathbf{A}_{1*}D_*$$

where

$$E(\Delta\mathbf{B}\Delta\mathbf{B}_*) = \begin{pmatrix} r_1^2(-q^2 + 2 - q^{-2}) & 0 \\ 0 & 3r_2^2 \end{pmatrix}$$

By using the Newton-based algorithm described in [18], a stable averaged spectral factor, with $\beta(0)$ nonsingular, was found to be (4.9), as shown at the bottom of the page.

In the Diophantine equation (3.11), we use $m = 0$, $\mathbf{V} = \mathbf{V} = 1$, $\mathbf{S} = 1$, $\mathbf{C}\mathbf{C}_* = 1$, $\mathbf{N}_* = \mathbf{I}_2$, $\mathbf{U} = 1$, and $\mathbf{T} = 1$. Equation (3.11) thus reduces to

$$\mathbf{B}_{o*}\mathbf{A}_{1*} = \mathbf{Q}\beta_* + \mathbf{L}_*qD\mathbf{I}_2 \quad (4.10)$$

The degrees (3.12) are $n_Q = 0$, $n_{L_*} = 2$. By expressing the polynomial matrices as matrix polynomials, (4.10) becomes

$$\begin{aligned} (\mathbf{B}_0^* + \mathbf{B}_1^*q + \mathbf{B}_2^*q^2)(\mathbf{I}_2 + \mathbf{A}_1^*q) &= \mathbf{Q}_0(\beta_0^* + \beta_1^*q + \beta_2^*q^2 + \beta_3^*q^3) \\ &\quad + (\mathbf{L}_0^* + \mathbf{L}_1^*q + \mathbf{L}_2^*q^2) \\ &\quad \times (-0.5 + q)\mathbf{I}_2 \end{aligned}$$

Transpose this equation and note that since the coefficient matrices are real-valued, $\mathbf{P}_i^{*T} = \mathbf{P}_i$. By equating the two sides for each power of q separately, a linear system of eight equations, in block-Toeplitz form, is obtained

$$\begin{pmatrix} \mathbf{B}_0 \\ \mathbf{B}_1 + \mathbf{A}_1\mathbf{B}_0 \\ \mathbf{B}_2 + \mathbf{A}_1\mathbf{B}_1 \\ \mathbf{A}_1\mathbf{B}_2 \end{pmatrix} = \begin{pmatrix} \beta_0 & -0.5\mathbf{I}_2 & \mathbf{0} & \mathbf{0} \\ \beta_1 & \mathbf{I}_2 & -0.5\mathbf{I}_2 & \mathbf{0} \\ \beta_2 & \mathbf{0} & \mathbf{I}_2 & -0.5\mathbf{I}_2 \\ \beta_3 & \mathbf{0} & \mathbf{0} & \mathbf{I}_2 \end{pmatrix} \begin{pmatrix} \mathbf{Q}_0^T \\ \mathbf{L}_0^T \\ \mathbf{L}_1^T \\ \mathbf{L}_2^T \end{pmatrix}$$

With numerical values from (4.1) and (4.9), we obtain (x), as found at the bottom of the page. The solution is

$$\mathbf{Q} = (0.4005 \quad 0.7746)$$

$$\mathbf{L}_* = (0.0290 + 0.0200q \quad -0.2053 + 0.3224q - 0.1299q^2) \quad (4.11)$$

$$\beta = \begin{pmatrix} 0.1339 - 0.01867q^{-1} + 0.01622q^{-2} & 0.07862 - 0.01488q^{-1} + 0.06905q^{-2} \\ -0.1474q^{-1} + 0.2908q^{-2} - 0.1325q^{-3} & 1.1585 - 2.0327q^{-1} + 1.6219q^{-2} - 0.4765q^{-3} \end{pmatrix} \quad (4.9)$$

$$\begin{pmatrix} 1 \\ 1 \\ 0 \\ -2 \\ 0.8 \\ 1.76 \\ 0 \\ -5.52 \end{pmatrix} = \begin{pmatrix} 1.339 & 0.7862 & -5 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1.1585 & 0 & -5 & 0 & 0 & 0 & 0 \\ -0.1867 & -0.1488 & 1 & 0 & -5 & 0 & 0 & 0 \\ -1.474 & -2.0327 & 0 & 1 & 0 & -5 & 0 & 0 \\ 0.1622 & 0.6905 & 0 & 0 & 1 & 0 & -5 & 0 \\ 2.908 & 1.6219 & 0 & 0 & 0 & 1 & 0 & -5 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ -1.325 & -4.765 & 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} Q_0^{11} \\ Q_0^{12} \\ \ell_0^{11} \\ \ell_0^{12} \\ \ell_1^{11} \\ \ell_1^{12} \\ \ell_2^{11} \\ \ell_2^{12} \end{pmatrix} \quad (x)$$

Fig 3 Bode magnitude plots for the nominal models of the two transducers $B^{11}(q^{-1})$ and $B^{21}(q^{-1})$ (solid). The dotted curves show fifteen realizations of possible true systems. Magnitude plots for the gains from $u_1(k)$ (upper) and $u_2(k)$ (lower) are shown for the robust estimator (dash dotted) and for the nominal Wiener filter design (dashed).

Finally the robust estimator (3.10) becomes

$$\mathbf{R} = \mathbf{Q}\beta^{-1}\mathbf{A}_1 = \frac{1}{R_r}(K_r^{11} K_r^{12}) \quad (4.12)$$

where the monic denominator is $R_r(q^{-1}) = \det \beta(q^{-1}) / \det \beta_0$. We obtain

$$\begin{aligned} K_r^{11} &= 2.9922 - 1.5138q^{-1} + 2.7365q^{-2} - 0.5687q^{-3} \\ K_r^{12} &= 0.4675 - 0.3341q^{-1} - 0.06115q^{-2} + 0.05841q^{-3} \\ R_r &= 1 - 1.8193q^{-1} + 1.6043q^{-2} - 0.6584q^{-3} \\ &\quad + 0.08179q^{-4} + 0.009182q^{-5} \end{aligned}$$

A corresponding nominal estimator (with no uncertainty assumed) is given by $(K_n^{11} K_n^{12})/R_n$ with

$$\begin{aligned} K_n^{11} &= 0.7419 - 1.0943q^{-1} + 0.3617q^{-2} \\ K_n^{12} &= 0.8792 - 0.3767q^{-1} - 0.03145q^{-2} \\ R_n &= 1 - 1.7786q^{-1} + 1.4269q^{-2} - 0.3938q^{-3} \end{aligned}$$

Fig 3 shows the Bode magnitude plots for the robust and nominal estimators. Also shown is the nominal transducer model and 15 randomly chosen systems. These were generated by using $\mathbf{B} = \mathbf{B}_0 + \mathbf{A}_1^{-1}\Delta\mathbf{B}$, with covariance matrix (4.4) and Gaussian distributions. The channel B^{11} has its uncertainty concentrated around the notch while B^{21} is uncertain mainly at low frequencies.

The gains of the nominal estimator (dashed curves) are determined exclusively by the nominal signal to noise ratios. The gains of the robust estimator (dash-dotted) are determined by the balance between noise levels and model uncertainties in the two channels. For example, the robust filter “knows” that channel 1 is well known, as compared to channel 2. Consequently, a higher gain is used from $y_1(k)$ as compared to the nominal case, and a lower gain from $y_2(k)$. The difference, as compared to nominal design, is largest at low frequencies. There, the dynamics of channel 1 is almost perfectly known, while channel 2 is very uncertain. The nominal filter gain in channel 2 is an approximate inverse of the nominal transducer. In contrast to the nominal filter, the robust filter has hardly

Fig 4 Bode magnitude plots for the transfer function from $u(k)$ to $u(k|k)$ for the nominal system with robust and nominal estimators.

Fig 5 MSE for robust (dashed) and nominal filter (solid). One of the four uncertain parameters is varied while the others are held at nominal values. Also shown is the variance of $u(k)$ (upper dotted). It corresponds to the error caused by the trivial estimate $u(k) = 0$. The lower dotted curve is the lower bound achievable with knowledge of the true parameter values. Rings (o) indicate the two standard deviation limits of each parameter.

any peak at the (uncertain) notch around $\omega = 0.7$. It utilizes channel 1 more at this frequency.

Fig 4 shows Bode magnitude plots of transfer functions from $u(k)$ to $u(k|k)$. Since the noise levels are rather low the nominal estimator performs an almost complete inversion of the nominal transducers. The robust estimator is somewhat more cautious, but it also accomplishes a rather good inversion. It utilizes the two measurement signals differently than the nominal estimator.

Fig 5 shows the mean square estimation error when one of the uncertain parameters

$$\Delta b_1^{11} = -\Delta b_2^{11} \triangleq \tau, \quad \Delta b_0^{21} = \Delta b_1^{21} = \Delta b_2^{21}$$

is varied while the others are zero. The four parameters above span the set of assumed true systems, the extended design model. On average, over the four uncorrelated stochastic coefficients, the MSE is 0.32 for the robust filter and 0.90 for the nominal design. Note, however, that when τ is varied, the robust design (dashed) is actually slightly more sensitive than the nominal design. This is a price paid for reducing the sensitivity in the other dimensions.⁶

⁶It is natural that the robust filter has a somewhat increased sensitivity to model errors in channel 1: it has higher gain in that channel. This result is due to the much larger uncertainty in channel 2 at most frequencies. A designer worried about this effect could simply increase the value of the standard deviation τ_1 used in the design.

Fig. 6. The average spectral density of the estimation error $u(k) - \hat{u}(k|k)$. Shown in the plot are the lower bound, according to (3.15), (dash-dotted) and the average spectral densities obtained with (dashed) and without (solid) frequency weighting.

The robust estimator, of course, does not perform as well as the nominal one in the nominal case. This is mainly due to its somewhat lower gain from $u(k)$ to $\hat{u}(k|k)$; see Fig. 4. It is evident from Fig. 5 that this performance loss is very small, as compared to the improvement in nonideal situations.⁷

As an alternative, we tried to investigate minimax designs, i.e., worst case \mathcal{H}_2 -designs, assuming rectangular parameter distributions. This turned out to be prohibitively difficult, since no point where $\min_{\mathcal{R}} \max_{\Delta B} \varepsilon(k)^2 = \max_{\Delta B} \min_{\mathcal{R}} \varepsilon(k)^2$ could be found. These difficulties were in marked contrast to the ease of designing a cautious Wiener filter based on the averaged \mathcal{H}_2 -criterion.

Let us finally illustrate the effect of using a frequency-dependent weighting function in the criterion (2.3). Assume that the performance at frequencies close to $\omega = 0.9$ is of particular importance. The choice

$$\mathbf{W} = \frac{\mathbf{V}}{U} = \frac{1}{1 - 1.2184q^{-1} + 0.9604q^{-2}} \quad (4.13)$$

with a high resonance peak ($|z| = 0.98$) at $\omega = 0.9$ should, according to Corollary 1, result in a performance, at that frequency, close to the lower bound. Fig. 6 confirms this. Performance is substantially degraded at higher frequencies, however, where estimation accuracy is not emphasized.

V. ROBUST FEEDFORWARD CONTROL

A class of feedforward control problems turns out to be dual to the filtering problems discussed in Section II. We include a brief separate discussion of them, since it offers several engineering insights. Feedforward compensation does not affect the classical sensitivity function. The effect of an $x\%$ model deviation at a particular frequency, however, on e.g., the step response, will very much depend on the (nominal) magnitude of the transfer function at that frequency. As the gain at a particular frequency is increased by a feedforward link, model errors at that frequency become more and more noticeable. Therefore, it is of value to take model uncertainty into account explicitly in the feedforward design.

⁷It can also be noted that it is of advantage to use both channels. The minimal MSE, for channels equal to the nominal models, is 0.07 if both channels are used. It is 0.59 if only channel 1 is used and 0.11 if only channel 2 is used. The average MSE of the robust filter (0.32) is in fact lower than the nominal MSE for an estimator which uses only channel 1 (0.59).

Fig. 7. A block diagram which is dual to the one in Fig. 1. Arrows are reversed, summation points and node points are interchanged, and transfer functions are transposed. The corresponding robust control problem is to design \mathcal{R}^T to minimize the average, over the class of models, of the \mathcal{H}_2 -norm of the transfer function from v to $z = (z_1^T \ z_2^T)^T$.

To stress the duality to filtering problems, the output of an uncertain but stable model will be described by

$$\begin{aligned} y(k) &= (\mathbf{G}_o^T + \Delta \mathbf{G}^T) u(k) + \mathbf{D}^T w(k) \\ &= (\mathbf{B}_o^T \mathbf{A}_o^{-T} + \Delta \mathbf{B}^T \mathbf{B}_1^T \mathbf{A}_1^{-T}) u(k) + \frac{1}{T} \mathbf{S}^T w(k) \end{aligned} \quad (5.1)$$

where \mathbf{A}^{-T} denotes inverse and transpose. The rational and polynomial matrices above have properties as outlined in Section II. The matrices \mathbf{G}^T and \mathbf{D}^T may contain delays. Based on possibly delayed or advanced measurements of

$$\begin{aligned} w(k) &= (\mathbf{W}_o^T + \Delta \mathbf{W}^T) v(k) \\ &= \left(\frac{1}{U_o} \mathbf{V}_o^T + \frac{1}{U_1} \Delta \mathbf{V}^T \mathbf{V}_1^T \right) v(k); \\ E(v(k)^T v(k)) &= \mathbf{I}_l \end{aligned} \quad (5.2)$$

a stable controller

$$u(k) = -\mathbf{R}^T w(k + m) \quad (5.3)$$

is to be designed to minimize the averaged \mathcal{H}_2 -norm of the transfer function from v to $(z_1^T \ z_2^T)^T \triangleq ((\mathcal{F}^T y)^T (\mathcal{H}^T u)^T)^T$

$$J' = E \left\| \begin{bmatrix} \mathcal{F}^T (\mathbf{D}^T - \mathbf{G}^T \mathbf{R}^T z^m) \mathbf{W}^T \\ -\mathcal{H}^T \mathbf{R}^T z^m \mathbf{W}^T \end{bmatrix} \right\|_2^2. \quad (5.4)$$

The control weighting $\mathcal{H}^T = \mathbf{M}^T \mathbf{N}^{-T}$ and the output weighting $\mathcal{F}^T = \mathbf{G}^T / D$ are normally specified by the designer and exactly known, i.e., $\Delta \mathcal{H}^T = 0$, $\Delta \mathcal{F}^T = 0$.

Problem formulation (5.1)–(5.4) may represent a disturbance measurement feedforward design. When $m > 0$, the disturbance $w(k)$ can be measured before it affects the system via \mathbf{D}^T . (Such a situation could, equivalently, be described by a delay q^{-m} in \mathbf{D}^T .) The formulation also covers reference feedforward problems, feedforward decoupling, and model matching. Then, $w(k)$ is a command signal and $\mathbf{W}^T v(k)$ is a (possibly uncertain) stochastic model, describing its second order properties. A servo filter \mathbf{R}^T is to be designed, so that the output $-\mathbf{G}^T u(k)$ optimally follows the response model $\mathbf{D}^T w(k)$.⁸ In decoupling problems, \mathbf{D}^T is diagonal.

The duality of feedforward control to the previously discussed filtering problem has been described in [5] for the

⁸The corresponding nominal result (without uncertainty) was discussed in [35] and in [5]. See also [27], where common denominator forms were used. The robust controller for SISO systems was presented in [36]. In [6], the applicability of the averaged \mathcal{H}_2 -criterion is demonstrated for a somewhat more general class of open-loop type problems.

nominal case. The corresponding result in the presence of model errors is given below.

Theorem 4: A feedforward filter, which solves the robust control problem (5.1)–(5.4) under assumptions A1–A4 is given by transposing \mathcal{R} from (3.10), or

$$u(k) = -A^T N^T \beta^{-T} Q^T \hat{V}^{-T} \frac{1}{T} w(k+m) \quad (5.5)$$

where β , Q , and \hat{V} are given by (3.6), (3.11), and (3.9), respectively. \square

Proof: The averaged \mathcal{H}_2 -norm is invariant under transposition. Thus, it fulfills the basic requirement of [5]. By extending the discussion in [5] to uncertain models the result is obtained. \blacksquare

The uncertainty ΔW^T of the disturbance or reference model (5.2) enters via the spectral factorization (3.9). Transposition of (3.9) gives

$$\hat{V}^T \hat{V}_*^T = U_1 V_o^T V_{o*}^T U_{1*} + U_o V_1^T \bar{E}(\Delta V^T \Delta V_*^T) V_{1*}^T U_{o*}. \quad (5.6)$$

This is the kind of left spectral factorization encountered when two noise sources are described by one innovations model. In fact, the uncertainty ΔW^T has exactly the same effect on the controller design as would a measurement noise on $w(k)$, with spectral density $V_1^T \bar{E}(\Delta V^T \Delta V_*^T) V_{1*}^T / U_1 U_{1*}$. We do not need to solve a right spectral factorization (3.9) in this problem. The left spectral factorization (5.6) can be solved instead.

As in the dual filtering case, uncertainty in the direct feedthrough, or response model $\mathcal{D}^T = S^T/T$ does not affect the optimal solution, if it is independent of the uncertainties in \mathcal{G}^T .

VI. CONCLUSIONS

A method for designing robust filters and feedforward controllers, based on imperfectly known linear models, has been presented. Modeling errors were described by sets of models, parameterized by random variables with known covariances. A robust design was obtained by minimizing the \mathcal{H}_2 -norm, averaged with respect to the assumed model errors. The estimator minimizes this criterion by balancing model uncertainties against noise properties, at different frequencies and in different measurement channels. When using robust filtering, the greatest sensitivity reduction is obtained at moderate and high signal to noise ratios. Dually, the largest impact of robust control is obtained for designs with low input penalties.

One variant of the discussed filtering problems is to explicitly define a part of the measurement vector as being a noise-free signal. This signal could e.g., represent known inputs to the system. Such a formulation is also of use in the optimization of decision feedback equalizers for digital communications [33], [34].

There exist efficient numerical algorithms based on a polynomial equations approach. (We have implemented them as MATLAB .m-files, and the code is available upon request.) For multivariable problems of high order and high signal vector dimension p , Riccati-based algorithms do, however, perform better numerically. For dimensions of the measurement vector

up to, say, four, algorithms based directly on polynomial manipulation can in general be used safely. For higher dimensions, we recommend analytical solutions to be obtained by an input–output approach, to gain engineering insight, but algorithms e.g., for spectral factorization to be based on state space formulations, cf. [22]

APPENDIX

A. Proofs of Lemmas

Proof of Lemma 1: Let $G = [G_1^T \cdots G_n^T]^T$, where $G_1 \cdots G_n$ represent the n polynomial row vectors of the $n|m$ matrix. Then, with H of dimension $m|m$, the ij th element of $\bar{E}(GHG_*)$ can be expressed as

$$\begin{aligned} [\bar{E}(GHG_*)]_{ij} &= \bar{E}(G_i H G_{j*}) \\ &= \bar{E}(\text{tr} G_{j*} G_i H) = \text{tr} \bar{E}(G_{j*} G_i) \bar{E}(H). \end{aligned}$$

In the last equality, we used the fact that all elements of $G_{j*} G_i$ are independent of all those of H . We also have that

$$\text{tr} \bar{E}(G_{j*} G_i) \bar{E}(H) = \bar{E}(G_i \bar{E}(H) G_{j*}) = [\bar{E}(G \bar{E}(H) G_*)]_{ij}$$

which proves (3.3), since $\bar{E}(\cdot)$ operates on all elements of GHG_* . \blacksquare

Proof of Lemma 2: If the coefficients of the elements of a polynomial matrix $\Delta P(q^{-1})$ are stochastic variables, then so are the coefficients of the elements in $\Delta P \Delta P_*$. The coefficients of the polynomial elements in ΔC and ΔB are independent and so are the coefficients of the elements in $\Delta C \Delta C_*$ and $\Delta B \Delta B_*$. By defining CC_* as H and ΔB as G in Lemma 1 and using (3.4), the right-hand side of (3.1) becomes

$$\begin{aligned} N \bar{E}[BCC_* B_*] N_* + D A \bar{E}(MM_*) A_* D_* &= \\ = N \bar{E}[B \bar{E}(CC_*) B_*] N_* + D A \bar{E}(MM_*) A_* D_* &= \\ = N \bar{E}[B \hat{C} \hat{C}_* B_*] N_* + D A \hat{M} \hat{M}_* A_* D_* & \end{aligned}$$

By once more utilizing (3.4), we obtain (3.6).

B. Calculation of Averaged Polynomial Matrices

Consider the matrices discussed in Lemma 1. Let the polynomial matrices $G = \Delta P$ and H be of dimensions $n|m$ and $m|m$, respectively. Denote the i -th row of ΔP by

$$\Delta P_i = [\Delta P^{i1} \cdots \Delta P^{im}]$$

where ΔP^{ij} are polynomials with stochastic coefficients. If H is assumed deterministic, the ij th element of $\bar{E}(\Delta P H \Delta P_*)$ can be written as

$$\begin{aligned} \bar{E}[\Delta P H \Delta P_*]_{ij} &= \text{tr} \bar{E}(\Delta P_{j*} \Delta P_i) H = \\ &= \text{tr} H \bar{E}[\Delta P_{j*}^{j1} \cdots \Delta P_{j*}^{jm}]^T [\Delta P^{i1} \cdots \Delta P^{im}] \\ &= \text{tr} H \bar{E} \begin{bmatrix} \Delta P^{i1} \Delta P_{j*}^{j1} & \cdots & \Delta P^{im} \Delta P_{j*}^{jm} \\ \vdots & \ddots & \vdots \\ \Delta P^{i1} \Delta P_{j*}^{jm} & \cdots & \Delta P^{im} \Delta P_{j*}^{jm} \end{bmatrix}. \end{aligned}$$

By using (2.10), we readily obtain (3.7). \blacksquare

C. Proof of Theorem 1

A technique for constructive derivation of polynomial design equations for Wiener filters was presented in [1]. This method is utilized here to minimize (2.3). The estimation error is given by

$$\varepsilon(k) = \mathbf{W}(f(k) - \hat{f}(k|k+m)). \quad (\text{C.1})$$

All admissible alternatives to a proposed estimate $\hat{f}(k|k+m)$, can be described by

$$\hat{d}(k) = \mathbf{R}y(k+m) + \hat{\nu}(k); \quad \hat{\nu}(k) = \mathbf{M}y(k+m). \quad (\text{C.2})$$

Here, \mathbf{M} is a rational, stable and causal, but otherwise arbitrary transfer function. Define the weighted variation

$$\begin{aligned} \nu(k) &\triangleq \mathbf{W}\hat{\nu}(k) \\ &= \frac{1}{U}\mathbf{V}\mathbf{M}q^m \left(\mathbf{A}^{-1}\mathbf{B}\frac{1}{D}\mathbf{C}e(k) + \mathbf{N}^{-1}\mathbf{M}v(k) \right). \end{aligned}$$

Optimality of (2.2) is obtained if no perturbation $\nu(k)$ will improve the average estimator performance. This occurs if and only if the error $\varepsilon(k)$ is orthogonal to any admissible weighted estimator variation $\nu(k)$. In other words

$$\text{tr} \bar{E}E(\varepsilon(k)\nu(k)^*) = \text{tr} \bar{E}E(\varepsilon(k)^*\nu(k)) = 0.$$

Then, the perturbed criterion value becomes

$$\begin{aligned} \bar{J} &= \text{tr} \bar{E}E[\mathbf{W}(f(k) - \hat{d}(k))][\mathbf{W}(f(k) - \hat{d}(k))]^* \\ &= \text{tr} \bar{E}E(\varepsilon(k)\varepsilon(k)^* - \varepsilon(k)\nu(k)^* \\ &\quad - \varepsilon(k)^*\nu(k) + \nu(k)\nu(k)^*) \\ &= \text{tr} \bar{E}E(\varepsilon(k)\varepsilon(k)^* + \nu(k)\nu(k)^*). \end{aligned} \quad (\text{C.3})$$

This expression is evidently minimized by $\nu(k) = 0$.

Since all transfer functions in (2.4) are assumed stable, both $\varepsilon(k)$ and $\nu(k)$ are stationary. Parseval's formula may then be used to express $\text{tr} \bar{E}E\varepsilon(k)\nu(k)^*$ as

$$\begin{aligned} &\text{tr} \bar{E}E \frac{1}{U} \mathbf{V} \left\{ \left(\frac{1}{T} \mathbf{S} - q^m \mathbf{R} \mathbf{A}^{-1} \mathbf{B} \right) \frac{1}{D} \mathbf{C} e(k) - q^m \mathbf{R} \mathbf{N}^{-1} \mathbf{M} v(k) \right\} \\ &\quad \times \left\{ \frac{1}{U} \mathbf{V} \mathbf{M} q^m \left(\mathbf{A}^{-1} \mathbf{B} \frac{1}{D} \mathbf{C} e(k) + \mathbf{N}^{-1} \mathbf{M} v(k) \right) \right\}^* \\ &= \text{tr} \bar{E} \frac{1}{2\pi j} \oint_{|z|=1} \frac{1}{UU_*DD_*} \\ &\quad \times \mathbf{V} \left\{ z^{-m} \frac{1}{T} \mathbf{S} \mathbf{C} \mathbf{C}_* \mathbf{B}_* \mathbf{A}_*^{-1} - \mathbf{R} \mathbf{A}^{-1} \mathbf{N}^{-1} \right. \\ &\quad \times (\mathbf{N} \mathbf{B} \mathbf{C} \mathbf{C}_* \mathbf{B}_* \mathbf{N}_* + \mathbf{D} \mathbf{A} \mathbf{M} \mathbf{M}_* \mathbf{A}_* \mathbf{D}_*) \mathbf{N}_*^{-1} \mathbf{A}_*^{-1} \} \\ &\quad \times \mathbf{M}_* \mathbf{V}_* \frac{dz}{z}. \end{aligned} \quad (\text{C.4})$$

Note that \mathbf{A} and \mathbf{N} commute, since they are diagonal. We are allowed to move the expectation \bar{E} inside the integration, since, for any particular realization of the elements of $\Delta \mathbf{C}$, $\Delta \mathbf{B}$, $\Delta \mathbf{M}$, and $\Delta \mathbf{V}$, all elements of the integrand are Riemann integrable on the unit circle; see e.g., [17, Theorem 3.8]. The use of the trace rotation, $\text{tr} \mathbf{V}\{\cdots\} \mathbf{M}_* \mathbf{V}_* = \text{tr} \mathbf{V}_* \mathbf{V}\{\cdots\} \mathbf{M}_*$,

the spectral factorizations (3.1) and (3.9) and the Assumption A3, leads to

$$\begin{aligned} \text{tr} \bar{E}E\varepsilon(k)\nu(k)^* &= \text{tr} \frac{1}{2\pi j} \oint \frac{1}{UU_*DD_*} \tilde{\mathbf{V}}_* \tilde{\mathbf{V}} \\ &\quad \times \left\{ z^{-m} \bar{E} \left(\frac{1}{T} \mathbf{S} \mathbf{C} \mathbf{C}_* \mathbf{B}_* \right) \mathbf{A}_*^{-1} \right. \\ &\quad \left. - \mathbf{R} \mathbf{A}^{-1} \mathbf{N}^{-1} \beta \beta_* \mathbf{N}_*^{-1} \mathbf{A}_*^{-1} \right\} \mathbf{M}_* \frac{dz}{z}. \end{aligned} \quad (\text{C.5})$$

From (C.5) it is now easy to see that uncertainties in

$$\mathbf{D} = \frac{1}{T_o} \mathbf{S}_o + \frac{1}{T_1} \mathbf{S}_1 \Delta \mathbf{S} = \frac{1}{T_o T_1} (\hat{\mathbf{S}}_o + \hat{\mathbf{S}}_1 \Delta \mathbf{S}) \triangleq \frac{1}{T} \mathbf{S} \quad (\text{C.6})$$

independent of $\Delta \mathbf{C}$, $\Delta \mathbf{B}$ and $\Delta \mathbf{V}$, will not affect the filter design since, using Assumption A1

$$\bar{E} \left(\frac{1}{T} \mathbf{S} \mathbf{C} \mathbf{C}_* \mathbf{B}_* \right) = \bar{E} \left(\frac{1}{T} \mathbf{S} \right) \bar{E} (\mathbf{C} \mathbf{C}_*) \bar{E} (\mathbf{B}_*) = \frac{1}{T_o} \mathbf{S}_o \tilde{\mathbf{C}} \tilde{\mathbf{C}}_* \hat{\mathbf{B}}_{o*}. \quad (\text{C.7})$$

(The minimal criterion value will be affected, however, which is evident from (C.12), below.) In the sequel we thus use $T_o = T$ and $\mathbf{S}_o = \mathbf{S}$.

Using (C.7) in (C.5) and extracting T to the left and \mathbf{A}_*^{-1} to the right now gives

$$\begin{aligned} \text{tr} \bar{E}E\varepsilon(k)\nu(k)^* &= \text{tr} \frac{1}{2\pi j} \oint \frac{1}{UU_*TDD_*} \tilde{\mathbf{V}}_* \tilde{\mathbf{V}} \\ &\quad \left\{ z^{-m} \mathbf{S} \tilde{\mathbf{C}} \tilde{\mathbf{C}}_* \hat{\mathbf{B}}_{o*} - T \mathbf{R} \mathbf{A}^{-1} \mathbf{N}^{-1} \beta \beta_* \mathbf{N}_*^{-1} \right\} \\ &\quad \times \mathbf{A}_*^{-1} \mathbf{M}_* \frac{dz}{z}. \end{aligned} \quad (\text{C.8})$$

To make (C.8) zero, all poles inside $|z| = 1$ are eliminated. This is achieved if, in every element of the integrand, all such poles are cancelled by zeros. We first cancel what can be cancelled by means of \mathbf{R} directly. Thus

$$\mathbf{R} = \frac{1}{T} \tilde{\mathbf{V}}^{-1} \mathbf{Q} \beta \beta^{-1} \mathbf{N} \mathbf{A} \quad (\text{C.9})$$

where $\mathbf{Q}(z^{-1})$ is undetermined. Inserting (C.9) into (C.8) gives $\text{tr} \bar{E}E\varepsilon(k)\nu(k)^*$ as

$$\begin{aligned} &\text{tr} \frac{1}{2\pi j} \oint \frac{1}{UU_*TDD_*} \tilde{\mathbf{V}}_* \\ &\quad \left\{ z^{-m} \tilde{\mathbf{V}} \mathbf{S} \tilde{\mathbf{C}} \tilde{\mathbf{C}}_* \hat{\mathbf{B}}_{o*} \mathbf{N}_* - \mathbf{Q} \beta_* \right\} \mathbf{N}_*^{-1} \mathbf{A}_*^{-1} \mathbf{M}_* \frac{dz}{z}. \end{aligned} \quad (\text{C.10})$$

Now, $U, T, D, \mathbf{A}, \mathbf{N}$ are all stable, so they have zeros only inside $|z| = 1$. The poles of \mathbf{M} are inside $|z| = 1$. This means that $U_*^{-1}, D_*^{-1}, \mathbf{A}_*^{-1}, \mathbf{N}_*^{-1}$, and \mathbf{M}_* have all their poles outside $|z| = 1$. No poles will thus exist inside $|z| = 1$ in (C.10), if and only if

$$z^{-m} \tilde{\mathbf{V}} \mathbf{S} \tilde{\mathbf{C}} \tilde{\mathbf{C}}_* \hat{\mathbf{B}}_{o*} \mathbf{N}_* - \mathbf{Q} \beta_* = z \mathbf{L}_* \mathbf{U} \mathbf{T} \mathbf{D} \mathbf{I}_p \quad (\text{C.11})$$

for some polynomial matrix $\mathbf{L}_*(z)$. This is (3.11), if q is substituted for z . The filter (C.9) coincides with (3.10). Necessity follows because choices of \mathbf{R} other than (C.9) correspond to $\nu(k) \neq 0$ in (C.3).

Unique solvability of (3.11) is demonstrated as follows. The Diophantine equation will always have one or several solutions, since the invariant polynomials of $\mathbf{U} \mathbf{T} \mathbf{D} \mathbf{I}_p$ are all

able, while those of β_* are all unstable. Thus, there exist no common invariant factors. Let (Q_0, L_{0*}) be one solution pair. Every solution to (3.11) can then be expressed as

$$(Q, L_*) = (Q_0 - XqUTDI_p, L_{0*} + X\beta_*)$$

where the polynomial matrix $X(q, q^{-1})$ is undetermined. Now, Q is required to be causal, so it can not have any positive powers of q as arguments, while L_* must contain no negative powers of q , to assure optimality. Thus, $X(q, q^{-1}) = 0$ is the only choice. We conclude that the solution to (3.11) is unique.

The degrees (3.12) are determined by the requirement that the maximum powers of q^{-1} and q are covered on both sides of (3.11). They assure that the number of unknowns equal the number of equations in the corresponding linear system of equations. For details, see [1] or [3].

The minimal average estimation error, $J_{min} = \text{tr} \bar{E}E(\varepsilon(k))_{min}$, is obtained as follows. First insert (3.10) into the criterion (2.3), use Parseval's formula, take expectation and use (3.1), (3.9) and (3.5) in this order. Then we obtain

$$\begin{aligned} J_{min} = & \text{tr} \frac{1}{2\pi j} \oint_{|z|=1} \frac{1}{UU^*TT^*DD_*} \tilde{V}^* \tilde{V} \left\{ S\tilde{C}\tilde{C}_*S_* \right. \\ & - S\tilde{C}\tilde{C}_* \hat{B}_{0*} A_*^{-1} R_* T_* z^{-m} - z^m T^* R A^{-1} \hat{B}_0 \tilde{C}\tilde{C}_* S_* \\ & \left. + T^* R A^{-1} N^{-1} \beta \beta_* N_*^{-1} A_*^{-1} R_* T_* \right\} \frac{dz}{z}. \quad (C.12) \end{aligned}$$

Now, the use of (C.9), $\text{tr} \tilde{V}^* \tilde{V} \{ \dots \} = \text{tr} \tilde{V} \{ \dots \} \tilde{V}^*$ and completing the square gives

$$\begin{aligned} J_{min} = & \text{tr} \frac{1}{2\pi j} \oint_{|z|=1} \frac{1}{UU^*TT^*DD_*} \tilde{V} S\tilde{C}\tilde{C}_* S_* \tilde{V}^* \\ & + \left(z^{-m} \tilde{V} S\tilde{C}\tilde{C}_* \hat{B}_{0*} N_* \beta_*^{-1} - Q \right) \\ & \times \left(\beta^{-1} N \hat{B}_0 \tilde{C}\tilde{C}_* S_* \tilde{V}^* z^m - Q_* \right) \\ & - \tilde{V} S\tilde{C}\tilde{C}_* \hat{B}_{0*} N_* \beta_*^{-1} \beta^{-1} N \hat{B}_0 \tilde{C}\tilde{C}_* S_* \tilde{V}^* \left\} \frac{dz}{z}. \end{aligned}$$

Finally, use Diophantine equation (C.11) in the middle term and rearrange the terms to obtain expression (3.13).

Kenth Öhrn (S'92) was born in Västerås, Sweden, in 1960. He received the M.Sc. degree in engineering physics in 1991 from the Institute of Technology, Uppsala University, Sweden. He is working toward the Swedish Licentiate degree from the same institution.

He works on control problems at ABB Traction AB, Electrical Division in Västerås, Sweden. His current research interests include robust deconvolution and robust feedforward control.

Anders Ahlén (S'80-M'89-SM'90) received the Ph.D. degree in automatic control in 1986 from the Institute of Technology, Uppsala University, Sweden.

Dr. Ahlén held positions as Assistant and Associate Professor of Automatic Control at Uppsala University from 1984-1989 and 1989-1992, respectively. He spent 1991 with the Department of Electrical and Computer Engineering, University of Newcastle, Australia. From July 1992, he has been Associate Professor of Signal Processing at the Systems and Control Group, Uppsala University.

His research interests are currently focused on the robust and adaptive systems in the area of signal processing, communications, and control.

Mikael Sternad (S'83-M'86-SM'90) received the M.S. degree in engineering physics in 1981 and the Ph.D. degree in automatic control in 1987, both from the Institute of Technology, Uppsala University, Sweden.

Dr. Sternad is an Associate Professor at the University of Uppsala, Sweden. He has worked with the Systems and Control Group at Uppsala from 1981-1986 as teaching assistant and from 1987 as Assistant Professor and Associate Professor.

His current research interests include the use of polynomial equations approach on problems in control estimation, digital communications, and the design of adaptive tracking algorithms for systems with fast time variations.

A New Model for Control of Systems with Friction

C. Canudas de Wit, Associate, IEEE, H. Olsson, Student Member, IEEE, K. J. Åström, Fellow, IEEE, and P. Lischinsky

Abstract—In this paper we propose a new dynamic model for friction. The model captures most of the friction behavior that has been observed experimentally. This includes the Stribeck effect, hysteresis, spring-like characteristics for stiction, and varying break-away force. Properties of the model that are relevant to control design are investigated by analysis and simulation. New control strategies, including a friction observer, are explored, and stability results are presented.

I. INTRODUCTION

FRICITION is an important aspect of many control systems both for high quality servo mechanisms and simple pneumatic and hydraulic systems. Friction can lead to tracking errors, limit cycles, and undesired stick-slip motion. Control strategies that attempt to compensate for the effects of friction, without resorting to high gain control loops, inherently require a suitable friction model to predict and to compensate for the friction. These types of schemes are therefore named model-based friction compensation techniques. A good friction model is also necessary to analyze stability, predict limit cycles, find controller gains, perform simulations, etc. Most of the existing model-based friction compensation schemes use classical friction models, such as Coulomb and viscous friction. In applications with high precision positioning and with low velocity tracking, the results are not always satisfactory. A better description of the friction phenomena for low velocities and especially when crossing zero velocity is necessary. Friction is a natural phenomenon that is quite hard to model, and it is not yet completely understood. The classical friction models used are described by static maps between velocity and friction force. Typical examples are different combinations of Coulomb friction, viscous friction, and Stribeck effect [1]. The latter is recognized to produce a destabilizing effect at very low velocities. The classical models explain neither hysteretic behavior when studying friction for nonstationary velocities nor variations in the break-away force with the experimental condition nor small displacements that occur at the contact interface during stiction. The latter

very much resembles that of a connection with a stiff spring with damper and is sometimes referred to as the Dahl effect. Later studies (see, e.g., [1], [2]) have shown that a friction model involving dynamics is necessary to describe the friction phenomena accurately.

A dynamic model describing the spring-like behavior during stiction was proposed by Dahl [3]. The Dahl model is essentially Coulomb friction with a lag in the change of friction force when the direction of motion is changed. The model has many nice features, and it is also well understood theoretically. Questions such as existence and uniqueness of solutions and hysteresis effects were studied in an interesting paper by Bliman [4]. The Dahl model does not, however, include the Stribeck effect. An attempt to incorporate this into the Dahl model was done in [5] where the authors introduced a second-order Dahl model using linear space invariant descriptions. The Stribeck effect in this model is only transient, however, after a velocity reversal and is not present in the steady-state friction characteristics. The Dahl model has been used for adaptive friction compensation [6], [7], with improved performance as the result. There are also other models for dynamic friction. Armstrong-Hélouvy proposed a seven parameter model in [1]. This model does not combine the different friction phenomena but is in fact one model for stiction and another for sliding friction. Another dynamic model suggested by Rice and Ruina [8] has been used in connection with control by Dupont [9]. This model is not defined at zero velocity. In this paper we will propose a new dynamic friction model that combines the stiction behavior, i.e., the Dahl effect, with arbitrary steady-state friction characteristics which can include the Stribeck effect. We also show that this model is useful for various control tasks.

II. A NEW FRICTION MODEL

The qualitative mechanisms of friction are fairly well understood (see, e.g., [1]). Surfaces are very irregular at the microscopic level and two surfaces therefore make contact at a number of asperities. We visualize this as two rigid bodies that make contact through elastic bristles. When a tangential force is applied, the bristles will deflect like springs which gives rise to the friction force; see Fig. 1.

If the force is sufficiently large some of the bristles deflect so much that they will slip. The phenomenon is highly random due to the irregular forms of the surfaces. Haessig and Friedland [10] proposed a bristle model where the random behavior was captured and a simpler reset-integrator model which describes the aggregated behavior of the bristles. The model we propose is also based on the average behavior of

IEEE Log Number 9408272.

Fig. 1. The friction interface between two surfaces is thought of as a contact between bristles. For simplicity the bristles on the lower part are shown as being rigid.

the bristles. The average deflection of the bristles is denoted by z and is modeled by

$$\frac{dz}{dt} = v - \frac{|v|}{g(v)} z \quad (1)$$

where v is the relative velocity between the two surfaces. The first term gives a deflection that is proportional to the integral of the relative velocity. The second term asserts that the deflection z approaches the value

$$z_{ss} = \frac{v}{|v|} g(v) = g(v) \operatorname{sgn}(v) \quad (2)$$

in steady state, i.e., when v is constant. The function g is positive and depends on many factors such as material properties, lubrication, temperature. It need not be symmetrical. Direction dependent behavior can therefore be captured. For typical bearing friction, $g(v)$ will decrease monotonically from $g(0)$ when v increases. This corresponds to the Stribeck effect. The friction force generated from the bending of the bristles is described as

$$F = \sigma_0 z + \sigma_1 \frac{dz}{dt}$$

where σ_0 is the stiffness and σ_1 a damping coefficient. A term proportional to the relative velocity could be added to the friction force to account for viscous friction so that

$$F = \sigma_0 z + \sigma_1 \frac{dz}{dt} + \sigma_2 v. \quad (3)$$

The model given by (1) and (3) is characterized by the function g and the parameters σ_0 , σ_1 and σ_2 . The function $\sigma_0 g(v) + \sigma_2 v$ can be determined by measuring the steady-state friction force when the velocity is held constant. A parameterization of g that has been proposed to describe the Stribeck effect is

$$\sigma_0 g(v) = F_C + (F_S - F_C) e^{-(v/v_s)^2} \quad (4)$$

where F_C is the Coulomb friction level, F_S is the level of the stiction force, and v_s is the Stribeck velocity; see [1]. With this description the model is characterized by six parameters σ_0 , σ_1 , σ_2 , F_C , F_S , and v_s . It follows from (2)–(4) that for steady-state motion the relation between velocity and friction force is given by

$$\begin{aligned} F_{ss}(v) &= \sigma_0 g(v) \operatorname{sgn}(v) + \sigma_2 v \\ &= F_C \operatorname{sgn}(v) + (F_S - F_C) e^{-(v/v_s)^2} \operatorname{sgn}(v) + \sigma_2 v. \end{aligned}$$

Note, however, that when velocity is not constant, the dynamics of the model will be very important and give rise to different types of phenomena. This will be discussed in Section IV.

Relation to the Dahl Model

The model reduces to the Dahl model if $g(v) = F_C/\sigma_0$, and $\sigma_1 = \sigma_2 = 0$. Equations (1) and (3) then give

$$\frac{dF}{dt} = \sigma_0 \frac{dz}{dt} = \sigma_0 v \left(1 - \frac{F}{F_C} \operatorname{sgn}(v) \right). \quad (5)$$

Dahl actually suggested the more general model

$$\frac{dF}{dt} = \sigma_0 v |1 - \frac{F}{F_C} \operatorname{sgn}(v)|^n \operatorname{sgn} \left(1 - \frac{F}{F_C} \operatorname{sgn}(v) \right)$$

see [11]. Most references to Dahl's work, however, do use the simpler model (5). Dahl's model accounts for Coulomb friction but it does not describe the Stribeck effect.

An Extension of the Dahl Model

An attempt to extend Dahl's model to include the Stribeck effect was made by Bliman and Sorine [5]. They replaced the time variable t by a space variable s through the transformation

$$s = \int_0^t |v(\tau)| d\tau.$$

Equation (5) then becomes

$$\frac{dF}{ds} = -\sigma_0 \frac{F}{F_C} + \sigma_0 \operatorname{sgn}(v) \quad (6)$$

which is a linear first-order system if $\operatorname{sgn}(v)$ is regarded as an input. Bliman and Sorine then replaced (6) by the second-order model

$$\frac{d^2 F}{ds^2} + 2\zeta\omega \frac{dF}{ds} + \omega^2 F = \omega^2 F_C \operatorname{sgn}(v)$$

to imitate the Stribeck effect with an overshoot in the response to sign changes in the velocity. This model, however, will only give a spatially transient Stribeck effect after a change of the direction of motion. The Stribeck effect is not present in the steady-state relation between velocity and friction force.

III. MODEL PROPERTIES

The properties of the model given by (1) and (3) will now be explored. To capture the intuitive properties of the bristle model in Fig. 1, the deflection z should be finite. This is indeed the case because we have the following property.

Property 1: Assume that $0 < g(v) \leq a$. If $|z(0)| \leq a$ then $|z(t)| \leq a \forall t \geq 0$.

Proof: Let $V = z^2/2$, then the time derivative of V evaluated along the solution of (1) is

$$\begin{aligned} \frac{dV}{dt} &= z \left(v - \frac{|v|}{g(v)} z \right) \\ &= -|v| |z| \left(\frac{|z|}{g(v)} - \operatorname{sgn}(v) \operatorname{sgn}(z) \right) \end{aligned}$$

TABLE I
PARAMETER VALUES USED IN ALL SIMULATIONS

Parameter	Value	Unit
σ_0	10^5	[N/m]
σ_1	$\sqrt{10^5}$	[Ns/m]
σ_2	0.4	[Ns/m]
F_C	1	[N]
F_S	1.5	[N]
v_S	0.001	[m/s]

The derivative $\frac{dV}{dt}$ is negative when $|z| > g(v)$. Since $g(v)$ is strictly positive and bounded by a , we see that the set $\Omega = \{z : |z| \leq a\}$ is an invariant set for the solutions of (1), i.e., all the solutions of $z(t)$ starting in Ω remain there.

Dissipativity

Intuitively we may expect that friction will dissipate energy. Since our model given by (1) and (3) is dynamic, there may be phases where friction stores energy and others where it gives energy back. It can be proven that the map $\varphi : v \mapsto z$ is dissipative for our model. For more details on the concepts and definitions concerning dissipative systems, see [12].

Property 2: The map $\varphi : v \mapsto z$, as defined by (1), is dissipative with respect to the function $V(t) = \frac{1}{2}z^2(t)$, i.e.,

$$\int_0^t z(\tau)v(\tau) d\tau \geq V(t) - V(0).$$

Proof: It follows from (1) that

$$\begin{aligned} zv &= z \frac{dz}{dt} + \frac{|v|}{g(v)} z^2 \\ &\geq z \frac{dz}{dt}. \end{aligned}$$

Hence

$$\int_0^t z(\tau)v(\tau) d\tau \geq \int_0^t z(\tau) \frac{dz(\tau)}{d\tau} d\tau \geq V(t) - V(0).$$

Linearization in Stiction Regime

To get some insight into the behavior of the model in the stiction regime we will consider a mass m in contact with a fixed horizontal surface. Let x be the coordinate of the mass, i.e., $v = dx/dt$. The equation of motion becomes

$$m \frac{d^2x}{dt^2} = -F = -\sigma_0 z - \sigma_1 \frac{dz}{dt} - \sigma_2 \frac{dx}{dt} \quad (7)$$

where z is given by (1). Linearizing (1) around $z = 0$ and $v = 0$ we get

$$\frac{dz}{dt} = \frac{dx}{dt} \quad (8)$$

Inserting (8) into (7) gives

$$m \frac{d^2x}{dt^2} + (\sigma_1 + \sigma_2) \frac{dx}{dt} + \sigma_0 x = 0. \quad (9)$$

This shows that the system behaves like a damped second-order system. Notice that the bristle stiffness, σ_0 , is usually

Fig. 2. Presliding displacement as described by the model. The simulation was started with zero initial conditions.

very large, and therefore it is essential to have $\sigma_1 \neq 0$ to have a sufficiently damped motion. The viscous friction coefficient, σ_2 , is normally not sufficiently large to provide good damping.

IV. DYNAMICAL MODEL BEHAVIOR

As a preliminary assessment of the model we will investigate its behavior in some typical cases. They correspond to standard experiments that have been performed. In all the simulations the function g has been parameterized according to (4) and the parameter values in Table I have been used. The parameter values have to some extent been based on experimental results [1]. The stiffness σ_0 was chosen to give a presliding displacement of the same magnitude as reported in various experiments. The value of the damping coefficient σ_1 was chosen to give a damping of $\zeta = 0.5$ for the linearized equation (9) with a unit mass. The Coulomb friction level F_C corresponds to a friction coefficient $\mu \approx 0.1$ for a unit mass, and F_S gives a 50% higher friction for very low velocities. The viscous friction σ_2 and the Stribeck velocity v_s are also of the same order of magnitude as given in [1].

The different behaviors shown in the following subsections cannot be attributed to single parameters but rather to the behavior of the nonlinear differential equation (1) and the shape of the function g . The presliding displacement and the varying break-away force are due to the dynamics. This behavior is also present in the Dahl model. The Stribeck shape of g together with the dynamics give rise to the type of hysteresis observed in the subsection on frictional lag.

A. Presliding Displacement

Courtney-Pratt and Eisner have shown that friction behaves like a spring if the applied force is less than the break-away force. If a force is applied to two surfaces in contact there will be a displacement. A simulation was performed to investigate if our model captures this phenomenon. An external force was applied to a unit mass subjected to friction. The applied force was slowly ramped up to 1.425 N which is 95% of F_S . The force was then kept constant for a while and later ramped down to the value -1.425 N, where it was kept constant and then ramped up to 1.425 N again. The results of the simulation are shown in Fig. 2 where the friction force is shown as a function of displacement. The behavior shown in Fig. 2 agrees qualitatively with the experimental results in [13].

Fig. 3. Hysteresis in friction force with varying velocity. The velocity variation with the highest frequency shows the widest hysteresis loop

Fig. 4. Relation between break-away force and rate of increase of the applied force.

B. Frictional Lag

Hess and Soom [14] studied the dynamic behavior of friction when velocity is varied during unidirectional motion. They showed that there is hysteresis in the relation between friction and velocity. The friction force is lower for decreasing velocities than for increasing velocities. The hysteresis loop becomes wider at higher rates of the velocity changes. Hess and Soom explained their experimental results by a pure time delay in the relation between velocity and friction force. Fig. 3 shows a simulation of the Hess–Soom experiment using our friction model. The input to the friction model was the velocity which was changed sinusoidally around an equilibrium. The resulting friction force is given as a function of velocity in Fig. 3. Our model clearly exhibits hysteresis. The width of the hysteresis loop also increases with frequency. Our model thus captures the hysteretic behavior of real friction described in [14].

C. Varying Break-Away Force

The break-away force can be investigated through experiments with stick-slip motion. In [15] it is pointed out that in such experiments the dwell-time when sticking and the rate of increase of the applied force are always related and hence the effects of these factors cannot be separated. The experiment was therefore redesigned so that the time in stiction and the rate of increase of the applied force could be varied independently. The results showed that the break-away force

Fig. 5. Experimental setup for stick-slip motion.

Fig. 6. Simulation of stick-slip motion

did depend on the rate of increase of the force but not on the dwell-time; see also [16]. Simulations were performed using our model to determine the break-away force for different rates of force application. Since the model is dynamic, a varying break-away force can be expected. A force applied to a unit mass was ramped up at different rates, and the friction force when the mass started to slide was determined. Note that since the model behavior in stiction is essentially that of a spring, there will be microscopic motion, i.e., velocity different from zero, as soon as a force is applied. The break-away force was therefore determined at the time where a sharp increase in the velocity could be observed. Fig. 4 shows the force at break-away as a function of the rate of increase of the applied force. The results agree qualitatively with the experimental results in [15] and [16].

D. Stick-Slip Motion

Stick-slip motion is a typical behavior for systems with friction. It is caused by the fact that friction is larger at rest than during motion. A typical experiment that may give stick-slip motion is shown in Fig. 5. A unit mass is attached to a spring with stiffness $k = 2$ N/m. The end of the spring is pulled with constant velocity, i.e., $dy/dt = 0.1$ m/s. Fig. 6 shows results of a simulation of the system based on the friction model in Section II. The mass is originally at rest and the force from the spring increases linearly. The friction force counteracts the spring force, and there is a small displacement. When the applied force reaches the break-away force, in this case approximately $\sigma_0 g(0)$, the mass starts to slide and the friction decreases rapidly due to the Stribeck effect. The spring contracts, and the spring force decreases. The mass slows down and the friction force increases because of the Stribeck effect and the motion stops. The phenomenon then repeats itself. In Fig. 6 we show the positions of the mass and the spring, the friction force and the velocity. Notice the highly irregular behavior of the friction force around the region where the mass stops.

Fig. 8 Simulation of the PID position control problem in Fig. 7

V FEEDBACK CONTROL

To further illustrate the properties of our friction model we will investigate its application to some typical servo problems. First we will use it to show that it predicts limit cycle oscillations in servos with PID control. We will then use it to design observer based friction compensators.

A Limit Cycles Caused by Friction

It has been observed experimentally that friction may give rise to limit cycles in servo drives where the controller has integral action, for references see [2]. This phenomenon is often referred to as hunting.

Consider the linear motion of a mass m at position x . The equation of motion is

$$m \frac{d^2 x}{dt^2} = u - F \quad (10)$$

where $dx/dt = v$ is the velocity, F the friction force given by (3) and u the control force which is given by the PID controller

$$u = -K_v v - K_p (x - x_d) - K_i \int (x - x_d) \quad (11)$$

A block diagram of the system is shown in Fig. 7. In Fig. 8 we show the results of a simulation of the system. The friction parameters are given by Table 1, $m = 1$ and the controller parameters are $K_v = 6$, $K_p = 3$, and $K_i = 4$. The reference position is chosen as $x_d = 1$. The model clearly predicts limit cycles as have been observed experimentally in systems of this type.

B Friction Compensation

Only linear feedback from the position was used in the PID control law (11). Knowledge about friction was not used. It is of course more appealing to make a model-based control that uses the model to predict the friction to compensate for

Fig. 9 Block diagram for the position control problem using a friction observer

it. Since the model is dynamic and has an unmeasurable state, some kind of observer is necessary. This will be discussed next.

Position Control with a Friction Observer Consider the problem of position tracking for the process (10). Assume that the parameters σ_0 , σ_1 , and σ_2 , and the function q in the friction model are known. The state z is, however, not measurable and hence has to be observed to estimate the friction force. For this we use a nonlinear friction observer given by

$$\frac{dz}{dt} = v - \frac{|v|}{q(v)} z - k \epsilon, \quad k > 0 \quad (12)$$

$$\hat{F} = \sigma_0 z + \sigma_1 \frac{dz}{dt} + \sigma_2 v \quad (13)$$

and the following control law

$$u = -H(v) \epsilon + \hat{F} + m \frac{d^2 x_d}{dt^2} \quad (14)$$

where $\epsilon = x - x_d$ is the position error and x_d is the desired reference which is assumed to be twice differentiable. The term $k \epsilon$ in the observer is a correction term from the position error. The closed-loop system is represented by the block diagram in Fig. 9. With the observer based friction compensation, we achieve position tracking as shown in the following theorem.

Theorem 1 Consider system (10) together with the friction model (1) and (3), friction observer (12) and (13), and control law (14). If $H(v)$ is chosen such that

$$G(s) = \frac{\sigma_1 s + \sigma_0}{m s^2 + H(s)}$$

is strictly positive real (SPR) then the observer error, $F - \hat{F}$, and the position error, ϵ , will asymptotically go to zero.

Proof The control law yields the following equations

$$\epsilon = \frac{1}{m s^2 + H(s)} (-\hat{F}) = \frac{\sigma_1 s + \sigma_0}{m s^2 + H(s)} (-z) = -G(s) z$$

$$\frac{dz}{dt} = -\frac{|v|}{q(v)} \tilde{z} + k \epsilon$$

where $\tilde{F} = F - \hat{F}$ and $z = z - \tilde{z}$. Now introduce

$$V = \xi^T P \xi + \frac{z^2}{k}$$

as a Lyapunov function and

$$\begin{aligned} \frac{d\xi}{dt} &= A\xi + B(-z) \\ \dot{\epsilon} &= C\xi \end{aligned}$$

Fig. 10. The block diagram in Fig. 9 redrawn with e and \tilde{z} as outputs of a linear and a nonlinear block, respectively.

which is a state-space representation of $G(s)$. Since $G(s)$ is SPR [17] it follows from the Kalman–Yakubovitch Lemma [17] that there exist matrices $P = P^T > 0$ and $Q = Q^T > 0$ such that

$$\begin{aligned} A^T P + P A &= -Q \\ P B &= C^T. \end{aligned}$$

Now

$$\begin{aligned} \frac{dV}{dt} &= -\xi^T Q \xi - 2\xi^T P B \tilde{z} + \frac{2}{k} \tilde{z} \frac{d\tilde{z}}{dt} \\ &= -\xi^T Q \xi - 2c\tilde{z} + \frac{2}{k} \tilde{z} \left(-\frac{|v|}{g(v)} \tilde{z} + k e \right) \\ &= -\xi^T Q \xi - \frac{2}{k} \frac{|v|}{g(v)} \tilde{z}^2 \\ &\leq -\xi^T Q \xi. \end{aligned}$$

The radial unboundedness of V together with the semi-definiteness of dV/dt implies that the states are bounded. We can now apply LaSalle's theorem to see that $\xi \rightarrow 0$ and $\tilde{z} \rightarrow 0$ which means that both e and \tilde{F} tends to zero and the theorem is proven.

The theorem can also be understood from the following observations. By introducing the observer we get a dissipative map from e to \tilde{z} and by adding the friction estimate to the control signal, the position error will be the output of a linear system operating on \tilde{z} . This means that we have an interconnection of a dissipative system and a linear SPR system as seen in Fig. 10. Such a system is known to be asymptotically stable.

Velocity Control: The same type of observer-based control can be used for velocity control. For this control problem the controller is changed to

$$\begin{aligned} u &= -H(s)e + \hat{F} + m \frac{dv_d}{dt} \\ \frac{d\tilde{z}}{dt} &= v - \frac{|v|}{g(v)} \tilde{z} - k(v - v_d), \quad k > 0 \\ \hat{F} &= \sigma_0 \tilde{z} + \sigma_1 \frac{d\tilde{z}}{dt} + \sigma_2 v \end{aligned} \quad (15)$$

where $v - v_d$ is the velocity error and v_d the desired velocity which is assumed to be differentiable. Velocity tracking is achieved as shown in the following theorem.

Theorem 2: Consider system (10) together with friction model (1) and (3) and observer based control law (15). If $H(s)$ is chosen such that

$$G(s) = \frac{\sigma_1 s + \sigma_0}{m s + H(s)}$$

is strictly positive real, then the observer error, $F - \hat{F}$, and the velocity error will asymptotically go to zero.

Proof: The theorem is proven in the same way as Theorem 1 after observing that the control law yields the following error equations

$$\begin{aligned} v - v_d &= \frac{1}{m s + H(s)} (-\hat{F}) = \frac{\sigma_1 s + \sigma_0}{m s + H(s)} (-\tilde{z}) = -G(s) \tilde{z} \\ \frac{d\tilde{z}}{dt} &= -\frac{|v|}{g(v)} \tilde{z} + k(v - v_d). \end{aligned}$$

This is again an interconnection of a dissipative system with \tilde{z} as its output and a linear SPR system with $v - v_d$ as its output.

To assume that the friction model and its parameters are known exactly is of course a strong assumption. Investigation of the sensitivity of the results to these assumptions is an interesting problem that is outside the scope of this paper. The accuracy required in the velocity measurement is a similar problem.

VI. CONCLUSIONS

A new dynamic model for friction has been presented. The model is simple yet captures most friction phenomena that are of interest for feedback control. The low velocity friction characteristics are particularly important for high performance pointing and tracking. The model can describe arbitrary steady-state friction characteristics. It supports hysteretic behavior due to frictional lag, spring-like behavior in stiction and gives a varying break-away force depending on the rate of change of the applied force. All these phenomena are unified into a first-order nonlinear differential equation. The model can readily be used in simulations of systems with friction.

Some relevant properties of the model have been investigated. The model was used to simulate position control of a servo with a PID controller. The simulations predict hunting as has been observed in applications of position control with integral action. The model has also been used to construct a friction observer and to perform friction compensation for position and velocity tracking. When the parameters are known the observer error and the control error will asymptotically go to zero. Sensitivity studies, parameter estimation and adaptation are natural extensions of this work.

From 1981 to 1982 he worked as a Research Engineer at the Department of Electrical Engineering at the CINVESTAV-IPN in Mexico City. He was a Visiting Researcher in 1985 at Lund Institute of Technology, Sweden. Since 1987 he has been an

Associate Professor in the Department of Automatic Control, Polytechnic of Grenoble, where he teaches and conducts research in the area of adaptive and robot control. He wrote *Adaptive Control of Partially Known Systems: Theory and Applications* (Elsevier, 1988). He is an editor of *Advanced Robot Control* (Springer-Verlag) and also an associate editor of *IEEE TRANSACTIONS ON AUTOMATIC CONTROL*.

Henrik Olsson (S'91) received the M.Sc. degree in electrical engineering from Lund Institute of Technology, Lund, Sweden in 1989.

He spent the academic year 1989-1990 at the Department of Electrical Engineering at University of California, Santa Barbara. Since 1990 he has been with the Department of Automatic Control at Lund Institute of Technology where he is currently completing the Ph.D. degree. His main research interest is in control of nonlinear servosystems.

Karl Johan Åström (M'71-SM'77-F'79) received the Ph.D. degree in automatic control and mathematics from the Royal Institute of Technology (KTH), Stockholm, in 1960.

He has been Professor of Automatic Control at Lund Institute of Technology/Lund University since 1965. His research interests include broad aspects of automatic control, stochastic control, system identification, adaptive control, computer control, and computer-aided control engineering.

Dr. Åström has published five books and many papers. He is a member of the Royal Swedish Academy of Sciences, and the Royal Swedish Academy of Engineering Sciences (IVA). He has received many awards among them the Quazza medal from IFAC in 1987 and the IEEE Medal of Honor in 1993.

Pablo Lischinsky was born in Montevideo, Uruguay, on September 24, 1960. He received the B.S. degree and the M.S. degree in control engineering from the Escuela de Ingeniería de Sistemas, Universidad de Los Andes, Mérida, Venezuela, in 1985 and 1990, respectively. He received the M.S. degree in automatic control in 1993 from the Institut Nationale Polytechnique (INPG-ENSIEG), Laboratoire d'Automatique, Grenoble, France. Since 1990, he has been with the Department of Automatic Control at the Universidad

de Los Andes. Currently he is on leave, working on his Ph.D. dissertation at the Institut Nationale Polytechnique (INPG-ENSIEG). His current research interests are in adaptive control, identification, and computer control of mechanical systems.

Adaptive Nonlinear Design with Controller-Identifier Separation and Swapping

Miroslav Krstić, *Student Member, IEEE*, and Petar V. Kokotović, *Fellow, IEEE*

Abstract—We present a new adaptive nonlinear control design which achieves a complete controller-identifier separation. This modularity is made possible by a strong input-to-state stability property of the new controller with respect to the parameter estimation error and its derivative as inputs. These inputs are independently guaranteed to be bounded by the identifier. The new design is more flexible than the Lyapunov-based design because the identifier can employ any standard update law gradient and least-squares, normalized and unnormalized. A key ingredient in the identifier design and convergence analysis is a nonlinear extension of the well-known linear swapping lemma.

I. INTRODUCTION

THE estimation-based approach to adaptive control has been extremely successful in linear systems. In contrast to the Lyapunov-based approach, which restricts the choice of parameter update laws and controller structures, the estimation-based designs are versatile. For linear systems, any common update law and any stabilizing controller can be employed as long as the boundedness properties of the identifier are sufficient to allow a “certainty-equivalence” design of the controller. This versatility is of conceptual and practical importance. It is due to a modularity feature: the identifier module achieves its boundedness properties independently of the controller module.

Thanks to its versatility, the estimation-based approach unifies many diverse adaptive schemes. For linear systems, this unification, initiated by Egardt [5], was extended by Goodwin and Mayne [6].

Attempts to apply estimation-based designs to nonlinear systems have had only limited success. The nonlinearities were either matched [24], [2], [3] or severely restricted [27], [35], [9], [10], [39]. Otherwise the results were local, i.e., valid in regions which were not a priori verifiable. A cause for this difficulty is a fundamental difference between the instability phenomena in linear and nonlinear systems. The states of an unstable linear system remain bounded over any finite interval, so that there is enough time for the identifier to “catch up.” The situation is fundamentally different in a system with nonlinearities whose growth is faster than linear (x^2 , x_1x_2 , e^{x^2} , etc.). Even a small parameter estimation error may drive the state of such a nonlinear system to infinity in

finite time. This explains why estimation-based designs have been mostly for systems with linearly bounded nonlinearities. Typically, linear growth constraints had to be imposed not only on the plant nonlinearities, but also on those derived during the design.

The only nonlinear estimation-based results which go beyond the linear growth constraints were obtained by Praly *et al.* [29]–[33]. In [32] a unified framework of control Lyapunov functions was used to characterize relationships between nonlinear growth constraints and controller stabilizing properties. In the absence of matching conditions, all the nonlinear estimation-based schemes presented in [32] involved some growth restrictions.

In contrast to the difficulties experienced by the estimation-based designs, the new recursive Lyapunov-based designs for systems in the parametric-strict-feedback form [12], [8], [19], [36] and the output-feedback form [21], [22], [14] were successful in achieving global boundedness and tracking without any restrictions on nonlinearities. However, these designs do not allow any flexibility in the choice of the parameter update law, excluding, for example, the least-squares update laws.

In spite of the previous difficulties with nonlinear estimation-based approaches, their flexibility and modularity motivate us to pursue their development. Since the independence of the identifier is not sufficient for modularity, we place the burden of the task of boundedness on the controller. For parametric-strict-feedback systems we seek (and find!) nonlinear controllers which guarantee boundedness in the presence of bounded parameter uncertainty. More precisely, we consider the parameter estimation error and its derivative as two independent disturbance inputs and design controllers which achieve input-to-state stability [37] (ISS) with respect to those inputs. In addition to such ISS-controllers, we also design weaker SG-controllers which only provide a small gain property and are presented for comparison with linear designs.

These new controllers create a possibility for a complete identifier-controller modularity. The remaining task is to design identifiers with guaranteed boundedness properties. A key ingredient in the identifier design and convergence analysis in this paper is our nonlinear extension of the well known linear swapping lemma [25]. Various forms of swapping were also used in most of the early nonlinear estimation-based results [27], [24], [29], [30], [35], [2], [9], [10], [39]. The identifiers in this paper are based on two different parametric models: the plant model and the error system. They allow a wide variety of update laws—gradient and least-squares, normalized and unnormalized.

The paper is organized as follows. After the problem statement in Section II, in Section III we design the ISS controllers and prove that the input-to-state stability is achieved. Section IV presents the nonlinear swapping lemma. Parameter identifiers with gradient and least-squares update laws are developed in Section V, and the stability proofs for the resulting adaptive systems are given in Section VI. In Section VII we analyze performance of the new adaptive systems. To reveal the connection with linear estimation-based designs we present in Section VIII the design of a weaker SG-controller. The new controller designs and performance are illustrated by examples in Section IX.

II. PROBLEM STATEMENT

The problem is to adaptively control nonlinear systems transformable into the parametric strict-feedback form

$$\begin{aligned} \dot{x}_i &= x_{i+1} + \theta^T \varphi_i(x_1, \dots, x_i), \quad 1 \leq i \leq n-1 \\ \dot{x}_n &= f_0(x)u + \theta^T \varphi_n(x) \\ y &= x_1 \end{aligned} \quad (2.1)$$

where $\theta \in \mathbb{R}^l$ is the vector of unknown constant parameters, f_0 and the components of $\phi = [\varphi_1 \dots \varphi_n]$ are smooth nonlinear functions in \mathbb{R}^n and $f_0(x) \neq 0 \forall x \in \mathbb{R}^n$. Necessary and sufficient conditions for a nonlinear system to be transformable into the form (2.1) are given in [12]. It should be noted that (2.1) is feedback linearizable for any bounded $\theta \in \mathbb{R}^p$.

The control objective is to force the output y of the system (2.1) to asymptotically track the output y_r of a known linear reference model while keeping all the closed-loop signals bounded. The reference model has the form

$$\begin{aligned} \dot{x}_m &= \begin{bmatrix} 0 & & \\ & I_{n-1} & \\ 0 & & \end{bmatrix} x_m + \begin{bmatrix} 0 \\ 0 \\ k_m \end{bmatrix} u_r \\ y_r &= x_{m,1} \end{aligned} \quad (2.2)$$

where $M(s) = s^n + m_{n-1}s^{n-1} + \dots + m_1s + m_0$ is Hurwitz, $k_m > 0$ and $u_r(t)$ is bounded and piecewise continuous. Another way of stating the same objective is to asymptotically track a given reference signal $y_r(t)$ with its first n derivatives known, bounded and piecewise continuous.

The above problem was first posed and solved in [12] using np estimates for p unknown parameters. This number of estimates was subsequently reduced in half in [8]. The over-parametrization was completely removed in [19] by the use of "tuning functions." In [40] the adaptive scheme of [12] was extended and recast in the observer based setting for the case when the nonlinearities in (2.1) are polynomial, a solution employing growth conditions was given in [33]. Possibilities to enlarge the class of systems that can be adaptively stabilized using the approach of [12] were explored in [1] and [36].

The Lyapunov-based results [12], [8], [19], and [36] employ only one type of parameter update laws. To increase the

flexibility in the update law selection we now develop an estimation-based design which treats the controller and identifier as separate modules.

Notation. For vectors we use $\|x\|_P \triangleq (x^T P x)^{1/2}$ to denote the weighted Euclidean norm of x . For matrices $\|X\|_F \triangleq (\text{tr}\{X^T X\})^{1/2} = (\text{tr}\{X X^T\})^{1/2}$ denote the Frobenius and $\|X\|_2$ the induced 2-norm of X . The \mathcal{L}_∞ , \mathcal{L}_2 and \mathcal{L} norms for signals are denoted by $\|\cdot\|_\infty$, $\|\cdot\|_2$ and $\|\cdot\|$ respectively. By referring to a matrix $A(t)$ as exponentially stable we mean that the corresponding LTV system $\dot{x} = A(t)x$ is exponentially stable. The spaces of all signals which are globally bounded, locally bounded and square integrable on $[0, t_f)$, $t_f > 0$ are denoted by $\mathcal{L}_\infty[0, t_f)$, $\mathcal{L}_\infty^l[0, t_f)$ and $\mathcal{L}_2[0, t_f)$ respectively. By saying that a signal belongs to $\mathcal{L}_\infty[0, t_f)$ or to $\mathcal{L}_2[0, t_f)$ we mean that the corresponding bound is independent of t_f .

III. ISS CONTROLLER DESIGN

Our modular estimation-based adaptive design for (2.1) places the burden of achieving boundedness on the controller module. We require that the controller guarantee input to state stability (ISS) with respect to the parameter error $\theta - \hat{\theta} = \tilde{\theta}$ and its derivative $\dot{\theta} = \dot{\tilde{\theta}}$ as disturbance inputs.

Using the backstepping procedure, which is well known from [12], [19] and [18] the adaptive nonlinear controller is recursively designed as follows:

$$z_i = x_i - x_{m,i} - \alpha_{i-1}$$

$$\begin{aligned} \alpha_i(\bar{x}_i, \tilde{\theta}, \bar{x}_{m,i-1}) &= -x_{i-1} - c_i z_i - \theta^T w_i \\ &+ \sum_{k=1}^{i-1} \left(\frac{\partial \alpha_{i-1}}{\partial x_k} x_{k+1} + \frac{\partial \alpha_{i-1}}{\partial x_{m,k}} x_{m,k+1} \right) \\ &- s_i(\bar{x}_i, \tilde{\theta}, \bar{x}_{m,i-1}) \end{aligned}$$

$$u_r(\bar{x}_i, \tilde{\theta}, \bar{x}_{m,i-1}) = \varphi_i - \sum_{k=1}^{i-1} \frac{\partial \alpha_{i-1}}{\partial x_k} \varphi_k, \quad i = 1, \dots, n$$

$$\begin{aligned} u &= \frac{1}{f_0(x)} [\alpha_n(\bar{x}_n, \tilde{\theta}, \bar{x}_{m,n-1}) - m_0 x_{m,1} - \\ &- m_{n-1} x_{m,n} + k_m u_r] \end{aligned} \quad (3.1)$$

where $\bar{x}_i = [x_1 \dots x_i]^T$, $\bar{x}_{m,i-1} = [x_{m,1} \dots x_{m,i-1}]^T$, $c_i > 0$, $i = 1, \dots, n$ and, for notational convenience $\alpha_0 \triangleq 0$, $\alpha_n \triangleq 0$. In these expressions the nonlinear damping functions $s_i(\bar{x}_i, \tilde{\theta}, \bar{x}_{m,i-1})$ are yet to be designed. We will employ these functions to achieve the desired ISS property of the system obtained by the recursive design procedure (3.1). This nonlinear system, called the error system, is readily shown to be

$$\dot{z} = A_-(z, \tilde{\theta}, t)z + W(z, \tilde{\theta}, t)^T \tilde{\theta} + D(z, \tilde{\theta}, t)^T \dot{\tilde{\theta}}, \quad z \in \mathbb{R}^n \quad (3.2)$$

where $z_1 = x_1 - x_{m1} = y - y_r$ represents the tracking error, and A_z, W, D are matrix-valued functions of z, θ and t

$$A_z(z, \theta, t) = \begin{bmatrix} -c_1 - \gamma_1 & 1 & 0 & 0 \\ -1 & -c_2 - \gamma_2 & 1 & 0 \\ 0 & -1 & 0 & 1 \\ 0 & 0 & 0 & -1 - c_n - \gamma_n \end{bmatrix}$$

$$W(z, \theta, t)^T = \begin{bmatrix} w_1^T \\ w_2^T \\ \vdots \\ w_n^T \end{bmatrix} \in \mathbb{R}^{n \times p},$$

$$D(z, \theta, t)^T = \begin{bmatrix} 0 \\ -\frac{\partial \alpha_{i-1}}{\partial \theta} \\ \vdots \\ -\frac{\partial \alpha_{n-1}}{\partial \theta} \end{bmatrix} \in \mathbb{R}^{n \times p} \quad (3.3)$$

The explicit dependence of w_i and $\partial \alpha_{i-1} / \partial \theta$ (and hence γ_i) on t is due to the reference model, for example, $\varphi_1(t_1) = \varphi_1(z_1 + x_{m1}(t))$.

Except for the term $D(z, \theta, t)^T \theta$ the error system (3.2)–(3.3) is similar to the error system in [19] where the term $D(z, \theta, t)^T \theta$ was accounted for by using tuning functions. Here we let both θ and $\dot{\theta}$ appear as disturbance inputs. Their boundedness will later be guaranteed by parameter identifiers.

To design the nonlinear damping functions γ_i , we will employ the following lemma which evolved from [15] and [37].

Lemma 3.1 (Nonlinear Damping) Assume that for the system

$$\dot{x} = f(x, t) + g(x, t)[u + p(x, t)^T d(t)] \quad x \in \mathbb{R}^n, u \in \mathbb{R} \quad (3.4)$$

a feedback control $u = \mu(x, t)$ guarantees

$$\frac{\partial V}{\partial x} [f(x, t) + g(x, t)\mu(x, t)] + \frac{\partial V}{\partial t} \leq -U(x, t) \quad \forall x \in \mathbb{R}^n, \forall t \geq 0 \quad (3.5)$$

where $V, U: \mathbb{R}^n \times \mathbb{R}_+ \rightarrow \mathbb{R}_+$ are positive definite and radially unbounded and V is decrescent and continuously differentiable in x uniformly in t ; $f: \mathbb{R}^n \times \mathbb{R}_+ \rightarrow \mathbb{R}^n$, $g: \mathbb{R}^n \times \mathbb{R}_+ \rightarrow \mathbb{R}^n$, $p: \mathbb{R}^n \times \mathbb{R}_+ \rightarrow \mathbb{R}^q$, $\mu: \mathbb{R}^n \times \mathbb{R}_+ \rightarrow \mathbb{R}$ are continuously differentiable in x and piecewise continuous and bounded in t , and $d: \mathbb{R}_+ \rightarrow \mathbb{R}^q$ is piecewise continuous. Then the feedback control

$$u = \mu(x, t) - \lambda |p(x, t)|^2 \frac{\partial V}{\partial x} (x, t) q(x, t) \quad (3.6)$$

where $\lambda > 0$, guarantees that

- 1) If $d \in \mathcal{L}_\infty$ then $x \in \mathcal{L}_\infty$.
- 2) If $d \in \mathcal{L}_2$ and $U(x, t) \geq c|x|^2 \quad \forall x \in \mathbb{R}^n, \forall t \geq 0$, $c > 0$ then $x \in \mathcal{L}_2$. If, in addition, $d \in \mathcal{L}_\infty$ then $\tau \in \mathcal{L}_\infty$ and $x(t) \rightarrow 0$ as $t \rightarrow \infty$.

Proof 1) Due to (3.5), the derivative of V along (3.4)–(3.6) is

$$\begin{aligned} \dot{V} &= \frac{\partial V}{\partial x} \left[f + g\mu + g \left(-\lambda p^T p \frac{\partial V}{\partial x} q + p^T d \right) \right] + \frac{\partial V}{\partial t} \\ &\leq -U - \lambda \left| p \frac{\partial V}{\partial x} q - \frac{1}{2\lambda} d \right|^2 + \frac{1}{4\lambda} |d|^2 \\ &\leq -U + \frac{1}{4\lambda} |d|^2 \end{aligned} \quad (3.7)$$

and, hence $x \in \mathcal{L}_\infty$.

2) Integrating (3.7) over $[0, \infty)$, we obtain

$$c \|x\|_2^2 \leq \|U\|_1 \leq \frac{1}{4\lambda} \|d\|_2^2 + V(0) \quad (3.8)$$

which implies that $x \in \mathcal{L}_2$. If, in addition, $d \in \mathcal{L}_\infty$ then by part 1) of this lemma, $x \in \mathcal{L}_\infty$ and therefore, $u \in \mathcal{L}_\infty$. Hence $x \in \mathcal{L}_\infty$. By Barbalat's lemma, $x(t) \rightarrow 0$ as $t \rightarrow \infty$. \square

To apply this lemma to the error system (3.2)–(3.3) we first note that the coefficients multiplying θ and $\dot{\theta}$ are w_i and $-\partial \alpha_{i-1} / \partial \theta$ respectively. They play the role of the function p in the lemma, while the part of $(\partial V / \partial x) q$ in (3.6) is played by z_i . Therefore, our choice of nonlinear damping functions is

$$\gamma_i = \kappa_i |w_i|^2 + q_i \left| \frac{\partial \alpha_{i-1}}{\partial \theta} \right|^2 \quad (3.9)$$

where $\kappa_i, q_i, i = 1, \dots, n$ are positive scalar constants.¹ The usefulness of the first term for achieving boundedness was stressed by Kanellakopoulos [16].

With this choice of γ_i , we now prove input-to-state stability of the error system (3.2), (3.3), (3.9) making use of the following constants $c_0 = \min_{1 \leq i \leq n} c_i$, $1/\kappa_0 = \sum_{i=1}^n (1/\kappa_i)$ and $1/q_0 = \sum_{i=1}^n (1/q_i)$.

Lemma 3.2 (ISS) In the error system (3.2), (3.3), (3.9) if $\theta, \dot{\theta} \in \mathcal{L}_\infty[0, t_f)$ then $z, x \in \mathcal{L}_\infty[0, t_f)$ and

$$|z(t)| \leq \frac{1}{2\sqrt{c_0}} \left(\frac{1}{\kappa_0} \|\theta\|_\infty^2 + \frac{1}{q_0} \|\dot{\theta}\|_\infty^2 \right)^{1/2} + |z(0)| e^{-c_0 t} \quad (3.10)$$

Proof Differentiating $\frac{1}{2}|z|^2$ along the solutions of (3.2) we compute

$$\begin{aligned} \frac{d}{dt} \left(\frac{1}{2} |z|^2 \right) &= - \sum_{i=1}^n c_i z_i^2 - \sum_{i=1}^n \left(\kappa_i |w_i|^2 + q_i \left| \frac{\partial \alpha_{i-1}}{\partial \theta} \right|^2 \right) z_i^2 \\ &\quad + \sum_{i=1}^n z_i \left(w_i^T \theta - \frac{\partial \alpha_{i-1}}{\partial \theta} \dot{\theta} \right) \\ &\leq -c_0 |z|^2 - \sum_{i=1}^n \kappa_i \left| w_i z_i - \frac{1}{2\kappa_i} \dot{\theta} \right|^2 \\ &\quad - \sum_{i=1}^n q_i \left| \frac{\partial \alpha_{i-1}}{\partial \theta} z_i + \frac{1}{2q_i} \dot{\theta} \right|^2 \\ &\quad + \left(\sum_{i=1}^n \frac{1}{4\kappa_i} \right) |\dot{\theta}|^2 + \left(\sum_{i=1}^n \frac{1}{4q_i} \right) |\dot{\theta}|^2 \end{aligned} \quad (3.11)$$

¹The constant coefficients q_i are not components of the vector field $g(x)$.

and arrive at

$$\frac{d}{dt} \left(\frac{1}{2} |z|^2 \right) \leq -c_0 |z|^2 + \frac{1}{4} \left(\frac{1}{\kappa_0} |\hat{\theta}|^2 + \frac{1}{g_0} |\dot{\hat{\theta}}|^2 \right). \quad (3.12)$$

From Lemma A.1(i), it follows that

$$\begin{aligned} |z(t)|^2 &\leq |z(0)|^2 e^{-2c_0 t} \\ &\quad + \frac{1}{2} \int_0^t e^{-2c_0(t-\tau)} \left(\frac{1}{\kappa_0} |\hat{\theta}(\tau)|^2 + \frac{1}{g_0} |\dot{\hat{\theta}}(\tau)|^2 \right) d\tau \\ &\leq |z(0)|^2 e^{-2c_0 t} + \frac{1}{4c_0} \left(\frac{1}{\kappa_0} \|\hat{\theta}\|_\infty^2 + \frac{1}{g_0} \|\dot{\hat{\theta}}\|_\infty^2 \right) \end{aligned} \quad (3.13)$$

which proves $z \in \mathcal{L}_\infty$ and (3.10), and by (3.1), $x \in \mathcal{L}_\infty$. \square

The quadratic form of the nonlinear damping functions is only one out of many possible forms. Any power greater than one would yield an ISS property, but the proof with quadratic nonlinear damping is by far the simplest.

A consequence of Lemma 3.2 is that, even when the adaptation is switched off, that is, when the parameter estimate $\hat{\theta}$ is constant ($\dot{\hat{\theta}} = 0$) and the only disturbance input is $\tilde{\theta}$, the state z of the error system (3.2), (3.3), (3.9) remain bounded and converges exponentially to a positively invariant compact set. (Note that since $\dot{\hat{\theta}} = 0$, the terms $-g_i |(\partial \alpha_{i-1} / \partial \hat{\theta})^T|^2 z_i$ are not needed.) Moreover, when the adaptation is switched off, this boundedness result holds even when the unknown parameter is time varying.

Corollary 3.1 (Boundedness Without Adaptation): If $\theta: \mathbb{R}_+ \rightarrow \mathbb{R}^p$ is piecewise continuous and bounded, and $\hat{\theta}$ is constant, then $z, x \in \mathcal{L}_\infty$, and

$$|z(t)| \leq \frac{1}{2\sqrt{c_0 \kappa_0}} \sup_{\tau \geq 0} |\theta(\tau) - \hat{\theta}| + |z(0)| e^{-c_0 t}. \quad (3.14)$$

Proof: Since $\dot{\hat{\theta}}(t) \equiv 0$, (3.12) holds with $\hat{\theta}(t) = \theta(t) - \hat{\theta}$. \square

Thus, the controller module alone guarantees boundedness, and the task of the adaptation is to achieve tracking.

IV. NONLINEAR SWAPPING

The desired boundedness property having been achieved by the controller module, we can now proceed to the identifier module design. To make this design as close to linear designs as possible, we derive a nonlinear counterpart of the ubiquitous Swapping Lemma [25]. This lemma is an analytical device which uses regressor filtering to account for the time-varying nature of the parameter estimates. It was used in the early nonlinear estimation-based results [27], [24], [29], [30], [35], [2], [9], [10], [39]. For a class of nonlinear systems, including our error system (3.2), we provide the following two nonlinear swapping lemmas.

Lemma 4.1 (Nonlinear Swapping): Consider the nonlinear time-varying system

$$\begin{aligned} \Sigma_1: \quad \dot{z} &= A(z, t)z + g(z, t)W(z, t)^T \hat{\theta} - D(z, t)^T \dot{\hat{\theta}} \\ y_1 &= h(z, t)z + l(z, t)W(z, t)^T \hat{\theta} \end{aligned} \quad (4.1)$$

where $\hat{\theta}: \mathbb{R}_+ \rightarrow \mathbb{R}^p$ is differentiable, $A: \mathbb{R}^n \times \mathbb{R}_+ \rightarrow \mathbb{R}^{n \times n}$, $g: \mathbb{R}^n \times \mathbb{R}_+ \rightarrow \mathbb{R}^{n \times m}$, $W: \mathbb{R}^n \times \mathbb{R}_+ \rightarrow \mathbb{R}^{p \times n}$, $D: \mathbb{R}^n \times \mathbb{R}_+ \rightarrow \mathbb{R}^{p \times n}$, $l: \mathbb{R}^n \times \mathbb{R}_+ \rightarrow \mathbb{R}^{r \times m}$ are locally Lipschitz in z and continuous and bounded in t , and $h: \mathbb{R}^n \times \mathbb{R}_+ \rightarrow \mathbb{R}^{r \times n}$ is bounded in z and t . Along with (4.1) consider the linear time-varying systems

$$\Sigma_2: \quad \begin{aligned} \dot{\chi}^T &= A(z, t)\chi^T + g(z, t)W(z, t)^T \\ y_2 &= h(z, t)\chi^T + l(z, t)W(z, t)^T \end{aligned} \quad (4.2)$$

$$\Sigma_3: \quad \begin{aligned} \dot{\psi} &= A(z, t)\psi + \chi^T \dot{\hat{\theta}} + D(z, t)^T \dot{\hat{\theta}} \\ y_3 &= -h(z, t)\psi. \end{aligned} \quad (4.3)$$

Assume that $z(t)$ is continuous on $[0, \infty)$ and there exists a continuously differentiable function $V: \mathbb{R}^n \times \mathbb{R}_+ \rightarrow \mathbb{R}_+$ such that

$$\alpha_1 |\zeta|^2 \leq V(\zeta, t) \leq \alpha_2 |\zeta|^2 \quad (4.4)$$

and for each $z \in C^0$

$$\frac{\partial V}{\partial \zeta} A(z, t)\zeta + \frac{\partial V}{\partial t} \leq -\alpha_3 |\zeta|^2 \quad (4.5)$$

$\forall t \geq 0, \forall \zeta \in \mathbb{R}^n, \alpha_1, \alpha_2, \alpha_3 > 0$. Then for $\forall z(0), \psi(0) \in \mathbb{R}^n, \forall \chi(0) \in \mathbb{R}^{p \times n}, \forall t \geq 0$ the outputs of systems (4.1)–(4.3) are related by

$$y_1 = y_2 \hat{\theta} + y_3 + y_e \quad (4.6)$$

where y_e is bounded and exponentially decaying.

Proof: Due to the continuity of $z(t)$, we see that $g(z(t), t)$, $W(z(t), t)$ and $D(z(t), t)$ are continuous in t . Since $gW \in \mathcal{L}_{\infty}$ and Σ_2 is a linear time-varying system, then $\chi \in \mathcal{L}_{\infty}$. Therefore $(\chi + D)^T \hat{\theta} \in \mathcal{L}_{\infty}$, which implies $\psi \in \mathcal{L}_{\infty}$ because Σ_3 is a linear time-varying system. Differentiating $\tilde{z} = z + \psi - \chi^T \hat{\theta}$, we obtain

$$\dot{\tilde{z}} = \dot{z} + \dot{\psi} - \dot{\chi}^T \hat{\theta} - \chi^T \dot{\hat{\theta}} = A(z, t)\tilde{z} \quad (4.7)$$

which together with (4.4)–(4.5) yields

$$\dot{V}(\tilde{z}, t) = \frac{\partial V}{\partial \tilde{z}} A(z, t)\tilde{z} + \frac{\partial V}{\partial t} \leq -\alpha_3 |\tilde{z}|^2 \leq -\frac{\alpha_3}{\alpha_2} V. \quad (4.8)$$

Therefore $V(t) \leq V(0)e^{-(\alpha_3/\alpha_2)t}$, and, hence

$$|\tilde{z}(t)| \leq \sqrt{\frac{\alpha_2}{\alpha_1}} |\tilde{z}(0)| e^{-(\alpha_3/2\alpha_2)t}. \quad (4.9)$$

Now, (4.1)–(4.3) imply that $y_e = y_1 - y_2 \hat{\theta} - y_3 = h(z, t)\tilde{z}$. Since $h(z, t)$ is bounded then y_e is bounded and decays to zero exponentially.

Remark 4.1: When $D(z, t) \equiv 0$, the result of Lemma 4.1 is reminiscent of Morse's linear Swapping Lemma [25]. To see this we rewrite (4.6) as

$$T_z[W^T \hat{\theta}] = T[W^T] \hat{\theta} + T_h[T_g[W^T] \hat{\theta}] + y_e. \quad (4.10)$$

In this notation $T_z W^T \tilde{\theta} \mapsto y_1$ is the nonlinear operator defined by (4.1) with $D(z, t) \equiv 0$, while the system

$$\begin{aligned}\xi &= A(z(t), t)\xi + g(z(t), t)u \\ y &= h(z(t), t)\xi + l(z(t), t)u\end{aligned}\quad (4.11)$$

is used to define the linear time-varying operators $T u \mapsto y$, $T_g u \mapsto y$ for $h = I$ and $l = 0$, $T_h u \mapsto y$ for $g = I$ and $l = 0$. When A , g , h and l are constant, then the operator $T_z(y) = T(s) = h(sI - A)^{-1}g + l$ is a proper stable rational transfer function, $T_g(s) = (sI - A)^{-1}g$, $T_h(s) = -h(sI - A)^{-1}$, and Lemma 4.1 reduces to Lemma 3.6.5 from [34]. \square

In some texts on adaptive linear control, an extended result which guarantees that $\tilde{\theta} \in \mathcal{L}_2 \Rightarrow T_z[W^T \tilde{\theta}] - T[W^T] \tilde{\theta} \in \mathcal{L}_2$ is also referred to as Swapping Lemma. Our next lemma is a nonlinear time-varying generalization of this result.

Lemma 4.2 Consider systems (4.1)–(4.3) with the same set of assumptions as in Lemma 4.1. Further, assume that $z \in \mathcal{L}_\infty$. If $\tilde{\theta} \in \mathcal{L}_2$, then

$$y_1 - y_2 \tilde{\theta} \in \mathcal{L}_2 \quad (4.12)$$

If $\theta \in \mathcal{L}_2 \cap \mathcal{L}_\infty$ then

$$\lim_{t \rightarrow \infty} [y_1(t) - y_2(t)\theta(t)] = 0 \quad (4.13)$$

Proof Since $z \in \mathcal{L}_\infty$ then $gW^T D \in \mathcal{L}_\infty$. Due to the exponential stability of $A(z, t)$, it follows that $\chi \in \mathcal{L}_\infty$. By Lemma 4.1, $y_e \in \mathcal{L}_2$. We need to prove that $y_3 \in \mathcal{L}_2$. The solution of (4.3) is

$$\begin{aligned}\psi(t) &= \Phi_z(t, 0)\psi(0) \\ &+ \int_0^t \Phi_z(t, \tau)[\chi(\tau) + D(z(\tau), \tau)]^T \tilde{\theta}(\tau) d\tau\end{aligned}\quad (4.14)$$

where (4.4)–(4.5) guarantee that the state transition matrix $\Phi_z: \mathbb{R}_+ \times \mathbb{R}_+ \rightarrow \mathbb{R}^{n \times n}$ is such that $|\Phi_z(t, \tau)|_2 \leq ke^{-\alpha(t-\tau)}$, $k, \alpha > 0$. Since χ and D are bounded then

$$\begin{aligned}|\psi(t)| &\leq ke^{-\alpha t}|\psi(0)| + k\|\chi + D\|_\infty \int_0^t e^{-\alpha(t-\tau)}|\tilde{\theta}(\tau)| d\tau \\ &\leq ke^{-\alpha t}|\psi(0)| + k\|\chi + D\|_\infty \left(\int_0^t e^{-\alpha(t-\tau)} d\tau \right)^{1/2} \\ &\quad \left(\int_0^t e^{-\alpha(t-\tau)} |\tilde{\theta}(\tau)|^2 d\tau \right)^{1/2} \\ &\leq ke^{-\alpha t}|\psi(0)| + k\|\chi + D\|_\infty \frac{1}{\sqrt{\alpha}} \\ &\quad \left(\int_0^t e^{-\alpha(t-\tau)} |\tilde{\theta}(\tau)|^2 d\tau \right)^{1/2}\end{aligned}\quad (4.15)$$

where the second inequality is obtained using the Schwartz inequality. By squaring (4.15) and integrating over $[0, t]$ we obtain

$$\begin{aligned}\int_0^t |\psi(\tau)|^2 d\tau &\leq \frac{k^2}{2\alpha} |\psi(0)|^2 + \frac{k^2}{\alpha} \|\chi + D\|_\infty^2 \\ &\quad \int_0^t \left[\int_0^\tau e^{-\alpha(\tau-s)} |\tilde{\theta}(s)|^2 ds \right] d\tau\end{aligned}\quad (4.16)$$

Changing the sequence of integration, (4.16) becomes

$$\begin{aligned}\int_0^t |\psi(\tau)|^2 d\tau &\leq \frac{k^2}{2\alpha} |\psi(0)|^2 + \frac{k^2}{\alpha} \|\chi + D\|_\infty^2 \\ &\quad \int_0^t e^{-\alpha s} |\tilde{\theta}(s)|^2 \left(\int_s^t e^{-\alpha \tau} d\tau \right) ds \\ &\leq \frac{k^2}{2\alpha} |\psi(0)|^2 + \frac{k^2}{\alpha} \|\chi + D\|_\infty^2 \\ &\quad \int_0^t e^{-\alpha s} |\tilde{\theta}(s)|^2 \frac{1}{\alpha} e^{-\alpha s} ds\end{aligned}\quad (4.17)$$

because $\int_s^t e^{-\alpha \tau} d\tau = 1/\alpha (e^{-\alpha s} - e^{-\alpha t}) \leq (1/\alpha) e^{-\alpha s}$. Now the cancellation $e^{\alpha s} e^{-\alpha s} = 1$ in (4.17) yields

$$\|\psi\|_2 \leq \frac{k}{\sqrt{2\alpha}} |\psi(0)| + \frac{k}{\alpha} \|\chi + D\|_\infty \|\tilde{\theta}\|_2 < \infty \quad (4.18)$$

which proves $\psi \in \mathcal{L}_2$. Due to the uniform boundedness of h it follows that $y_3 \in \mathcal{L}_2$. This proves (4.12). When $\theta \in \mathcal{L}_2 \cap \mathcal{L}_\infty$ then $\psi \in \mathcal{L}_2 \cap \mathcal{L}_\infty$ and $\psi \in \mathcal{L}_\infty$. Thus, by Barbalat's lemma $\psi(t) \rightarrow 0$ and hence $y_3(t) \rightarrow 0$ as $t \rightarrow \infty$. This proves (4.13) because $y_e(t) \rightarrow 0$ as $t \rightarrow \infty$.

Remark 4.2 When $D(\cdot, t) \equiv 0$ we rewrite (4.12) as

$$T[W^T \tilde{\theta}] - I[W^T] \tilde{\theta} \in \mathcal{L}_2 \quad (4.19)$$

and (4.13) as

$$\lim_{t \rightarrow \infty} \{T_z[W^T \tilde{\theta}](t) - (I[W^T] \tilde{\theta})(t)\} = 0 \quad (4.20)$$

with T_z and T as in Remark 4.1. For constant A , g , h and l the operator $T_z = T$ is a proper stable rational transfer function, and Lemma 4.2 reduces to Lemma 2.11 from [28]. \square

V. PARAMETER IDENTIFIERS

We are now in the position to design the identifier module by applying the Nonlinear Swapping Lemma 4.1 to either z - or x -system. Each of the two types of identifiers, with z -swapping and with x -swapping, can be implemented with either gradient or least-squares update laws. These parameter identifiers are variants of the regressor filtering identifiers in [32].

A. z -Swapping

For the error system (3.2) we introduce the filters

$$\begin{aligned}\chi_0 &= A_z(z, \theta, t)\chi_0 + W(z, \theta, t)^T \theta - D(z, \theta, t)^T \theta, \\ \chi_0 &\in \mathbb{R}^n\end{aligned}\quad (5.1)$$

$$\chi^T = A_z(z, \theta, t)\chi^T + W(z, \theta, t)^T, \quad \chi \in \mathbb{R}^{p \times n} \quad (5.2)$$

and define the estimation error as

$$\epsilon = z + \chi_0 - \chi^T \theta, \quad \epsilon \in \mathbb{R}^n \quad (5.3)$$

Along with ϵ we define

$$\epsilon = z + \chi_0 - \chi^T \theta \quad \epsilon \in \mathbb{R}^n \quad (5.4)$$

Then we obtain

$$\dot{\epsilon} = \chi^T \dot{\theta} + \dot{\epsilon} \quad (5.5)$$

and, by differentiating (5.4) and substituting (3.2), (5.1) and (5.2), recognize that \tilde{e} is governed by

$$\dot{\tilde{e}} = A_z(z, \hat{\theta}, t)\tilde{e}. \quad (5.6)$$

The update laws for $\hat{\theta}$ employ the estimation error ϵ and the filtered regressor χ . The gradient update law is

$$\dot{\hat{\theta}} = \Gamma \frac{\chi \epsilon}{1 + \nu |\chi|_{\mathcal{F}}^2}, \quad \Gamma = \Gamma^T > 0, \nu \geq 0 \quad (5.7)$$

and the least-squares law is

$$\dot{\hat{\theta}} = \Gamma \frac{\chi \epsilon}{1 + \nu |\chi|_{\mathcal{F}}^2}$$

$$\dot{\Gamma} = -\Gamma \frac{\chi \chi^T}{1 + \nu |\chi|_{\mathcal{F}}^2} \Gamma, \quad \Gamma(0) = \Gamma^T(0) > 0, \nu \geq 0. \quad (5.8)$$

By allowing $\nu = 0$ we encompass unnormalized update laws.

Since the regressor χ is a matrix, we use the Frobenius norm $|\chi|_{\mathcal{F}}$ to avoid the need for on-line matrix inversion, as well as unnecessary algebraic complications in the stability arguments that would arise from applying update laws $\dot{\hat{\theta}} = \Gamma \chi (I_p + \nu \chi^T \Gamma \chi)^{-1} \epsilon$ with Γ fixed or updated with $\dot{\Gamma} = -\Gamma \chi (I_p + \nu \chi^T \Gamma \chi)^{-1} \chi^T \Gamma$.

The boundedness properties of the z -swapping identifiers are as follows.

Lemma 5.1: Suppose the solution $x(t)$ is defined on $[0, t_f)$. The update laws (5.7) and (5.8) guarantee that

- 1) if $\nu = 0$ then $\hat{\theta} \in \mathcal{L}_{\infty}[0, t_f)$ and $\epsilon \in \mathcal{L}_2[0, t_f)$,
- 2) if $\nu > 0$ then $\hat{\theta} \in \mathcal{L}_{\infty}[0, t_f)$ and

$$\hat{\theta}, \frac{\epsilon}{\sqrt{1 + \nu |\chi|_{\mathcal{F}}^2}} \in \mathcal{L}_2[0, t_f) \cap \mathcal{L}_{\infty}[0, t_f).$$

Proof: (Sketch) Noting from (5.6) and (3.3) that $d/dt (\frac{1}{2} |\tilde{e}|^2) = -\sum_{i=1}^n c_i \tilde{e}_i^2 \leq -c_0 |\tilde{e}|^2$ it is clear that the positive definite function $V = \frac{1}{2} |\hat{\theta}|_{\Gamma^{-1}}^2 + 1/2 c_0 |\tilde{e}|^2$ can be used as in [6], [34], [7] to prove the lemma. \square

As explained in [6], various modifications of the least-squares algorithm (covariance resetting, exponential data weighting, etc.) do not affect the properties established by Lemma 5.1. *A priori* knowledge of parameter bounds can also be incorporated via projection.

B. x -Swapping

A different identifier results if instead of the error system (3.2) we consider the plant (2.1) rewritten in the form

$$\dot{x} = Ex + e_n \beta_0(x)u + \phi(x)^T \theta \quad (5.9)$$

where

$$E = \begin{bmatrix} 0 & & & \\ \vdots & I_{n-1} & & \\ 0 & \cdots & 0 & \end{bmatrix}.$$

We employ the following filters

$$\dot{\Omega}_0 = \bar{A}(t)(\Omega_0 - x) + Ex + e_n \beta_0(x)u, \quad \Omega_0 \in \mathbb{R}^n \quad (5.10)$$

$$\dot{\Omega}^T = \bar{A}(t)\Omega^T + \phi(x)^T, \quad \Omega \in \mathbb{R}^{p \times n} \quad (5.11)$$

where $\bar{A}(t)$ is an exponentially stable matrix. We define the estimation error vector

$$\epsilon = x - \Omega_0 - \Omega^T \hat{\theta}, \quad \epsilon \in \mathbb{R}^n. \quad (5.12)$$

and along with it

$$\tilde{\epsilon} = x - \Omega_0 - \Omega^T \theta, \quad \tilde{\epsilon} \in \mathbb{R}^n. \quad (5.13)$$

Then we obtain

$$\epsilon = \Omega^T \tilde{\theta} + \tilde{\epsilon} \quad (5.14)$$

and, by differentiating (5.13) and substituting (5.9), (5.10) and (5.11), recognize that $\tilde{\epsilon}$ is governed by

$$\dot{\tilde{\epsilon}} = \bar{A}(t)\tilde{\epsilon}. \quad (5.15)$$

The update laws for $\hat{\theta}$ employ the estimation error ϵ and the filtered regressor Ω . The gradient update law is

$$\dot{\hat{\theta}} = \Gamma \frac{\Omega \epsilon}{1 + \nu |\Omega|_{\mathcal{F}}^2}, \quad \Gamma = \Gamma^T > 0, \nu \geq 0 \quad (5.16)$$

and the least-squares law is

$$\dot{\hat{\theta}} = \Gamma \frac{\Omega \epsilon}{1 + \nu |\Omega|_{\mathcal{F}}^2}$$

$$\dot{\Gamma} = -\Gamma \frac{\Omega \Omega^T}{1 + \nu |\Omega|_{\mathcal{F}}^2} \Gamma, \quad \Gamma(0) = \Gamma^T(0) > 0, \nu \geq 0. \quad (5.17)$$

Again, by allowing $\nu = 0$ we encompass unnormalized gradient and least-squares. Concerning the update law modifications, the same comments from the preceding subsection are also in order here.

Lemma 5.2: Suppose $x(t)$ is defined on $[0, t_f)$, and $\bar{A}(t)$ is continuous and bounded on $[0, t_f)$ and exponentially stable. The update laws (5.16) and (5.17) guarantee that

- 1) if $\nu = 0$ then $\hat{\theta} \in \mathcal{L}_{\infty}[0, t_f)$ and $\epsilon \in \mathcal{L}_2[0, t_f)$,
- 2) if $\nu > 0$ then $\hat{\theta} \in \mathcal{L}_{\infty}[0, t_f)$ and

$$\hat{\theta}, \frac{\epsilon}{\sqrt{1 + \nu |\Omega|_{\mathcal{F}}^2}} \in \mathcal{L}_2[0, t_f) \cap \mathcal{L}_{\infty}[0, t_f).$$

Proof: (Sketch) There exists a continuously differentiable, bounded, positive definite, symmetric $P: \mathbb{R}_+ \rightarrow \mathbb{R}^{n \times n}$ such that $\dot{P} + P\bar{A} + \bar{A}^T P = -I, \forall t \in [0, t_f)$, and the positive definite function $V = \frac{1}{2} \|\hat{\theta}\|_{P^{-1}}^2 + |\tilde{\epsilon}|_P^2$ can be used as in [6], [34], [7] to prove the lemma. \square

VI. STABILITY AND TRACKING

Either of the identifiers from the preceding sections can now be connected with the ISS-controller (3.1), (3.9). We give stability proofs for the resulting adaptive systems. These proofs encompass both normalized and unnormalized update laws.

Theorem 6.1 (z -Swapping Scheme): All the signals in the adaptive system consisting of the plant (2.1), controller (3.1), (3.9), filters (5.1), (5.2), and either the gradient (5.7) or the least-squares (5.8) update law, are globally uniformly bounded for all $t \geq 0$, and $\lim_{t \rightarrow \infty} z(t) = 0$. This means, in particular, that global asymptotic tracking is achieved: $\lim_{t \rightarrow \infty} [y(t) - y_r(t)] = 0$. Furthermore, if $\lim_{t \rightarrow \infty} r(t) = 0$ and $\phi(0) = 0$ then $\lim_{t \rightarrow \infty} x(t) = 0$.

Proof: Due to the continuity of x_m and the smoothness of the nonlinear terms appearing in (2.1), (3.1), (3.9), (5.1), (5.2), (5.7), (5.8), the solution of the closed-loop adaptive system exists and is unique. Let its maximum interval of existence be $[0, t_f)$.

For the normalized update laws, from Lemma 5.1 we obtain

$$\bar{\theta}, \dot{\bar{\theta}}, \frac{\epsilon}{\sqrt{1+\nu|\chi|^2_{\mathcal{F}}}} \in \mathcal{L}_{\infty}[0, t_f).$$

When the update laws are unnormalized, Lemma 5.1 gives only $\bar{\theta} \in \mathcal{L}_{\infty}[0, t_f)$ and we have to establish boundedness of $\dot{\bar{\theta}}$. To this end, we treat (5.2) in a fashion similar to (3.11)

$$\begin{aligned} & \frac{d}{dt} \left(\frac{1}{2} |\chi|_{\mathcal{F}}^2 \right) \\ &= \text{tr} \frac{d}{dt} \left(\frac{1}{2} \chi \chi^T \right) \\ &\leq -c_0 \text{tr} \{ \chi \chi^T \} - \text{tr} \{ \chi \text{diag}(\kappa_1 |w_1|^2, \dots, \kappa_n |w_n|^2) \chi^T \} \\ &\quad + \text{tr} \{ W^T \chi \} \\ &= -c_0 |\chi|_{\mathcal{F}}^2 + \sum_{i=1}^n (-\kappa_i |w_i|^2 |\chi_i|^2 + w_i^T \chi_i) \\ &\leq -c_0 |\chi|_{\mathcal{F}}^2 + \frac{1}{4\kappa_0}. \end{aligned} \quad (6.1)$$

This proves that $\chi \in \mathcal{L}_{\infty}[0, t_f)$. Therefore, by (5.5) and because of the boundedness of $\bar{\epsilon}$ we conclude that $\epsilon \in \mathcal{L}_{\infty}[0, t_f)$. Now by (5.7) or (5.8), $\dot{\bar{\theta}} \in \mathcal{L}_{\infty}[0, t_f)$. Therefore, by Lemma 3.2, $z, r \in \mathcal{L}_{\infty}[0, t_f)$. Finally, by (5.3), $\chi_0 \in \mathcal{L}_{\infty}[0, t_f)$.

We have thus shown that all of the signals of the closed-loop adaptive system are bounded on $[0, t_f)$ by constants depending only on the initial conditions, design gains, the external signals x_m and r , and not depending on t_f . The independence of the bounds of t_f proves that $t_f = \infty$. Hence, all signals are globally uniformly bounded on $[0, \infty)$.

Now we set out to prove that $z \in \mathcal{L}_2$, and eventually that $z(t) \rightarrow 0$ as $t \rightarrow \infty$. For the normalized update laws, from Lemma 5.1 we obtain $\dot{\bar{\theta}} \in \mathcal{L}_2$. Since $\chi \in \mathcal{L}_{\infty}$ then $\epsilon \in \mathcal{L}_2$. When the update laws are unnormalized Lemma 5.1 gives $\epsilon \in \mathcal{L}_2$, and since $\chi \in \mathcal{L}_{\infty}$ then by (5.7) or (5.8), $\dot{\bar{\theta}} \in \mathcal{L}_2$. Consequently in both the normalized and the unnormalized cases $\chi^T \dot{\bar{\theta}} \in \mathcal{L}_2$ because $\bar{\epsilon} \in \mathcal{L}_2$. With $V = \frac{1}{2} |\zeta|^2$, all the conditions of Lemmas 4.1 and 4.2 are satisfied. Thus, by Lemma 4.2, $z - \chi^T \dot{\bar{\theta}} \in \mathcal{L}_2$. Hence $z \in \mathcal{L}_2$. To prove the convergence of z to zero, we note that (3.2), (3.3) implies that $\dot{z} \in \mathcal{L}_{\infty}$. Therefore, by Barbalat's lemma $z(t) \rightarrow 0$ as $t \rightarrow \infty$. When $r(t) \rightarrow 0$ then $x_m(t) \rightarrow 0$ as $t \rightarrow \infty$, and from the definitions in (3.1) we conclude that, if $\phi(0) = 0$, then $x(t) \rightarrow 0$ as $t \rightarrow \infty$. \square

Now we proceed to prove stability of the x -swapping scheme. With normalized update laws, the proof is similar to the proof of Theorem 6.1. With the unnormalized update laws, it is not clear how to prove boundedness of all signals for

an arbitrary exponentially stable $\bar{A}(t)$. We avoid this difficulty by designing

$$\bar{A}(t) = A_0 - \lambda \phi^T(x) \phi(x) P \quad (6.2)$$

where $\lambda > 0$ and A_0 is an arbitrary constant matrix that satisfies $PA_0 + A_0^T P = -I$, $P = P^T > 0$. With this design the matrix $\bar{A}(t)$ is exponentially stable because

$$P\bar{A}(t) + \bar{A}^T(t)P = -I - 2\lambda P\phi^T\phi P \leq -I \quad (6.3)$$

Theorem 6.2 (x -Swapping Scheme) All the signals in the adaptive system consisting of the plant (2.1), controller (3.1), (3.9), filters (5.10), (5.11), and either the gradient (5.16) or the least-squares (5.17) update law are globally uniformly bounded for all $t \geq 0$, and $\lim_{t \rightarrow \infty} z(t) = 0$. This means, in particular, that global asymptotic tracking is achieved: $\lim_{t \rightarrow \infty} [y(t) - y_r(t)] = 0$. Furthermore, if $\lim_{t \rightarrow \infty} r(t) = 0$ and $\phi(0) = 0$ then $\lim_{t \rightarrow \infty} x(t) = 0$.

Proof We first consider the normalized update laws.

As in the proof of Theorem 6.1, we show that $\theta, \dot{\theta}, z, r \in \mathcal{L}_{\infty}[0, t_f)$ and hence $u \in \mathcal{L}_{\infty}[0, t_f)$. From (5.10) and (5.11) it follows that Ω_0, Ω , and therefore ϵ are in $\mathcal{L}_{\infty}[0, t_f)$. Now, by the same argument as in the proof of Theorem 6.1 we conclude that $t_f = \infty$.

Second, we consider the unnormalized update laws (5.16) and (5.17) with $\bar{A}(t)$ given by (6.2). Along the solutions of (5.11) we have

$$\begin{aligned} \frac{d}{dt} (\Omega P \Omega^T) &= -\Omega \Omega^T - 2\lambda \Omega P \phi^T \phi P \Omega^T + \Omega P \phi^T + \phi P \Omega^T \\ &= -\Omega \Omega^T - 2\lambda \left(\phi P \Omega^T - \frac{1}{2\lambda} I_p \right)^T \\ &\quad \cdot \left(\phi P \Omega^T - \frac{1}{2\lambda} I_p \right) + \frac{1}{2\lambda} I_p \end{aligned} \quad (6.4)$$

which implies

$$\frac{d}{dt} (\text{tr} \{ \Omega P \Omega^T \}) \leq -\text{tr} \{ \Omega \Omega^T \} + \frac{p}{2\lambda}. \quad (6.5)$$

Hence $\Omega \in \mathcal{L}_{\infty}[0, t_f)$. Lemma 5.2 gives² $\dot{\bar{\theta}} \in \mathcal{L}_{\infty}[0, t_f)$, and from (5.14) and (5.15) we conclude that $\epsilon \in \mathcal{L}_{\infty}[0, t_f)$. Now by (5.16) or (5.17), $\dot{\bar{\theta}} \in \mathcal{L}_{\infty}[0, t_f)$. Therefore, by Lemma 3.2, $z, r \in \mathcal{L}_{\infty}[0, t_f)$. Finally, by (5.12), $\Omega_0 \in \mathcal{L}_{\infty}[0, t_f)$. As before, $t_f = \infty$.

Now we set out to prove that $z \in \mathcal{L}_2$. For normalized update laws, from Lemma 5.2, we have that $\dot{\bar{\theta}}, \epsilon / \sqrt{1+\nu|\Omega|_{\mathcal{F}}^2} \in \mathcal{L}_2$. Since $\Omega \in \mathcal{L}_{\infty}$ then $\epsilon \in \mathcal{L}_2$. When the update laws are unnormalized, Lemma 5.2 gives $\epsilon \in \mathcal{L}_2$, and since $\Omega \in \mathcal{L}_{\infty}$ then by (5.16) or (5.17), $\dot{\bar{\theta}} \in \mathcal{L}_2$. Consequently for both the normalized and the unnormalized cases, $\Omega^T \dot{\bar{\theta}} \in \mathcal{L}_2$ because $\bar{\epsilon} \in \mathcal{L}_2$. Now, as in Theorem 6.1, we invoke Lemma 4.2 to deduce that $z - \chi^T \dot{\bar{\theta}} \in \mathcal{L}_2$. To show that $z \in \mathcal{L}_2$, we need to prove that $\Omega^T \dot{\bar{\theta}} \in \mathcal{L}_2$ implies $\chi^T \dot{\bar{\theta}} \in \mathcal{L}_2$, or, in the notation of Lemma A.2 from the Appendix, that $T_{\bar{A}}[\phi^T] \dot{\bar{\theta}} \in \mathcal{L}_2$ implies

²Since $\bar{A}(t)$ depends on $r(t)$ whose boundedness is yet to be proven, in invoking Lemma 5.2 we violate the boundedness condition for $\bar{A}(t)$. This, however, causes no difficulty because the boundedness condition is required only in order to establish the existence of P , and we know P in (6.2) *a priori*.

Let $[W^T]\tilde{\theta} \in \mathcal{L}_2$. To apply this lemma to our adaptive system note from (3.3) and (3.1) that

$$W^T(z, \hat{\theta}, t) = \begin{bmatrix} 1 & 0 & \cdots & 0 \\ -\frac{\partial \alpha_1}{\partial x_1} & 1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ -\frac{\partial \alpha_{n-1}}{\partial x_1} & -\frac{\partial \alpha_{n-1}}{\partial x_2} & \cdots & 1 \end{bmatrix} \phi^T(x) \triangleq M(z, \hat{\theta}, t) \phi^T(x). \quad (6.6)$$

Since $M(z(t), \hat{\theta}(t), t)$ satisfies the conditions of Lemma A.2 then $\chi^T \tilde{\theta} \in \mathcal{L}_2$ and hence $z \in \mathcal{L}_2$. The rest of the proof is the same as for Theorem 6.1. \square

Remark 6.1: All the above results are presented for the parametric-strict-feedback form (2.1) without zero dynamics. As in [12], they can be readily modified for the strict-feedback systems with zero-dynamics

$$\begin{aligned} \dot{x}_i &= x_{i+1} + \theta^T \varphi_i(x_1, \dots, x_i, x^r), & 1 \leq i \leq n-1 \\ \dot{x}_n &= \beta_0(x)u + \theta^T \varphi_n(x) \\ \dot{x}^r &= \Phi_0(y, x^r) + \Phi(y, x^r)\theta \\ y &= x_1 \end{aligned} \quad (6.7)$$

where the x^r -subsystem has a bounded-input bounded-state (BIBS) property with respect to y as its input. The procedure can also be modified, as in [12], to obtain a local result for the parametric-pure-feedback systems, i.e., the systems in which φ_i also depends on x_{i+1} . As in [40], the subset of pure-feedback systems that can be controlled globally can be enlarged using an appropriate filter and parameter estimate initialization. \square

VII. \mathcal{L}_∞ , MEAN-SQUARE AND \mathcal{L}_2 PERFORMANCE

For linear systems the issue of transient performance has recently received considerable attention (see [4], [20] and references therein). For the adaptive schemes presented in the preceding sections we now derive \mathcal{L}_∞ , mean-square, and \mathcal{L}_2 bounds for the error state z , which incorporate the bounds for the tracking error $y - y_r$.

First we give performance bounds for parameter identifiers and use them to establish \mathcal{L}_∞ and mean-square bounds for z that are valid for both the z -swapping and the x -swapping schemes. Then we derive an \mathcal{L}_2 norm bound on z for the z -swapping scheme. For the x -swapping scheme a similar \mathcal{L}_2 bound is not yet available.

We analyze in detail the scheme with the normalized gradient update laws and suggest in Remarks 7.1 and 7.4 how to modify the derivations for other update laws.

Without loss of generality we assume in our analysis, and recommend for implementation, that $\tilde{\epsilon}(0)$, $\chi(0)$ (in the z -swapping scheme), and $\Omega(0)$ (in the x -swapping scheme), be set to zero. This can be achieved by initializing $\chi_0(0) = -z(0)$, $\chi(0) = 0$, in the z -swapping scheme, and $\Omega_0(0) = x(0)$, $\Omega(0) = 0$, in the x -swapping scheme. For simplicity, we also let $\Gamma = \gamma I$. We explain in Remark 7.3 how the performance bounds differ in the absence of initialization.

Lemma 7.1: For both the z -swapping (5.7) and the x -swapping (5.16) normalized ($\nu > 0$) gradient update laws the following bounds hold

$$i) \quad \|\tilde{\theta}\|_\infty = |\tilde{\theta}(0)| \quad (7.1)$$

$$ii) \quad \|\dot{\tilde{\theta}}\|_\infty \leq \frac{\gamma}{\nu} |\tilde{\theta}(0)| \quad (7.2)$$

$$iii) \quad \|\dot{\tilde{\theta}}\|_2 \leq \sqrt{\frac{\gamma}{2\nu}} |\tilde{\theta}(0)|. \quad (7.3)$$

Proof: The proof is given for the z -swapping identifier (5.1), (5.2), (5.7). The proof for the x -swapping identifier (5.10), (5.11), (5.16) is identical.

Consider the positive definite function $V_{\tilde{\theta}} = 1/2\gamma|\tilde{\theta}|^2$. Its derivative along the solutions of (5.5), (5.7) is

$$\dot{V}_{\tilde{\theta}} = -\frac{|\epsilon|^2}{1 + \nu|\chi|_{\mathcal{F}}^2} \leq 0. \quad (7.4)$$

i) Due to the nonpositivity of $\dot{V}_{\tilde{\theta}}$ we have $V_{\tilde{\theta}}(t) \leq V_{\tilde{\theta}}(0)$ which implies (7.1).

ii) From (5.7) we can write

$$\begin{aligned} |\dot{\tilde{\theta}}|^2 &\leq \gamma^2 \frac{\epsilon^T \chi \chi^T \epsilon}{(1 + \nu|\chi|_{\mathcal{F}}^2)^2} \leq \gamma^2 \frac{|\epsilon|^2 |\chi|_{\mathcal{F}}^2}{(1 + \nu|\chi|_{\mathcal{F}}^2)^2} \\ &\leq \frac{\gamma^2}{\nu} \frac{|\epsilon|^2}{1 + \nu|\chi|_{\mathcal{F}}^2} \end{aligned} \quad (7.5)$$

By using (5.5) we get

$$|\dot{\tilde{\theta}}|^2 \leq \frac{\gamma^2}{\nu} \frac{\tilde{\theta}^T \chi \chi^T \tilde{\theta}}{1 + \nu|\chi|_{\mathcal{F}}^2} \leq \frac{\gamma^2}{\nu} \frac{|\tilde{\theta}|^2 |\chi|_{\mathcal{F}}^2}{1 + \nu|\chi|_{\mathcal{F}}^2} \leq \left(\frac{\gamma}{\nu}\right)^2 |\tilde{\theta}|^2 \quad (7.6)$$

which, in view of (7.1), proves (7.2).

iii) By integrating (7.4) over $[0, \infty)$ we obtain

$$\left\| \frac{\epsilon}{\sqrt{1 + \nu|\chi|_{\mathcal{F}}^2}} \right\|_2 \leq \sqrt{V_{\tilde{\theta}}(0)} = \frac{1}{\sqrt{2\gamma}} |\tilde{\theta}(0)|. \quad (7.7)$$

Integration of (7.5) over $[0, \infty)$ and substitution of (7.7) yields (7.3). \square

Remark 7.1: The only difference in the case of the normalized least-squares is that (7.3) becomes $\|\dot{\tilde{\theta}}\|_2 \leq \sqrt{\gamma/\nu} |\tilde{\theta}(0)|$. \square

Theorem 7.1: In the adaptive system (2.1), (3.1) using either the identifier (5.1), (5.2), (5.7) or (5.10), (5.11), (5.16) with normalized update laws, the following inequalities hold

$$i) \quad |z(t)| \leq \frac{|\tilde{\theta}(0)|}{2\sqrt{c_0}} \left(\frac{1}{\kappa_0} + \frac{\gamma^2}{g_0\nu^2} \right)^{1/2} + |z(0)|e^{-c_0 t}, \quad (7.8)$$

$$ii) \quad \left(\frac{1}{t} \int_0^t |z(\tau)|^2 d\tau \right)^{1/2} \leq \frac{|\tilde{\theta}(0)|}{2\sqrt{c_0}} \left(\frac{1}{\kappa_0} + \frac{1}{t} \frac{\gamma^2}{2g_0\nu^2} \right)^{1/2} + \frac{1}{\sqrt{2c_0}} |z(0)|. \quad (7.9)$$

Proof: i) This bound follows by substituting (7.1) and (7.2) into (3.10).

ii) By integrating the first line of (3.13) we get

$$\int_0^t |z(\tau)|^2 d\tau \leq \frac{1}{2c_0} |z(0)|^2 + \frac{1}{4c_0\kappa_0} \|\tilde{\theta}\|_\infty^2 t + \frac{1}{2g_0} \int_0^t \left(\int_0^\tau e^{-2c_0(\tau-s)} |\dot{\hat{\theta}}(s)|^2 ds \right) d\tau. \quad (7.10)$$

Now, to arrive at (7.9), the sequence of integration in (7.10) is interchanged as in the proof of Lemma A.1.(ii).

Remark 7.2: Although the initial states $z_2(0), \dots, z_p(0)$ may depend on c_i, κ_i, g_i , this dependence can be removed by setting $z(0) = 0$ with the following initialization of the reference model

$$x_{m,i}(0) = x_i(0) - \alpha_{i-1}(\bar{x}_{i-1}(0), \hat{\theta}(0), \bar{x}_{m,i-1}(0)). \quad (7.11)$$

It can also be proven that in this initialization $x_m(0)$ does not depend on c_i, κ_i, g_i . Therefore, the bounds (7.8), (7.9) can be made as small as desired by increasing c_0 , and/or κ_0, g_0 . A practical limit to the increase of these gain coefficients is that, in the presence of an error in the initial state measurement, they increase $z(0)$ and the performance deteriorates. As for the pure-feedback systems mentioned in Remark 6.1, the feasibility region may, in general, decrease as c_i, κ_i, g_i increase. \square

Remark 7.3: The above bounds are readily modified to also cover the case when $\tilde{e}(0) \neq 0$. For example, the \mathcal{L}_∞ bound (7.8) is augmented by the term

$$\frac{1}{2\sqrt{c_0}} \left[\frac{\gamma}{4c_0} \left(\frac{1}{\kappa_0} + \frac{2\gamma^2}{g_0\nu^2} \right) + \frac{2\gamma^2}{g_0\nu} \right]^{1/2} |\tilde{e}(0)|. \quad (7.12)$$

If we set both filter initial conditions to zero, namely, $\chi(0) = 0$ and $\chi_0(0) = 0$, we get $\tilde{e}(0) = z(0)$. (This initialization is always exact because it does not depend on the measured state.) In this case, (7.12) shows that, for $z(0) \neq 0$ the performance bound (7.8) is

$$|z(t)| \leq \frac{|\tilde{\theta}(0)|}{2\sqrt{c_0}} \left(\frac{1}{\kappa_0} + \frac{2\gamma^2}{g_0\nu^2} \right)^{1/2} + \frac{1}{2\sqrt{c_0}} \left[\frac{\gamma}{4c_0} \left(\frac{1}{\kappa_0} + \frac{2\gamma^2}{g_0\nu^2} \right) + \frac{2\gamma^2}{g_0\nu} \right]^{1/2} |z(0)| + |z(0)|e^{-c_0 t}. \quad (7.13)$$

\square

Lemma 7.2: For the adaptive system (2.1), (3.1), (5.1), (5.2), (5.7), the following inequalities hold

$$i) \quad \|\chi\|_\infty \leq \frac{1}{2\sqrt{c_0\kappa_0}} \quad (7.14)$$

$$ii) \quad \|\epsilon\|_\infty \leq \frac{|\tilde{\theta}(0)|}{2\sqrt{c_0\kappa_0}} \quad (7.15)$$

$$iii) \quad \|\epsilon\|_2 \leq \sqrt{\frac{1}{2\gamma} + \frac{\nu}{2\gamma} \frac{1}{4c_0\kappa_0}} |\tilde{\theta}(0)|. \quad (7.16)$$

Proof: i) By Lemma A.1-i), and since $\chi(0) = 0$, inequality (6.1) is rewritten as

$$|\chi(t)|_\mathcal{F}^2 \leq |\chi(0)|_\mathcal{F}^2 e^{-2c_0 t} + \int_0^t e^{-2c_0(t-\tau)} \frac{1}{2\kappa_0} d\tau \leq \frac{1}{4c_0\kappa_0} \quad (7.17)$$

and (7.14) follows.

ii) Now (5.5) implies $\|\epsilon\|_\infty \leq \|\chi\|_\infty \|\tilde{\theta}\|_\infty \leq (1/2\sqrt{c_0\kappa_0}) |\tilde{\theta}(0)|$ which proves (7.15).

iii) The bound on the \mathcal{L}_2 norm of ϵ is obtained using

$$\int_0^\infty |\epsilon(\tau)|^2 d\tau \leq \int_0^\infty \frac{|\epsilon(\tau)|^2}{1 + \nu \|\chi\|_\mathcal{F}^2} (1 + \nu \|\chi\|_\mathcal{F}^2) d\tau \leq (1 + \nu \|\chi\|_\mathcal{F}^2) \left\| \frac{\epsilon}{\sqrt{1 + \nu \|\chi\|_\mathcal{F}^2}} \right\|_2. \quad (7.18)$$

By substituting (7.7) and (7.14) into (7.18) we prove (7.16). \square

Remark 7.4: With the bounds (7.14)–(7.16) for the z -swapping scheme we can tighten the bounds on $\|\tilde{\theta}\|_2$ and $\|\tilde{\theta}\|_\infty$ in Lemma 7.1 and make them valid for the unnormalized update laws with $\nu = 0$. It is straightforward to show that $1/\nu$ in (7.2)–(7.3) can be replaced by $\min\{1/\nu, 1/4c_0\kappa_0\}$. The same is true for (7.8)–(7.9). We can also show that for the x -swapping scheme $1/\nu$ can be replaced by $\min\{1/\nu, (p/2\lambda)[\lambda_{\max}(P_0)/\lambda_{\min}(P_0)]\}$. \square

Theorem 7.2 In the adaptive system (2.1), (3.1) with the z -swapping identification scheme (5.1), (5.2), (5.7) the \mathcal{L}_2 norm of z is bounded by

$$\|z\|_2 \leq \frac{|\tilde{\theta}(0)|}{\sqrt{2c_0}} \left(\frac{\gamma}{g_0\nu} + \frac{\gamma}{2c_0^2\kappa_0\nu} + \frac{\nu}{2\kappa_0\gamma} \right)^{1/2} + \frac{|\tilde{\theta}(0)|}{\sqrt{2\gamma}} + \frac{1}{\sqrt{c_0}} |z(0)|. \quad (7.19)$$

Proof: We will calculate the \mathcal{L}_2 norm bound for z as $\|z\|_2 \leq \|\epsilon\|_2 + \|\psi\|_2$, where

$$\psi \triangleq \chi_0 - \chi^T \hat{\theta}. \quad (7.20)$$

A bound on $\|\epsilon\|_2$ is given by (7.16). To obtain a bound on $\|\psi\|_2$, we examine

$$\dot{\psi} = A_z(z, \hat{\theta}, t)\psi - D(z, \hat{\theta}, t)^T \dot{\hat{\theta}} - \chi^T \dot{\hat{\theta}}. \quad (7.21)$$

By using (3.3) and repeating the sequence of inequalities (3.11), we derive

$$\begin{aligned} \frac{d}{dt} \left(\frac{1}{2} |\psi|^2 \right) &\leq -c_0 |\psi|^2 + \frac{1}{4g_0} |\dot{\hat{\theta}}|^2 - \psi^T \chi^T \dot{\hat{\theta}} \\ &\leq -\frac{c_0}{2} |\psi|^2 - \frac{c_0}{2} \left| \psi - \frac{1}{c_0} \chi^T \dot{\hat{\theta}} \right|^2 \\ &\quad + \frac{1}{4g_0} |\dot{\hat{\theta}}|^2 + \frac{1}{2c_0} |\chi^T \dot{\hat{\theta}}|^2 \end{aligned} \quad (7.22)$$

which gives

$$\frac{d}{dt} \left(\frac{1}{2} |\psi|^2 \right) \leq -\frac{c_0}{2} |\psi|^2 + \frac{1}{2} \left(\frac{1}{2g_0} |\dot{\hat{\theta}}|^2 + \frac{1}{c_0} |\chi^T \dot{\hat{\theta}}|^2 \right). \quad (7.23)$$

applying Lemma A.1.(ii) to (7.23), we arrive at

$$\|\psi\|_2 \leq \frac{1}{\sqrt{c_0}} \left(|\psi(0)| + \frac{1}{\sqrt{2g_0}} \|\dot{\hat{\theta}}\|_2 + \frac{1}{\sqrt{c_0}} \|\chi^T \dot{\hat{\theta}}\|_2 \right). \quad (7.24)$$

substituting (7.3) and (7.14) into (7.24) we get

$$\begin{aligned} \|\psi\|_2 &\leq \frac{1}{\sqrt{c_0}} \left(|\psi(0)| + \frac{1}{\sqrt{2g_0}} \|\dot{\hat{\theta}}\|_2 + \frac{1}{\sqrt{c_0}} \|\chi\|_{\mathcal{F}} \|\dot{\hat{\theta}}\|_2 \right) \\ &\leq \frac{|\hat{\theta}(0)|}{2\sqrt{c_0}} \sqrt{\frac{\gamma}{\nu}} \left(\frac{1}{\sqrt{g_0}} + \frac{1}{\sqrt{2c_0^2 \kappa_0}} \right) + \frac{1}{\sqrt{c_0}} |z(0)| \end{aligned} \quad (7.25)$$

where we have assumed that $\chi_0(0) = z(0)$. Combining this and (7.16), and rearranging the terms, we obtain (7.19). \square

The form of the bound (7.19) is favorable because it is linear in $|\hat{\theta}(0)|$. It may not be possible to make the \mathcal{L}_2 norm of z as small as desired by c_0 alone because of the term $|\hat{\theta}(0)|/\sqrt{2\gamma}$. With the standard initialization $z(0) = 0$, however, a possibility to improve the \mathcal{L}_2 performance is by simultaneously increasing c_0 , g_0 and γ .

VIII. RAPPROCHEMENT WITH LINEAR DESIGNS

A connection of the adaptive nonlinear ISS-design presented in this paper with linear estimation-based designs will become clearer when the ISS-controller of Section III is replaced by the weaker SG-controller developed in this section. The only difference between the two controllers is that the SG-controller employs weaker nonlinear damping functions s_i . For example, for an uncertain term $\theta\varphi(x_1)$ in the first equation of the plant, the ISS and SG nonlinear damping functions are respectively

$$\begin{aligned} s_1^{\text{ISS}}(x_1) &= \varphi(x_1)^2 \quad \text{and} \\ s_1^{\text{SG}}(x_1) &= \left[\frac{\varphi(x_1) - \varphi(0)}{x_1} \right]^2 \triangleq \omega(x_1)^2. \end{aligned} \quad (8.1)$$

In this way the growth of s_1^{SG} is reduced by a factor of x_1^2 . In the process of backstepping this reduction is even more pronounced. However, the SG-controller can no longer guarantee the ISS property with respect to $\hat{\theta}$ and $\dot{\hat{\theta}}$. Instead, we reveal a small gain property and prove boundedness with a linear-like Gronwall lemma argument. The main interest in the SG-controller is that for linear systems it becomes linear in x and in that sense is similar to linear estimation-based designs. In contrast, the ISS-controller for linear systems remains nonlinear.

To derive the nonlinear damping expressions for the SG-controller we rewrite the regressor vectors w_i as follows

$$w_i(\bar{z}_i, \hat{\theta}, t) = w_i(0, \hat{\theta}, t) + \omega_i(\bar{z}_i, \hat{\theta}, t)^T \bar{z}_i, \quad (8.2)$$

where $\bar{z}_i \triangleq [z_1, \dots, z_i]^T$, and $\omega_i: \mathbf{R}^i \times \mathbf{R}^p \times \mathbf{R}_+ \rightarrow \mathbf{R}^{i \times p}$ is a matrix-valued function smooth in the first two arguments and continuous and bounded in the third argument (with a slight abuse of notation relative to (3.1) we now express w_i as a function of $\bar{z}_i, \hat{\theta}, t$). Thus we have

$$W = W_0 + [\omega_1^T \bar{z}_1, \dots, \omega_n^T \bar{z}_n] \quad (8.3)$$

where W_0 denotes $W(0, \hat{\theta}, t)$. Likewise, we rewrite (3.3)

$$D = D_0 + [0, \delta_2^T \bar{z}_1, \dots, \delta_n^T \bar{z}_{n-1}] \quad (8.4)$$

where $\delta_i: \mathbf{R}^{i-1} \times \mathbf{R}^p \times \mathbf{R}_+ \rightarrow \mathbf{R}^{(i-1) \times p}$ are matrix-valued functions smooth in the first two arguments and continuous and bounded in the third argument, and D_0 denotes $D(0, \hat{\theta}, t)$.

The SG-controller has the same form (3.1) as the ISS controller, but its nonlinear damping functions are defined as

$$s_i = \kappa_i |\omega_i|_{\mathcal{F}}^2 + g_i |\delta_i|_{\mathcal{F}}^2. \quad (8.5)$$

As in linear estimation-based adaptive control, the SG-controller employs an identifier with normalized update laws.

Theorem 8.1: All the signals in the adaptive system consisting of the plant (2.1), SG-controller (3.1) with (8.5), z -swapping filters (5.1), (5.2), and either the gradient (5.7) or the least-squares (5.8) normalized update law ($\nu > 0$), are globally uniformly bounded for all $t \geq 0$, and $\lim_{t \rightarrow \infty} z(t) = 0$. This means, in particular, that global asymptotic tracking is achieved: $\lim_{t \rightarrow \infty} [y(t) - y_r(t)] = 0$. Furthermore, if $\lim_{t \rightarrow \infty} r(t) = 0$ and $\phi(0) = 0$ then $\lim_{t \rightarrow \infty} x(t) = 0$.

Proof: Using (8.3) we write (5.2) as

$$\dot{\chi}^T = A_z \chi^T + W_0^T + [\omega_1^T \bar{z}_1, \dots, \omega_n^T \bar{z}_n]^T. \quad (8.6)$$

In a fashion similar to (6.1) we compute

$$\begin{aligned} \frac{d}{dt} \left(\frac{1}{2} |\chi|_{\mathcal{F}}^2 \right) &\leq -c_0 |\chi|_{\mathcal{F}}^2 - \sum_{i=1}^n \kappa_i |\omega_i|_{\mathcal{F}}^2 |\chi_i|^2 \\ &\quad + \sum_{i=1}^n \bar{z}_i^T \omega_i \chi_i + \text{tr} \{ W_0^T \chi \} \\ &\leq -\frac{c_0}{2} |\chi|_{\mathcal{F}}^2 + \sum_{i=1}^n \frac{1}{4\kappa_i} |\bar{z}_i|^2 + \frac{1}{2c_0} |W_0|_{\mathcal{F}}^2 \\ &\leq -\frac{c_0}{2} |\chi|_{\mathcal{F}}^2 + \frac{1}{4\kappa_0} |z|^2 + \frac{1}{2c_0} |W_0|_{\mathcal{F}}^2. \end{aligned} \quad (8.7)$$

On the other hand, using (8.4) we write (7.21) as

$$\dot{\psi} = A_z \psi - (\chi + D_0)^T \dot{\hat{\theta}} - [0, \delta_2^T \bar{z}_1, \dots, \delta_n^T \bar{z}_{n-1}]^T \dot{\hat{\theta}} \quad (8.8)$$

and compute

$$\begin{aligned} \frac{d}{dt} \left(\frac{1}{2} |\psi|^2 \right) &\leq -c_0 |\psi|^2 - \sum_{i=1}^n g_i |\delta_i|_{\mathcal{F}}^2 \psi_i^2 \\ &\quad - \psi^T (\chi + D_0)^T \dot{\hat{\theta}} - \sum_{i=1}^n \bar{z}_{i-1}^T \delta_i \psi_i \dot{\hat{\theta}} \\ &\leq -\frac{c_0}{2} |\psi|^2 + \frac{1}{2c_0} |(\chi + D_0)^T \dot{\hat{\theta}}|^2 \\ &\quad + \sum_{i=1}^n \frac{1}{4g_i} |\bar{z}_{i-1}|^2 |\dot{\hat{\theta}}|^2 \\ &\leq -\frac{c_0}{2} |\psi|^2 + \frac{1}{c_0} |\chi|_{\mathcal{F}}^2 |\dot{\hat{\theta}}|^2 \\ &\quad + \frac{1}{4g_0} |z|^2 |\dot{\hat{\theta}}|^2 + \frac{1}{c_0} |D_0|_{\mathcal{F}}^2 |\dot{\hat{\theta}}|^2. \end{aligned} \quad (8.9)$$

The system (8.7), (8.9) is summarized as

$$\frac{d}{dt}(|\chi|_{\mathcal{F}}^2) \leq -c_0|\chi|_{\mathcal{F}}^2 + \frac{1}{2\kappa_0}|z|^2 + \frac{1}{c_0}|W_0|_{\mathcal{F}}^2 \quad (8.10)$$

$$\begin{aligned} \frac{d}{dt}(|\psi|^2) &\leq -c_0|\psi|^2 + \frac{2}{c_0}|\dot{\theta}|^2|\chi|_{\mathcal{F}}^2 + \frac{1}{2g_0}|\dot{\theta}|^2|z|^2 \\ &\quad + \frac{2}{c_0}|D_0|_{\mathcal{F}}^2|\dot{\theta}|^2. \end{aligned} \quad (8.11)$$

From Lemma 5.1 we have $\hat{\theta} \in \mathcal{L}_\infty[0, t_f]$, so $|W_0|_{\mathcal{F}}^2 < k$ and $|D_0|_{\mathcal{F}}^2 < k$, where k denotes a generic positive finite constant. From Lemma 5.1 we also have $\dot{\theta}, \epsilon/\sqrt{1+\nu}|\chi|_{\mathcal{F}}^2 \in \mathcal{L}_2[0, t_f] \cap \mathcal{L}_\infty[0, t_f]$. Let us denote by l_1 a generic function in $\mathcal{L}_1[0, t_f] \cap \mathcal{L}_\infty[0, t_f]$. Since $\epsilon = z + \psi$, then we have

$$\begin{aligned} |z|^2 &\leq 2\frac{|\epsilon|^2}{1+\nu|\chi|_{\mathcal{F}}^2}(1+\nu|\chi|_{\mathcal{F}}^2) + 2|\psi|^2 \\ &\leq 2l_1(1+\nu|\chi|_{\mathcal{F}}^2) + 2|\psi|^2. \end{aligned} \quad (8.12)$$

Thus (8.10)–(8.11) become

$$\frac{d}{dt}(|\chi|_{\mathcal{F}}^2) \leq -(c_0 - l_1)|\chi|_{\mathcal{F}}^2 + \frac{1}{\kappa_0}|\psi|^2 + k \quad (8.13)$$

$$\frac{d}{dt}(|\psi|^2) \leq -(c_0 - l_1)|\psi|^2 + l_1|\chi|_{\mathcal{F}}^2 + k. \quad (8.14)$$

This is a loop with small gain because $|\chi|_{\mathcal{F}}^2$ appears multiplied by l_1 in (8.14). To finish the proof we define the “superstate”

$$X \triangleq |\chi|_{\mathcal{F}}^2 + \frac{2}{\kappa_0 c_0}|\psi|^2 \quad (8.15)$$

differentiate it and substitute (8.13)–(8.14). After straightforward rearrangements and majorizations, we get

$$\dot{X} \leq -\left(\frac{c_0}{2} - l_1\right)X + k. \quad (8.16)$$

By applying the Gronwall lemma we conclude that X is uniformly bounded on $[0, t_f]$. In view of (5.5), ϵ is bounded, which along with the boundedness of ψ , proves that z is bounded. Thus $t_f = \infty$. The rest of the proof is the same as for Theorem 6.1, and again uses Lemma 4.2 for proving convergence. \square

In contrast to the ISS design, the global result has been established only with normalized update laws. The issue of normalization in adaptive nonlinear design was discussed in [26].

Performance bounds similar to those in Section VII for the ISS design are not available for the SG design, nor is it clear how to develop its x -swapping version.

In Section IX we compare the linear SG design with the new ISS design for a linear plant.

IX. EXAMPLES AND DISCUSSION

The first example in this section illustrates the performance properties of the ISS design on the relative-degree two plant

$$\begin{aligned} \dot{x}_1 &= x_2 + \theta\varphi(x_1) \\ \dot{x}_2 &= u \end{aligned} \quad (9.1)$$

with the objective to regulate x to zero (without a reference model). The second example makes a comparison between the ISS design and the SG design.

We define the error variables

$$\begin{aligned} z_1 &= x_1 \\ z_2 &= x_2 - \alpha_1(x_1, \hat{\theta}). \end{aligned} \quad (9.2)$$

The two-step ISS-controller design

$$\begin{aligned} \alpha_1 &= -c_1 z_1 - \kappa_1 \varphi^2 z_1 - \hat{\theta} \varphi \\ u &= -z_1 - c_2 z_2 - \kappa_2 \left(\frac{\partial \alpha_1}{\partial x_1} \right)^2 \varphi^2 z_2 - g_2 \left(\frac{\partial \alpha_1}{\partial \hat{\theta}} \right)^2 z_2 \\ &\quad + \frac{\partial \alpha_1}{\partial x_1} (x_2 + \hat{\theta} \varphi) \end{aligned} \quad (9.3)$$

results in the error system

$$\dot{z} = A_z(z, \hat{\theta})z + \begin{bmatrix} -\frac{\varphi}{\partial x_1} \\ 0 \end{bmatrix} \dot{\hat{\theta}} + \begin{bmatrix} 0 \\ -\frac{\partial \alpha_1}{\partial \hat{\theta}} \end{bmatrix} \dot{\hat{\theta}} \quad (9.4)$$

where

$$A_z = \begin{bmatrix} -c_1 - \kappa_1 \varphi^2 & \\ -1 & -c_2 - \kappa_2 \left(\frac{\partial \alpha_1}{\partial x_1} \right)^2 \varphi^2 - g_2 \left(\frac{\partial \alpha_1}{\partial \hat{\theta}} \right)^2 \end{bmatrix} \quad (9.5)$$

The z -swapping identifier is designed with the following filters

$$\chi_0 = A_z(z, \hat{\theta})\chi_0 + \begin{bmatrix} \frac{\varphi}{\partial x_1} \\ 0 \end{bmatrix} \hat{\theta} - \begin{bmatrix} 0 \\ -\frac{\partial \alpha_1}{\partial \hat{\theta}} \end{bmatrix} \hat{\theta} \quad (9.6)$$

$$\chi^T = A_z(z, \hat{\theta})\chi^T + \begin{bmatrix} \frac{\varphi}{\partial x_1} \\ 0 \end{bmatrix} \hat{\theta} \quad (9.7)$$

which are used to implement the augmented error

$$\epsilon = z + \chi_0 - \chi^T \hat{\theta} \quad (9.8)$$

and the gradient update law

$$\dot{\hat{\theta}} = \gamma \frac{\chi \epsilon}{1 + \nu \chi \chi^T}. \quad (9.9)$$

The x -swapping identifier is designed with the following filters

$$\Omega_0 = -(\bar{\alpha} + \lambda \varphi^2)(\Omega_0 - x_1) + x_2, \quad \Omega_0 \in \mathbb{R} \quad (9.10)$$

$$\dot{\Omega} = -(\bar{\alpha} + \lambda \varphi^2)\Omega + \varphi, \quad \Omega \in \mathbb{R} \quad (9.11)$$

which are used to implement the equation error

$$\epsilon = x_1 - \Omega_0 - \Omega \theta \quad (9.12)$$

and the gradient update law

$$\dot{\hat{\theta}} = \gamma \frac{\Omega \epsilon}{1 + \nu \Omega^2}. \quad (9.13)$$

This reveals that the x -swapping approach is uncertainty specific in the sense that only the terms φ , multiplying the unknown parameter θ need to be filtered. This opens a possibility for a reduction in the dynamic order of the identifier.

In simulations, the only difference between the z -swapping and the x -swapping approach was in the value of γ needed to achieve the same speed of adaptation—higher value was needed in the z -swapping case. Since the responses were similar we show them only for the z -swapping scheme.

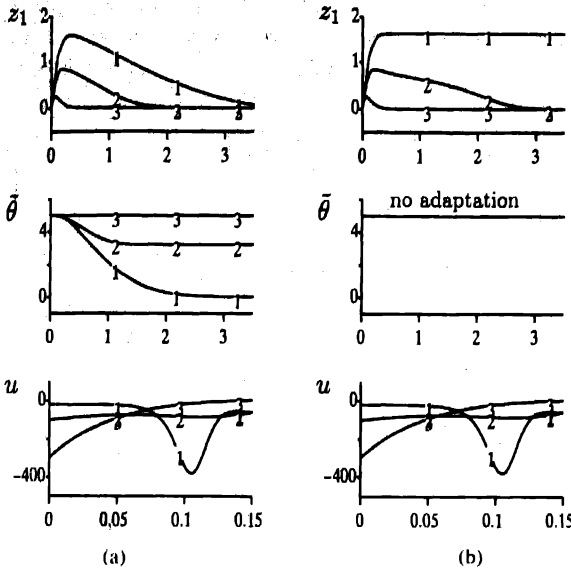

Fig. 1. Dependence of the transients on c_0 with $\kappa_0 = g_0 = 1$. (Note an expanded time scale for control u .) (a) $\gamma = 10$; (b) $\gamma = 0$. 1: $c_0 = 1$; 2: $c_0 = 5$; 3: $c_0 = 15$.

Example 8.1 (ISS-Performance): We consider system (9.1) with nonlinearity $\varphi(x_1) = x_1^2$. The simulations were carried out with nominal values $c_1 = c_2 = c_0 = \kappa_1 = \kappa_2 = \kappa_0 = g_2 = g_0 = 1$, $\gamma = 10$, $\theta = 5$, $\theta(0) = 0$ which were judged to give representative responses. All simulations are with following initial conditions: $x(0) = -\chi_0$ ($0 = [0, 10]^T$), $\chi(0) = 0$ (to set $\tilde{c}(0) = 0$).

Fig. 1(a) illustrates Theorems 7.1 and 7.2. The design parameter c_0 can be used for systematically improving the transient performance. Up to a certain point the error transients and the control effort in Fig. 1(a) are simultaneously decreasing as c_0 increases. Beyond that point the control effort starts increasing. The control u is given in an expanded time scale in order to clearly display the main qualitative differences among the three cases. Fig. 1(b) illustrates Corollary 3.1. When adaptation is switched off, the states are uniformly bounded and converge to (or remain inside) a compact residual set. Corollary 3.1 does not describe the behavior inside the residual set, which may contain multiple equilibria, limit cycles, etc. For this example (but not in general), there is an asymptotically stable equilibrium at the origin for any value of the parameter error. For small values of c_0 , this equilibrium has a basin of attraction which is strictly inside the residual set. For higher values of c_0 the global asymptotic stability is achieved.

Fig. 2 shows the influence of κ_0 on transients. According to Theorem 7.1 and Remark 7.4, the peak values can be decreased by increasing κ_0 , which is confirmed by the plot. The L_2 performance may not be improved, however, by increasing κ_0 because the κ -terms slow down the adaptation and make the transients longer. The effect of the g -terms was shown to be significant only for very small c_0 and κ_0 or for very large γ .

Fig. 3 demonstrates the influence of the adaptation gain γ on transients. Due to the slow initial adaptation, which should be attributed not only to the normalized gradient update law but also to the fact that the regressor is filtered, there is a clear separation of action of the nonadaptive controller, which

Fig. 2. Dependence of the transients on κ_0 with $c_0 = g_0 = 1$, $\gamma = 10$. 1: $c_0 = 1$; 2: $c_0 = 5$; 3: $c_0 = 15$.

Fig. 3. Dependence of the transients on γ with $c_0 = g_0 = \kappa_0 = 1$. 1: $c_0 = 1$; 2: $c_0 = 5$; 3: $c_0 = 15$.

at the beginning brings the state z quickly to the residual set, and the adaptive controller which takes over to drive the state to the origin. The property that the L_∞ bounds are increasing functions of γ , to be expected from Theorem 7.1, was exhibited in simulations only with extremely high values of γ . This indicates that some of the bounds derived are not very tight over the entire range of design parameter values.

Finally, an explanation is in order about the initial condition $x(0)$ in our simulations. We used $x(0) = [0, 10]^T$, and hence $z(0) = [0, 10]^T$ which is independent of the design gains c_0, κ_0, g_0 . This is why the peak of z_1 decreases monotonically as any of these gains increases. If, instead, we used $x_1(0) \neq 0$, then, according to Remark 7.2, we would have added an appropriately initialized reference model (with $r(t) \equiv 0$). In this way, bad transients would be eliminated by following a less aggressive path to the origin. \square

Example 8.2 (ISS vs. SG): Let us consider system (9.1) with $\varphi(x_1) = x_1$. For this linear system we make a comparison between the ISS and SG designs. The only difference is that the terms $\kappa_1 \varphi^2, \kappa_2 (\partial \alpha_1 / \partial x_1)^2 \varphi^2, g_2 (\partial \alpha_1 / \partial \theta)^2$ in the ISS design are, respectively, replaced by $\kappa_1, \kappa_2 (\partial \alpha_1 / \partial x_1)^2, g_2$ in the SG design. The same design coefficients and initial conditions are used as in Example 8.1, except for $\theta = 3$. The adaptation gains, $\gamma = 5$ for the ISS design, and $\gamma = 1.5$ for the SG design, are chosen so that the rate of parameter convergence is the same for both designs. The control law of the SG design is linear in x and nonlinear in $\hat{\theta}$.

Fig. 4 shows the difference in performance between the two designs. The ISS design uses larger control effort and achieves better attenuation of the z_1 -transient. The dashed responses illustrate the underlying nonadaptive behavior ($\gamma = 0$). While

Fig. 4. ISS design vs. SG design. The dashed lines show $z_1(t)$ when $\gamma = 0$. (Note an expanded time scale for control u .)

the response of the SG design exhibits linear exponential instability, the response of the ISS design, according to Corollary 3.1, is bounded. Hence, there is a clear trade-off of performance improvement versus control effort between the new ISS design and the linear adaptive designs such as the SG design. \square

X. CONCLUSIONS

Recent Lyapunov-based recursive designs of adaptive controllers for nonlinear systems transformable into the parametric-strict-feedback form [12], [8], [19], [36] achieve global stability and tracking, but do not allow a choice of parameter update laws. In these designs the wealth of knowledge about standard identifiers is not utilized because the identifier does not appear as a separate module of the adaptive system.

A complete separation of the controller and identifier modules is one of the main accomplishments of this paper. It has been achieved by a new nonlinear controller with an input-to-state stability property with respect to the parameter estimation error and its derivative as disturbance inputs. This strong ISS-controller remains nonlinear even when the plant is linear. For comparison with linear estimation-based designs, a weaker SG-controller is introduced, resulting in a small-gain rather than the ISS property. For linear plants this controller is linear.

As a separate module, the ISS-controller can be connected with the standard unnormalized or normalized gradient or least-squares identifiers, while the SG-controller requires normalization. The connection of the controller and identifier modules is made possible by a nonlinear extension of the well known swapping lemma.

In addition to the global boundedness and tracking, the new design also provides explicit bounds on the transient performance, which can be utilized for its systematic improvement.

The results of this paper assume that the full state is available for feedback. Relying on the experience gained with recent recursive output-feedback designs, such as [22], [14], it

is expected that the estimation-based design of this paper will be extended to nonlinear systems in the output-feedback form.

The applicability of various designs, Lyapunov-based or estimation-based, will ultimately depend on their robustness with respect to unmodeled phenomena. This is another important topic of current research.

APPENDIX

Lemma A.1: Let $v, \rho: \mathbb{R}_+ \rightarrow \mathbb{R}$, $c, b > 0$. If

$$\dot{v} \leq -cv + b\rho^2, \quad v(0) \geq 0 \quad (\text{A.1})$$

i) then

$$v(t) \leq v(0)e^{-ct} + b \int_0^t e^{-c(t-\tau)} \rho(\tau)^2 d\tau. \quad (\text{A.2})$$

ii) If, in addition, $\rho \in \mathcal{L}_2$, then $v \in \mathcal{L}_\infty \cap \mathcal{L}_1$ and

$$\|v\|_1 \leq \frac{1}{c}(v(0) + b\|\rho\|_2^2). \quad (\text{A.3})$$

Proof: i) Upon multiplication of (A.1) by e^{ct} , it becomes

$$\frac{d}{dt}(v(t)e^{ct}) \leq b\rho(t)^2 e^{ct}. \quad (\text{A.4})$$

Integrating (A.4) over $[0, t]$, we arrive at (A.2).

ii) Noting that (A.2) implies that

$$v(t) \leq v(0)e^{-ct} + b \sup_{\tau \in [0, t]} \{e^{-c(t-\tau)}\} \int_0^t \rho(\tau)^2 d\tau \quad (\text{A.5})$$

we conclude that $v \in \mathcal{L}_\infty$. By integrating (A.2) over $[0, t]$, we get

$$\begin{aligned} \int_0^t v(\tau) d\tau &\leq \int_0^t v(0)e^{-c\tau} d\tau + b \int_0^t \left[\int_0^\tau e^{-c(\tau-s)} \rho(s)^2 ds \right] d\tau \\ &\leq \frac{1}{c}v(0) + b \int_0^t e^{cs} \rho(s)^2 \left(\int_s^t e^{-c\tau} d\tau \right) ds \\ &\leq \frac{1}{c}v(0) + b \int_0^t e^{cs} \rho(s)^2 \frac{1}{c} e^{-cs} ds \\ &\leq \frac{1}{c} \left[v(0) + b \int_0^t \rho(\tau)^2 d\tau \right] \end{aligned} \quad (\text{A.6})$$

which proves (A.3). \square

Lemma A.2: Let $T_i: u \mapsto \zeta_i$, $i = 1, 2$ be linear time-varying operators defined by

$$\dot{\zeta}_i = A_i(t)\zeta_i + u \quad (\text{A.7})$$

where $A_i: \mathbb{R}_+ \rightarrow \mathbb{R}^{n \times n}$ are continuous, bounded and exponentially stable. Suppose $\tilde{\theta}: \mathbb{R}_+ \rightarrow \mathbb{R}^p$ is differentiable, $\phi: \mathbb{R}_+ \rightarrow \mathbb{R}^{p \times m}$ is piecewise continuous and bounded, and $M: \mathbb{R}_+ \rightarrow \mathbb{R}^{n \times n}$ is bounded and has a bounded derivative on \mathbb{R}_+ . If $\tilde{\theta} \in \mathcal{L}_2$ then

$$T_1[\phi^T]\tilde{\theta} \in \mathcal{L}_2 \Rightarrow T_2[M\phi^T]\tilde{\theta} \in \mathcal{L}_2. \quad (\text{A.8})$$

If moreover, $M(t)$ is nonsingular $\forall t$, and M^{-1} is bounded and has a bounded derivative on \mathbb{R}_+ then (A.8) holds in both directions.

Proof: Suppose that $T_1[\phi^T]\tilde{\theta} \in \mathcal{L}_2$. By Lemma 4.2, $T_1[\phi^T]\tilde{\theta} - T_1[\phi^T]\tilde{\theta} \in \mathcal{L}_2$ and therefore $\zeta_1 \triangleq T_1[\phi^T]\tilde{\theta} \in \mathcal{L}_2$. We will show first that $\zeta_2 \triangleq T_2[M\phi^T\tilde{\theta}] \in \mathcal{L}_2$. By substituting $\tilde{\theta} = \zeta_1 - A_1(t)\zeta_1$ into the variation of constants formula and applying partial integration we calculate

$$\begin{aligned} \zeta_2(t) &= \Phi_2(t, 0)\zeta_2(0) + \int_0^t \Phi_2(t, \tau)M(\tau)\phi^T(\tau)\tilde{\theta}(\tau) d\tau \\ &= \Phi_2(t, 0)\zeta_2(0) + \int_0^t \Phi_2(t, \tau)M(\tau) \\ &\quad \cdot [\dot{\zeta}_1(\tau) - A_1(\tau)\zeta_1(\tau)] d\tau \\ &= \Phi_2(t, 0)\zeta_2(0) + M(t)\zeta_1(t) - \Phi_2(t, 0)M(0)\zeta_1(0) \\ &\quad + \int_0^t \Phi_2(t, \tau)[\dot{M}(\tau) + A_2(\tau)M(\tau) - M(\tau)A_1(\tau)] \\ &\quad \cdot \zeta_1(\tau) d\tau \end{aligned} \quad (\text{A.9})$$

where $\Phi_2(t, \tau)$ is the state transition matrix of $A_2(t)$ that satisfies $\|\Phi_2(t, \tau)\|_2 \leq ke^{-\alpha(t-\tau)}$, $k, \alpha > 0$. It is clear that $\Phi_2(t, 0)\zeta_2(0) + M(t)\zeta_1(t) - \Phi_2(t, 0)M(0)\zeta_1(0) \in \mathcal{L}_2$ because $\Phi_2(t, 0)$ is exponentially decaying, $M(t)$ is bounded and $\zeta_1 \in \mathcal{L}_2$. Since

$$\begin{aligned} &\Phi_2(t, \tau)[\dot{M}(\tau) + A_2(\tau)M(\tau) - M(\tau)A_1(\tau)]\zeta_1(\tau) d\tau \\ &\leq \|\dot{M} + A_2M - MA_1\|_\infty^2 k^2 \int_0^t e^{-2\alpha(t-\tau)} |\zeta_1(\tau)|^2 d\tau \end{aligned} \quad (\text{A.10})$$

then similarly to (4.16)–(4.17) from the proof of Lemma 4.2, we can show that the expression (A.10) is in \mathcal{L}_2 . Thus $\zeta_2 = T_2[M\phi^T\tilde{\theta}] \in \mathcal{L}_2$. By Lemma 4.2, $T_2[M\phi^T\tilde{\theta}] - T_2[M\phi^T]\tilde{\theta} \in \mathcal{L}_2$ and therefore $T_2[M\phi^T\tilde{\theta}] \in \mathcal{L}_2$. The proof of the other direction of (A.8) when $M(t)$ is nonsingular $\forall t$, and M^{-1} is bounded and has a bounded derivative on \mathbb{R}_+ is identical. \square

He received the 1993 IEEE CDC Best Student Paper Award for the paper "Adaptive nonlinear control with nonlinear swapping" co-authored with P. V. Kokotović.

In 1993 he was also a recipient of the UCSB Engineering Fellowship. His research interests include adaptive control of nonlinear and linear systems, robust nonlinear control, dynamical systems, and control applications.

Petar V. Kokotović (SM'74-F'80) has been active for more than 30 years as a control engineer, researcher, and educator, first in his native Yugoslavia and then, from 1966 through 1990 at the University of Illinois, where he held the endowed Granger Chair. Since 1991 he has been Co-Director (with A. J. Laub) of the newly formed Center for Control Engineering and Computation at the University of California, Santa Barbara. He has coauthored eight books and numerous articles contributing to sensitivity analysis, singular perturbation methods, and robust adaptive and nonlinear control. He is also active in industrial applications of control theory. As a consultant to Ford, he was involved in the development of the first series of automotive computer controls, and at General Electric, he participated in large-scale systems studies.

Dr. Kokotović received the 1990 Quazza Medal, the 1983 and 1993 Outstanding IEEE TRANSACTIONS Paper Awards, and presented the 1991 Bodé Prize Lecture. He is the recipient of the 1995 IEEE Control Systems Award.

Approximate Decoupling and Asymptotic Tracking for MIMO Systems

D. N. Godbole, *Student Member, IEEE*, and S. S. Sastry, *Senior Member, IEEE*

Abstract—This paper presents an algorithm for approximate input-output decoupling of nonlinear MIMO systems that are either numerically ill-posed or exhibit nearly singular behavior in the application of decoupling algorithms. Although the systems considered are regular, so that the exact decoupling algorithms are applicable in this case, they require inversion of an ill-conditioned matrix, and yield high gain feedback solutions that may result in actuator saturation and cancellation of high frequency zeros. The approximate algorithms of this paper are numerically robust, and provide solutions that do not cancel far off right-half plane zeros. This latter characteristic is especially valuable when some of the far off right-half plane zeros are unstable. The algorithms are inspired by and are generalizations of some examples in the flight control literature [1], [2], [3].

I. INTRODUCTION

THE nonlinear control toolbox has grown enormously in the last decade. Central to this development is the theory of feedback linearization for nonlinear systems (see [4], [5]) and the solution to the multi-input multi-output (MIMO) decoupling problem. Several algorithms have been proposed in the literature for solving the problem of exact decoupling for nonlinear MIMO systems, see for example [4]–[9]. These algorithms all require the determination of the inverse of a so-called decoupling matrix. Practical implementation of these algorithms, however, is difficult when the decoupling matrix is ill conditioned or close to singularity, in which case the decoupling of such systems needs excessively large control effort. Further, the algorithm is not numerically robust since it requires the inverse of an ill conditioned matrix.

In this paper, we propose a numerically robust input-output decoupling algorithm for invertible nonlinear MIMO systems. Our efforts are motivated, in part, by the use in Hauser *et al.* [2], the work of Singh [1], [3] of such techniques to aircraft flight control problems and the work of Barbot *et al.* [10] with applications to models of electric motors and the Pelousov–Zhabotinsky reaction kinetics. In these examples, the intuition for approximation and the choice of parameters to be approximated is provided by the physics of the problem. This paper attempts to formalize the theory involved in

these examples and provide an algorithm for more general MIMO nonlinear systems, whose physical derivation may not be explicitly known by the designer. Another recent paper by Grizzle and Di Benedetto [11] provides an approximate decoupling algorithm for systems that are not decouplable by the exact decoupling algorithms by reason of their not being regular. The approximate algorithm in this paper aims at those systems that are regular and so decouplable by the exact decoupling algorithms, but the numerics of the decoupling are poorly conditioned.

In addition to the numerical robustness of our approximate algorithm, it also serves another important purpose: The exact input-output decoupling algorithm is essentially a pole-zero cancelling control law. Thus, this law cancels zeros of the open-loop system regardless of whether they are in the left half plane or the right-half plane and regardless of their magnitude. In particular the input-output decoupling control law can only be applied to minimum phase nonlinear systems. For systems with far off zeros, cancellation may not be necessary, since the zeros do not play a large role in the system dynamics and indeed may cause instability when the zeros lie in the right-half plane. In either case, cancellation of far off zeros results in high gain controllers. Our approximate decoupling algorithm does not cancel the far off zeros of the open-loop system, thereby providing reasonable gain, practically implementable solutions. The price to be paid is the replacement of asymptotically exact tracking control laws by approximate tracking control laws. This connection between regular perturbations of nonlinear systems and the far off zeros was first pointed out in [12] for the single-input single-output (SISO) case and in [13] for the MIMO case. Systems in which these far off zeros are in the right-half plane are called slightly nonminimum phase systems in [2]. The approximate decoupling controller, in this case, results in a stable closed-loop system.

It is possible to develop several different approximate decoupling algorithms starting from the different decoupling algorithms in the literature. The algorithm presented here is based on the Descusse and Moog dynamic decoupling algorithm (see [6], [14]). Section II reviews the Descusse–Moog algorithm. In Section III, we state the approximate algorithm and Section IV compares its convergence properties with that of the Descusse–Moog algorithm. In many cases, input-output decoupling is a first step in designing a tracking controller. Section V examines the effect of the approximate decoupling on the performance of tracking controller.

II. DECOUPLING ALGORITHMS FOR NONLINEAR SYSTEMS

Consider the square (i.e., number of inputs is equal to the number of outputs) MIMO nonlinear control system described by

$$\begin{aligned}\dot{x} &= f(x) + \sum_{i=1}^m g_i(x) u_i \\ y_j &= h_j(x) \quad j = 1, \dots, m\end{aligned}\quad (1)$$

where $x \in \mathcal{R}^n$, $f(x)$, $g_1(x), \dots, g_m(x)$ are analytic vector fields on \mathcal{R}^n and $h_1(x), \dots, h_m(x)$ analytic functions on \mathcal{R}^n . For convenience, these equations are written as

$$\sum_0: \begin{cases} \dot{x} = f(x) + g(x)u \\ y = h(x). \end{cases}$$

Throughout the analysis, we will assume that x_0 is an equilibrium point of the autonomous system, that is $f(x_0) = 0$. We will assume (without loss of generality) that $h(x_0) = 0$. All the analysis in this paper will be local and will be valid in a given open neighborhood U of x_0 . We now review some algorithms for decoupling of MIMO nonlinear systems.

We assume in what follows that each output y_j has a well defined relative degree γ_j , i.e., there exists an integer γ_j such that

$$L_{g_i} L_f^l h_j(x) \equiv 0 \quad \forall l < \gamma_j - 1, \forall 1 \leq i \leq m, \forall x \in U.$$

Collecting these calculation, we have

$$\begin{aligned} \begin{bmatrix} y_1^{\gamma_1} \\ y_2^{\gamma_2} \\ \vdots \\ y_m^{\gamma_m} \end{bmatrix} &= \begin{bmatrix} L_f^{\gamma_1} h_1(x) \\ L_f^{\gamma_2} h_2(x) \\ \vdots \\ L_f^{\gamma_m} h_m(x) \end{bmatrix} \\ &+ \begin{bmatrix} L_{g_1} L_f^{\gamma_1-1} h_1(x) & \dots & L_{g_m} L_f^{\gamma_1-1} h_1(x) \\ L_{g_1} L_f^{\gamma_2-1} h_2(x) & \dots & L_{g_m} L_f^{\gamma_2-1} h_2(x) \\ \vdots & \dots & \vdots \\ L_{g_1} L_f^{\gamma_m-1} h_m(x) & \dots & L_{g_m} L_f^{\gamma_m-1} h_m(x) \end{bmatrix} u \\ &:= b(x) + A(x)u. \end{aligned}\quad (2)$$

$A(x)$ is called the decoupling matrix. If $A(x)$ is invertible at every point in U , then the static-state feedback given by

$$u = (A(x))^{-1}[-b(x) + v] \quad (3)$$

will result in a closed-loop system that is decoupled from input v to output y . This decoupled and input-output linearized system is given by

$$\begin{bmatrix} y_1^{\gamma_1} \\ y_2^{\gamma_2} \\ \vdots \\ y_m^{\gamma_m} \end{bmatrix} = \begin{bmatrix} v_1 \\ v_2 \\ \vdots \\ v_m \end{bmatrix}. \quad (4)$$

If the matrix $A(x)$ is singular, we cannot use a static state feedback to decouple the nonlinear system ([4]), and we have

to look for a dynamic state feedback to achieve input-output decoupling.

A. Dynamic Decoupling

If decoupling of the system \sum_0 of (1) cannot be achieved by static state feedback, it may still be possible to find a dynamic compensator of the form

$$\sum_c: \begin{cases} \dot{z} = D(x, z) + E(x, z)v \\ u = F(x, z) + G(x, z)v \end{cases} \quad (5)$$

with $z \in \mathcal{R}^{n_c}$, $v \in \mathcal{R}^m$, such that the closed-loop system denoted by \sum_c (for extended system)

$$\sum_c: \begin{cases} \dot{x} = f(x) + g(x)F(x, z) + g(x)G(x, z)v \\ \dot{z} = D(x, z) + E(x, z)v \\ y = h(x) \end{cases} \quad (6)$$

is decoupled from v to y . The dynamic feedback that decouples the system \sum_0 of (1) is actually a static feedback to decouple the extended system \sum_c of (6). There are a number of algorithms in the literature for dynamic decoupling. The approximate decoupling algorithm we will propose is based on the Descusse and Moog algorithm of ([6], [14]). We will review the original algorithm to fix notation.

Descusse and Moog Dynamic Decoupling Algorithm: Define the extended system at the end of iteration $k-1$ to be \sum_k having x^c as its state and equilibrium point x_0^c . The algorithm will start at $k=0$ with the given system \sum_0 having state $x \in \mathcal{R}^n$ and x_0 as its equilibrium point. The outputs of the system are unchanged during the course of the algorithm.

Step i: Compute the relative degrees $\gamma_i^k (i \in \{1, \dots, m\})$ for the m outputs of \sum_k . Define the decoupling matrix $A_k(x^c)$ to have its ij th entry given by

$$a_{ij}^k(x^c) = L_{g_j} L_f^{\gamma_i^k-1} h_i(x^c).$$

Let r_k be the normal rank of $A_k(x^c)$ in an open neighborhood of x_0^c . If $r_k = m$, stop.

Step ii: If $r_k < m$, define a square and nonsingular matrix $\hat{G}_k(x^c)$ such that the $(m - r_k)$ last columns of $\hat{A}_k(x^c) := A_k(x^c)\hat{G}_k(x^c)$ are identically zero. Moreover, this process can be carried out such that there exists r_k rows which the nonzero elements form an $r_k \times r_k$ nonsingular diagonal matrix. It is shown in [6] that $\hat{G}_k(x^c)$ always exists and is an analytic function of x^c .

There are r_k columns of $\hat{A}_k(x^c)$ with nonzero elements, out of which q_k columns have two or more nonzero elements. Design a permutation matrix P_k such that the first q_k columns of $\hat{A}_k(x^c)P_k$ have two or more elements nonzero, followed by the $(r_k - q_k)$ columns having only one nonzero element and finally the last $(m - r_k)$ columns having all zero elements. Denote $G_k(x^c) = \hat{G}_k(x^c)P_k$. Define an intermediate input \hat{u} by

$$\hat{u} = [G_k(x^c)]^{-1}u. \quad (7)$$

Step iii: The system \sum_k now is

$$\begin{aligned}\dot{x}^e &= f(x^e) + g(x^e)G_k(x^e)\hat{u} \\ y &= h(x^e).\end{aligned}$$

Add integrators in series with the first q_k inputs. This creates the new input vector \hat{u} of the form

$$\hat{u} = \begin{bmatrix} \dot{\hat{u}}_1 \\ \vdots \\ \dot{\hat{u}}_{q_k} \\ \hat{u}_{q_k+1} \\ \vdots \\ \hat{u}_m \end{bmatrix}. \quad (8)$$

Thus the new system after adding these integrators is

$$\begin{bmatrix} \dot{x}^e \\ \vdots \\ \dot{\hat{u}}_1 \\ \vdots \\ \dot{\hat{u}}_{q_k} \end{bmatrix} = \begin{bmatrix} f(x^e) + \sum_{i=1}^{q_k} \tilde{g}_i(x^e)\hat{u}_i \\ \vdots \\ 0 \\ \vdots \\ 0 \end{bmatrix} + \begin{bmatrix} \sum_{i=q_k+1}^m \tilde{g}_i(x^e)\hat{u}_i \\ \vdots \\ \hat{u}_1 \\ \vdots \\ \hat{u}_{q_k} \end{bmatrix}$$

$$y = h(x^e) \quad (9)$$

where $\tilde{g}(x^e) = g(x^e)G_k(x^e)$. Call this system \sum_{k+1} .

Step iv: Go to Step i and resume the procedure with $k \leftarrow k+1$, new state variables $x^e \leftarrow \{x^e\} \cup \{\hat{u}_i\}_{i=1, \dots, q_k}$ and new input $u \leftarrow \hat{u}$. Let f, g, h still denote the extended f, g, h for notational simplicity. Let U still denote the open set of interest containing the equilibrium point of the extended system. \square

It has been shown by Descusse and Moog that if system (1) is right invertible and satisfies the accessibility rank condition (cf. [5, p. 86]) at x_0 , then the above algorithm converges in a finite number of steps, L , to an extended system \sum_L which is decouplable by static state feedback.

Note: At the end of i th iteration, the above algorithm adds q_i integrators ($q_i \leq r_i$) to the system \sum_i . Thus the dimension of x^e increases by q_i .

The Dynamic Extension algorithm (cf. [4]) and Singh's algorithm ([7], [15]) are similar, except that Singh's algorithm involves nonlinear transformations of the output space instead of the input space as in the Descusse-Moog algorithm.

The computation of the rank of $A_k(x^e)$ will be greatly simplified if $A_k(x^e)$ satisfies a regularity condition (see [16]), which guarantees that the normal rank of $A_k(x^e)$ is the same as the local rank for every $x^e \in U$. In this paper, we assume that \sum_0 is a regular system. If the given system is not regular, then one can use the procedure of [11] to get an approximate system that is regular and call this system \sum_0 .

Normal Form

Let us assume that the Descusse-Moog dynamic decoupling algorithm converges after L steps to a system of the form (6). Let us denote this extended system by \sum_e . Let (f^e, g^e, h^e) be the triple characterizing \sum_e , $x^e = (x, z) \in \mathbb{R}^{n+n_e}$ its state, u^e its input, and y^e its output. Let $x_0^e = (x_0, z_0)$ be the equilibrium point of interest. This system

\sum_e has a well defined vector relative degree $[\gamma_1^e, \dots, \gamma_m^e]$ at x_0^e . Let $\gamma^e := \sum_{i=1}^m \gamma_i^e$. We can construct a local change of coordinates $\phi(x^e) = (\xi, \eta)$ with $\xi = \text{col}(\xi^i)$, such that $\phi(x_0^e) = 0$, by choosing

$$\begin{aligned}\xi^i &= \text{col}(h_i^e(x^e), L_{f^e} h_i^e(x^e), \dots, L_{f^e}^{\gamma_i^e-1} h_i^e(x^e)) \\ &:= \text{col}(\xi_1^i, \xi_2^i, \dots, \xi_{\gamma_i^e}^i)\end{aligned} \quad (10)$$

and remaining $(n + n_e - \gamma^e)$ complementary coordinates η . In these coordinates, \sum_e takes the normal form (see [4])

$$\begin{aligned}\dot{\xi}_1^i &= \xi_2^i \\ &\vdots \\ \dot{\xi}_{\gamma_i^e-1}^i &= \xi_{\gamma_i^e}^i \\ \dot{\xi}_{\gamma_i^e}^i &= b_i^e(\xi, \eta) + \sum_{j=1}^m a_{ij}^e(\xi, \eta)u_j^e \\ \dot{\eta} &= q(\xi, \eta) + P(\xi, \eta)u^e \\ y_i^e &= \xi_1^i\end{aligned} \quad (11)$$

for $i = 1, \dots, m$, where

$$b_i^e(\xi, \eta) = L_{f^e}^{\gamma_i^e} h_i^e(\phi^{-1}(\xi, \eta)) \quad 1 \leq i \leq m$$

$$a_{ij}^e(\xi, \eta) = L_{g_j^e} L_{f^e}^{\gamma_i^e-1} h_i^e(\phi^{-1}(\xi, \eta)) \quad 1 \leq i, j \leq m.$$

The static state feedback that decouples the system \sum_e is given by

$$u^e = (A^e(\xi, \eta))^{-1}[-b^e(\xi, \eta) + v]. \quad (12)$$

The decoupling state feedback renders the η dynamics unobservable. The zero dynamics of system \sum_e are the dynamics of the η coordinates in the subspace $\xi = 0$ with the decoupling feedback law of (12) (with $v = 0$), i.e.,

$$\dot{\eta} = q(0, \eta) - P(0, \eta)[(A^e(0, \eta))^{-1}b^e(0, \eta)]. \quad (13)$$

For a detailed discussion of the zero dynamics and the transmission zeros of nonlinear systems we refer the reader to [17], [4, Chapter 6], [5, Chapter 11].

III. APPROXIMATE DYNAMIC DECOUPLING ALGORITHM

The difficulty in implementing the decoupling algorithm comes from the ill-conditioning of the decoupling matrix or from a situation in which the decoupling matrix may be nonsingular but close to singularity. To be precise, this occurs if the smallest singular value of $A^e(x^e)$ is smaller than a certain prespecified $\epsilon > 0$ for any $x \in U$. In this case, the algorithm calls for the inverse of an ill-conditioned matrix. In addition to the fact that the inverse is not numerically robust, it may cause large feedback gains in the controller and also cause the cancellation of far-off zeros (see [13, Section 4]). To alleviate these difficulties, we propose the following numerically robustified decoupling algorithm: while the algorithm appears to have numerical considerations in mind, it is, in fact, valuable for the reason that it does not cancel far off right-half plane zeros and may help control the magnitudes of the control inputs. To state the algorithm, recall a few basic facts and definitions about the numerical rank of a matrix.

Definition 1: A matrix $A \in \mathbb{R}^{n \times n}$ is said to have ϵ numerical rank r if

$$\inf \text{rank} \{B: \|B - A\| < \epsilon\} = r.$$

The norm in the above definition is the induced norm of the matrix induced by the Euclidean norm.

Thus, the numerical rank of a matrix is the lowest it can drop to in an ϵ neighborhood of the given matrix. In particular, if the matrix has $(n - r)$ of its singular values less than ϵ , then its numerical rank is r .

Approximate Dynamic Decoupling Algorithm. This algorithm starts at $k = 0$ with the given system Σ_0 having x_0 as its equilibrium point. We are given a threshold $\epsilon > 0$. Let the extended system at the end of iteration $(k - 1)$ be denoted by Σ_k having x^e as its state and x_k^e , the corresponding equilibrium point.

Step i: Compute the relative degrees of the outputs, namely, γ_i^k , $i = 1, \dots, m$, and the decoupling matrix $A_k(x^e)$. Let r_k be the normal rank of $A_k(x^e)$ in U . If $r_k = m$ and if the smallest singular value of $A_k(x^e)$ is greater than the threshold ϵ uniformly on U , stop.

Step ii: If all the nonzero singular values of $A_k(x^e)$ are less than ϵ uniformly on U , approximate $A_k(x^e)$ by a zero matrix. Go to Step i and recalculate the relative degrees γ_i^k with this approximation.

If $r_k = m$, go to Step iii, with $\hat{A}_k(x^e) = A_k(x^e)$ and $\hat{G}_k(x^e) = I_{m \times m}$.

Design a square, analytic and nonsingular matrix $\hat{G}_k(x^e)$ such that the last $m - r_k$ columns of $\hat{A}_k(x^e) := A_k(x^e)\hat{G}_k(x^e)$ are identically zero.

Step iii: If the smallest nonzero singular value of $A_k(x^e)$ is greater than the threshold ϵ , go to Step iv, with $\hat{A}_k(x^e) = \hat{A}_k(x^e)$, $G_k(x^e) = I_{m \times m}$ and $w_k = r_k$.

If the smallest nonzero singular value of $\hat{A}_k(x^e)$ is smaller than ϵ , then there exists a positive integer $w_k (< r_k)$ such that the ϵ rank of $\hat{A}_k(x^e)$ is w_k uniformly on U , i.e., $(r_k - w_k)$ nonzero singular values of $\hat{A}_k(x^e)$ are less than ϵ uniformly on U .

Design a square analytic nonsingular matrix $\hat{G}_k(x^e)^1$ such that

$$\begin{aligned} \hat{A}_k(x^e) &= \hat{A}_k(x^e)\hat{G}_k(x^e) \\ &= [a_1^k(x^e), \dots, a_{w_k}^k(x^e), \epsilon a_{w_k+1}^k(x^e), \dots, \\ &\quad \epsilon a_{r_k}^k(x^e), 0, \dots, 0]. \end{aligned} \quad (14)$$

Approximate the $r_k - w_k$ columns, which are small in norm, by identically zero columns. Go to Step iv with

$$\tilde{A}_k(x^e) = [a_1^k(x^e), \dots, a_{w_k}^k(x^e), 0, \dots, 0].$$

Note. The ϵ numerical rank of $\hat{A}_k(x^e)$ may not be constant over U . If the ϵ numerical rank passes through singularity at x_0^e , then the approximate algorithm will not work.² Throughout the analysis, we assume that the ϵ numerical rank of $\hat{A}_k(x^e)$ is constant in U .

¹ The proof of existence of such a matrix is given in the Appendix.

² The problem may be solved by reducing the value of ϵ . Since Σ_0 is a regular system (cf. [16]), the singularity does not exist for $\epsilon = 0$. However, reducing the value of ϵ defeats the purpose of the algorithm, by causing high gain solutions to the original decoupling problem.

Step iv: Out of w_k nonzero columns of $\tilde{A}_k(x^e)$, q_k columns will have two or more nonzero elements. Design a permutation matrix P_k such that the first q_k columns of $\tilde{A}_k(x^e)P_k(x^e)$ have two or more nonzero elements, followed by the $(w_k - q_k)$ columns having only one nonzero element and finally the last $(m - w_k)$ identically zero columns. Denote $G_k(x^e) = \tilde{G}_k(x^e)\tilde{G}_k(x^e)P_k$. Define an intermediate input by

$$\hat{u} = [G_k(x^e)]^{-1}u.$$

Step v: The system Σ_k now is

$$\begin{aligned} \dot{x}^e &= f(x^e) + g(x^e)G_k(x^e)\hat{u} \\ y &= h(x^e). \end{aligned}$$

Add an integrator in series with the first q_k inputs. This creates the new input vector \tilde{u} of the form

$$\tilde{u} = \begin{bmatrix} \hat{u}_1 \\ \vdots \\ \hat{u}_{q_k} \\ \hat{u}_{q_k+1} \\ \vdots \\ \hat{u}_m \end{bmatrix} = \begin{bmatrix} \tilde{u}_1 \\ \vdots \\ \tilde{u}_{q_k} \\ \hat{u}_{q_k+1} \\ \vdots \\ \hat{u}_m \end{bmatrix}. \quad (15)$$

Thus the new system after adding these integrators is

$$\begin{aligned} \begin{bmatrix} x^e \\ \vdots \\ \hat{u}_1 \\ \vdots \\ \hat{u}_{q_k} \end{bmatrix} &= \begin{bmatrix} f(x^e) = \sum_{i=1}^{q_k} \hat{q}_i(x^e)\hat{u}_i \\ \vdots \\ 0 \\ \vdots \\ 0 \end{bmatrix} + \begin{bmatrix} \sum_{i=1}^{m-q_k} \hat{q}_i(x^e)\hat{u}_i \\ \vdots \\ \hat{u}_1 \\ \vdots \\ u_{q_k} \end{bmatrix} \\ y &= h(x^e) \end{aligned} \quad (16)$$

where $q(x^e) = g(x^e)G_k(x^e)$. Call this system Σ_{k+1} .

Step vi: Return to Step i and resume the procedure with $k \leftarrow k + 1$, new state variables $x^e \leftarrow \{x^e\} \cup \{\hat{u}_i\}_{i=1, \dots, q_k}$ and new input $u \leftarrow \tilde{u}$. Let f, g, h still denote the extended f, g, h for notational simplicity. Let U still denote the open set containing the equilibrium point of the extended system. \square

Let us assume that the approximate dynamic decoupling algorithm converges after L steps to a system of the form of (6). Let us denote this extended system by $\tilde{\Sigma}_e$. Let $(\tilde{f}^e, \tilde{g}^e, \tilde{h}^e)$ be the triple characterizing $\tilde{\Sigma}_e$, $\tilde{x}^e = (x, z)$ its state, \tilde{u}^e its input, and \tilde{y}^e its output. Let $\tilde{x}_0^e = (x_0, z_0)$ be the equilibrium point of interest. The system $\tilde{\Sigma}_e$ has a well-defined vector relative degree $[\tilde{\gamma}_1^e, \dots, \tilde{\gamma}_l^e]$ at \tilde{x}_0^e . Thus we can construct a local diffeomorphism of the form of (10) such that $\tilde{\Sigma}_e$ will be transformed into the normal form $(\tilde{\xi}, \tilde{\eta})$ coordinates given by

$$\begin{aligned} \tilde{\xi}^e &= \text{col}(\tilde{h}_1^e(x^e), L_{\tilde{f}_e} \tilde{h}_1^e(\tilde{x}^e), \dots, L_{\tilde{f}_e}^{\tilde{\gamma}_1^e-1} \tilde{h}_1^e(\tilde{x}^e)) \\ &= \text{col}(\tilde{\xi}_1^e, \dots, \tilde{\xi}_{\tilde{\gamma}_1^e}^e) \end{aligned} \quad (17)$$

and remaining $(n + \tilde{n}_e - \sum_{i=1}^m \tilde{\gamma}_i^e)$ complementary coordinates $\tilde{\eta}$. In the course of the approximate dynamic decoupling algorithm, we have neglected order ϵ terms at each iteration of

algorithm. Thus the original or exact system in the normal coordinates of \sum_e will be

$$\begin{aligned}\dot{\tilde{\xi}}_1^i &= \tilde{\xi}_2^i \\ &\vdots \\ \dot{\tilde{\xi}}_{\gamma_i^0-1}^i &= \tilde{\xi}_{\gamma_i^0}^i \\ \dot{\tilde{\xi}}_{\gamma_i^0}^i &= \tilde{\xi}_{\gamma_i^0+1}^i + \epsilon \sum_{j=1}^m (\beta_{\gamma_i^0}^i)_j \tilde{u}_j^e \\ &\vdots \\ \dot{\tilde{\xi}}_{\gamma_i^e-1}^i &= \tilde{\xi}_{\gamma_i^e}^i + \epsilon \sum_{j=1}^m (\beta_{\gamma_i^e-1}^i)_j \tilde{u}_j^e \\ \dot{\tilde{\xi}}_{\gamma_i^e}^i &= \tilde{b}_i^e(\tilde{\xi}, \tilde{\eta}) + \sum_{j=1}^m \tilde{a}_{ij}^e(\tilde{\xi}, \tilde{\eta}) \tilde{u}_j^e \\ \dot{\tilde{\eta}} &= q(\tilde{\xi}, \tilde{\eta}) + P(\tilde{\xi}, \tilde{\eta}) \tilde{u}^e \\ \tilde{y}_i^e &= \tilde{\xi}_1^i\end{aligned}\quad (18)$$

for $i = 1, \dots, m$, where

$$\tilde{b}_i^e(\tilde{\xi}, \tilde{\eta}) = L_{f^e}^{\gamma_i^e} \tilde{h}_i^e(\phi^{-1}(\tilde{\xi}, \tilde{\eta})) \quad 1 \leq i \leq m$$

$$\tilde{a}_{ij}^e(\tilde{\xi}, \tilde{\eta}) = L_{g_j^e}^{\gamma_i^e-1} \tilde{h}_i^e(\phi^{-1}(\tilde{\xi}, \tilde{\eta})) \quad 1 \leq i, j \leq m.$$

Note: If we substitute $\epsilon = 0$ in (18), then we get the representation of the system \sum_e in its normal form, coordinates $(\tilde{\xi}, \tilde{\eta})$. The static state feedback that decouples the system \sum_e is given by

$$\tilde{u}^e = (\tilde{A}^e(\tilde{\xi}, \tilde{\eta}))^{-1} [-\tilde{b}^e(\tilde{\xi}, \tilde{\eta}) + v]. \quad (19)$$

If we compare the approximate and exact decoupling algorithm, we see that

- If the exact decoupling algorithm converges with a decoupling matrix $A^e(x^e)$ whose smallest singular value is greater than ϵ uniformly on U , then the approximate decoupling algorithm yields the same result.
- If, on the other hand, $A^e(x^e)$ obtained by exact decoupling algorithm has its smallest singular value of the order of ϵ uniformly on U , then the decoupling control law (12) will have terms of the order of $1/\epsilon$ that will result in a high gain controller that may not be practically feasible if the actuators have saturation limits.

The approximate decoupling algorithm is of use if we can answer the following two questions:

- 1) If the given system (1) is right invertible and locally accessible (i.e., the exact decoupling algorithm converges in L steps), then does the approximate decoupling algorithm converge in a finite number of steps?
- 2) If the answer to the first question is yes, then how much error do we introduce in tracking the reference outputs by using the approximate decoupling and tracking law instead of the exact one?

These questions will be answered in the following sections.

IV. CONVERGENCE OF APPROXIMATE DECOUPLING ALGORITHM

The approximate decoupling algorithm is based on the Descusse and Moog dynamic decoupling algorithm. Consequently, the convergence properties of the approximate decoupling algorithm will be compared with that of the Descusse and Moog algorithm. Ideally the approximate decoupling algorithm should preserve the convergence properties of the Descusse and Moog algorithm.

The algorithm of Descusse and Moog adds dynamics to the given system \sum_0 , to get an extended system \sum_L which is decouplable by static state feedback. The following theorem [6], relates this notion to the nonsingularity of the decoupling matrix $A_L(x)$.

Theorem 1: System \sum of the form of (1) is decouplable by static state feedback, if, the decoupling matrix for \sum is invertible.

The approximate decoupling algorithm converges to an extended system that is robustly decouplable by static state feedback. This notion is defined as follows.

Definition 2: An $m \times m$ matrix $A(x)$ is ϵ robustly invertible in an open set U with respect to a threshold ϵ if the ϵ numerical rank of $A(x)$ is m uniformly on U .

Definition 3: A system \sum of the form of (1) is ϵ robustly decouplable by static state feedback with respect to a threshold ϵ , if, \sum is decouplable by static state feedback and the decoupling matrix $A(x)$ is robustly invertible with respect to ϵ .

The following lemma considers the effect of one iteration of the approximate decoupling algorithm on a system that is decouplable by using the Descusse and Moog algorithm.

Lemma 1: Suppose that the Descusse and Moog algorithm converges for a system \sum_k of the form of (1). Apply the approximate decoupling algorithm. After one iteration, we get the extended system \sum_{k+1} . One of the following is true for \sum_{k+1} :

- 1) $\gamma_i^{k+1} = \infty$ for some i .
- 2) $A_{k+1}(x)$ is singular and the Descusse and Moog decoupling algorithm does not converge for \sum_{k+1} .
- 3) $\gamma^{k+1} = n_{\sum_{k+1}}$ and $A_{k+1}(x)$ is not robustly invertible.
- 4) $A_{k+1}(x)$ is singular, but the Descusse and Moog algorithm converges for \sum_{k+1} .
- 5) $A_{k+1}(x)$ is nonsingular, not robustly invertible and $\gamma^{k+1} < n_{\sum_{k+1}}$.
- 6) $A_{k+1}(x)$ is robustly invertible.

where $\gamma^{k+1} = \sum_{i=1}^m \gamma_i^{k+1}$ and $n_{\sum_{k+1}}$ = the dimension of state space of \sum_{k+1} .

Proof: This is a list of all the cases after application of one step of the approximate decoupling algorithm. It is easy to check that the list exhausts all the possibilities. \square

We will analyze each of the above cases in detail to understand why in some cases the approximate decoupling algorithm may not converge.

While applying the Descusse and Moog algorithm, we differentiate each output until at least one input appears on the right hand side. Some of the inputs show up earlier than others making the decoupling matrix singular. Integrators are

added in front of these inputs to delay their appearance for at least one more step of differentiation.

In this process, at a particular step, some of the inputs might be weakly connected to the outputs, i.e., the functions multiplying them are smaller than the threshold ϵ uniformly in U . These functions are approximated by zero in the approximate decoupling algorithm. This modification in the original Descusse and Moog algorithm might make the resulting systems noninvertible. The classification of various cases in the previous lemma helps detect such systems in the following manner:

Analysis of Lemma 1. Recall that γ_i^k are the relative degrees of the outputs of Σ_k . We have

$$\begin{bmatrix} y_1^{\gamma_1^k} \\ \vdots \\ y_m^{\gamma_m^k} \end{bmatrix} = b_k(x) + A_k(x)u$$

rank of $A_k(x) = r_k$. At the end of Step ii, $(m - r_k)$ columns of $\hat{A}_k(x)$ are identically zero and there is at least one nonzero element in each row of $\hat{A}_k(x)$.

At the end of Step iv, some of the rows of $A_k(x)G_k(x)$ might be identically zero because of the approximation of $(r_k - w_k)$ columns by zero. The number of such rows is less than or equal to $(r_k - w_k)$. Let us denote the set of outputs corresponding to these rows by \bar{Y}_k .

$(w_k - q_k)$ columns of $A_k(x)G_k(x)$ have only one nonzero element. By construction, these nonzero elements will be in $(w_k - q_k)$ different rows. Let us denote the $(w_k - q_k)$ outputs corresponding to these rows by \hat{Y}_k . The remaining outputs will be denoted by \tilde{Y}_k .

The outputs of Σ_k do not change in the process. Thus for Σ_{k+1} , we have

- $\gamma_i^{k+1} = \gamma_i^k, \forall i \text{ s.t. } y_i \in \hat{Y}_k$
- $\gamma_i^{k+1} = \gamma_i^k + 1, \forall i \text{ s.t. } y_i \in \tilde{Y}_k$
- $\gamma_i^{k+1} \geq \gamma_i^k + 1, \forall i \text{ s.t. } y_i \in \bar{Y}_k$

Case 1: If the only nonzero entries in the i th row are in the j th column, then when the j th column of $A_k(x)G_k(x)$ is approximated by zero, the i th row is made identically zero. y_i is only affected by u_j , and after the approximation, u_j never appears on the right hand side again. This makes $\gamma_i^{k+1} = \infty$.

Case 2: The situation here is that Case 1 recurs, but not immediately at the end of the $k - 1$ st step but later in the algorithm. Thus the system Σ_k loses invertibility because of the approximation. Some rows of $A_{k+l}(x)$ will be dependent for all $l > 0$. This case can also be avoided by normalizing the j th input.

In the course of the approximate decoupling algorithm, Case 2 goes unnoticed until you reach Case 3. Thus the reason for Case 3 is in fact the occurrence of Case 2 during one of the previous iterations.

If the approximate decoupling algorithm converges to a system Σ_L that can be decoupled by static state feedback, the outputs y_i and their respective derivatives up to the order of $(\gamma_i^L - 1)$ qualify as a partial change of coordinates. In the normal form notation these are the ξ coordinates.

During each iteration of the approximate decoupling algorithm, the state space dimension of Σ_k is extended by

q_k whereas at least $(m - w_k + q_k)$ new ξ coordinates are introduced. The difference between the state space dimension of Σ_{k+1} and the dimension of ξ coordinates decreases by $(m - w_k)$ during each iteration of the approximate decoupling algorithm.

Case 3: If we go through $(k + 1)$ th iteration, dimension of ξ coordinates will exceed the dimension of the state space of Σ_{k+2} . Thus we cannot proceed further.

Cases 4, 5, and 6 lead towards the convergence of approximate decoupling algorithm. \square

Definition 4: Suppose Σ_0 satisfies the hypothesis of Descusse and Moog algorithm. Apply the approximate decoupling algorithm, for given $\epsilon > 0$. Let $k \geq 0$ be the smallest integer such that either case 1, 2, or 3 of the previous lemma is true for Σ_{k+1} . Then the system Σ_0 is said to be ϵ -unnormalized.

Theorem 2. Suppose Σ_0 satisfies the hypothesis of the Descusse and Moog dynamic decoupling algorithm. Apply the approximate decoupling algorithm for a given $\epsilon > 0$. Then one of the following is true.

- The approximate decoupling algorithm converges in a finite number of steps.
- The system Σ_0 is ϵ -unnormalized.

Proof: During each step of the approximate decoupling algorithm, the difference between the state space dimension and the dimension of ξ coordinates decreases by $(m - w_k)$. Thus, if the first three cases of the previous lemma are avoided during each iteration, the algorithm has to converge in a finite number of steps.

The discussion following the previous lemma shows that the first three cases correspond to the underlying system being unnormalized. \square

In general, it is not possible, *a priori*, to find out whether a given system is normalized or not. If the approximate decoupling algorithm does not converge in n steps, then the system is unnormalized, provided it was decouplable by using the exact Descusse and Moog dynamic decoupling algorithm.

The design parameter ϵ is an input to the approximate decoupling algorithm. If the approximate algorithm does not converge for a given ϵ , because of the system being ϵ unnormalized, then the value of ϵ can be reduced. This might result in convergence of the algorithm but the original problem of numerical robustness and high gain solutions still exists. In the limit that $\epsilon \rightarrow 0$, one recovers the Descusse–Moog algorithm. For $\epsilon = 0$, the ϵ unnormalized systems are noninvertible. Thus given an invertible system that satisfies the accessibility rank condition, one can always find an ϵ so that the approximate algorithm converges. In particular, the algorithm converges for the specific examples of [1], [2], [3].

A. Multiple Time Scale Zero Dynamics

Since the zero dynamics of a system does not change by addition of integrators to its input channels [4, p. 389], by input space transformations or by state feedback, the zero dynamics of Σ_0 is same as that of Σ_L , where Σ_L is the extended system at the end of Descusse and Moog algorithm. The next lemma compares the zero dynamics of Σ_L and Σ_L where $\tilde{\Sigma}_L$ is the extended system at the end of approximate

coupling algorithm. Note that the approximate decoupling algorithm cannot converge in fewer steps than the Descusse and Moog algorithm.

Lemma 2: Suppose Σ_0 is right invertible (cf. [6]) and satisfies the strong accessibility rank condition (cf. [5, p. 86]) at r_0 . Suppose that the approximate decoupling algorithm converges for this system in exactly the same number of steps as the Descusse and Moog algorithm. Let Σ_L and $\tilde{\Sigma}_L$ be the system at the end of the Descusse and Moog algorithm and the approximate decoupling algorithms respectively. Then

$$\dim(\eta_{\tilde{\Sigma}_L}) \leq \dim(\eta_{\Sigma_L})$$

where η denotes the zero dynamics coordinates.

Proof: During each iteration, the difference between state space coordinates and the ξ coordinates decreases by $(m - w_k)$ for approximate decoupling algorithm and by $(m - r_k)$ for the Descusse and Moog decoupling algorithm. After L steps when both the algorithms converge, the zero dynamics dimension is given by the difference between the state space dimension of the extended system and the dimension of the ξ coordinates. Thus

$$\begin{aligned} \dim(\eta_{\tilde{\Sigma}_L}) &= \dim(\eta_{\Sigma_L}) - \sum_{i=0}^{L-1} (r_i - w_i) \\ &\leq \dim(\eta_{\Sigma_L}). \end{aligned} \quad \square$$

Thus, in general, the zero dynamics of the extended system at the end of the approximate decoupling algorithm (i.e., $\tilde{\Sigma}_L$) will have smaller dimension than that of Σ_L . We would like to investigate the relationship between $\eta_{\tilde{\Sigma}_L}$ and η_{Σ_L} .

Recent results in the area of singularly perturbed zero dynamics of nonlinear systems ([12], [13]) lead us to the following conclusion: under some suitable technical hypotheses, the zero dynamics of Σ_L can be decomposed into two or more time scales using singular perturbation theory (cf. [18]). The slow or reduced system is described by the zero dynamics of $\tilde{\Sigma}_L$ and the dynamics that were neglected during the process of approximation constitutes the faster time scale or boundary layer subsystem. In [13], the authors have proved the above conclusion for a restricted class of two-input/two-output systems. The full details and the technical hypotheses needed to guarantee the existence of singularly perturbed zero dynamics for this general class of systems remain to be worked out. We will conclude this section with the following remarks.

The approximate decoupling algorithm creates an extended system that does not include the far off zeros of the original system. Since the static state feedback that achieves decoupling of Σ_L is a pole zero cancellation law, we do not cancel the far off zeros of Σ_0 in the case of the approximate decoupling algorithm. The cancellation of these far off zeros requires a large control effort resulting in a high gain controller. If these far off zeros are unstable, then their cancellation makes the closed-loop system unstable. These systems are referred to as slightly nonminimum phase systems in [2]. Application of the approximate decoupling algorithm to slightly nonminimum phase systems results in a stable closed-loop system.

V. APPROXIMATE ASYMPTOTIC TRACKING

Input-output decoupling is closely related to tracking of reference trajectories by the outputs of a MIMO nonlinear system. If the desired trajectories to be tracked fall into a restricted class of functions, say constants or sinusoids with a finite spectrum, then we can use nonlinear regulator theory (see [4, Chapter 7], [19], [20]). If the class of desired trajectories is more general, for example, functions that are N times continuously differentiable but otherwise arbitrary, then according to [21] the decoupling controller forms an inner loop of the overall tracking controller. If the given system is not robustly decouplable by using exact decoupling algorithms, then we have to use the approximate decoupling feedback. This section considers the effects of approximate decoupling on the performance and stability of the overall tracking controller.

Let us assume that the approximate decoupling algorithm converges for Σ_0 giving us the approximate extended system $\tilde{\Sigma}_L$. Equations (18) with $\epsilon = 0$ represent $\tilde{\Sigma}_L$ in its normal form $(\tilde{\xi}, \tilde{\eta})$ coordinates. If the objective of the controller is to track the desired reference trajectory $y_d(t) = [y_{d_1}(t), \dots, y_{d_m}(t)]^T$ which is smooth and bounded with bounded derivatives, we design the control input \hat{u}_L to be

$$\hat{u}^c = (\hat{A}'(\tilde{\xi}, \tilde{\eta}))^{-1}[-b'(\tilde{\xi}, \tilde{\eta}) + v]$$

$$\begin{aligned} v &= \begin{bmatrix} v_1 \\ \vdots \\ v_m \end{bmatrix} \\ &= \begin{bmatrix} y_{d_1}^{\gamma_1^i} + \sigma_{\gamma_1^i-1}^1 (y_{d_1}^{\gamma_1^i-1} - \xi_{\gamma_1^i-1}^1) + \dots + \sigma_0^1 (y_{d_1} - \xi_1^1) \\ \vdots \\ y_{d_m}^{\gamma_m^i} + \sigma_{\gamma_m^i-1}^m (y_{d_m}^{\gamma_m^i-1} - \xi_{\gamma_m^i-1}^m) + \dots + \sigma_0^m (y_{d_m} - \xi_1^m) \end{bmatrix} \end{aligned} \quad (20)$$

where $(s^{\gamma_i^i} + \sigma_{\gamma_i^i-1}^i s^{\gamma_i^i-1} + \dots + \sigma_0^i)$ is a Hurwitz polynomial for $i = 1, \dots, m$.

Let us define the tracking errors to be

$$e_i^t := \tilde{\xi}_i^t - y_{d_i}, \quad 1 \leq i \leq m. \quad (21)$$

Let us define the error coordinates for system $\tilde{\Sigma}_L$ to be

$$\begin{bmatrix} e_1^t \\ \vdots \\ e_m^t \end{bmatrix} = \begin{bmatrix} \tilde{\xi}_1^t \\ \vdots \\ \xi_{\gamma_i^i-1}^t \end{bmatrix} - \begin{bmatrix} y_{d_1} \\ \vdots \\ y_{d_i}^{\gamma_i^i-1} \end{bmatrix} \quad 1 \leq i \leq m. \quad (22)$$

Thus the system $\tilde{\Sigma}_L$ with the feedback (20) can be expressed in $(e, \tilde{\eta})$ coordinates by

$$\dot{e}^t = \bar{A}' e^t \quad i = 1, \dots, m$$

$$\dot{\tilde{\eta}} = q(\tilde{\xi}, \tilde{\eta}) + P(\tilde{\xi}, \tilde{\eta}) \hat{u}^c(\tilde{\xi}, \tilde{\eta}, v) \quad (23)$$

where $\bar{A}' \in \mathbb{R}^{\tilde{\gamma}_i^i \times \tilde{\gamma}_i^i}$ given by

$$\bar{A}' = \begin{bmatrix} 0 & 1 & \dots & 0 \\ & & \ddots & \\ 0 & 0 & 0 & 1 \\ -\sigma_0^i & -\sigma_1^i & \dots & -\sigma_{\gamma_i^i-1}^i \end{bmatrix}.$$

It can be shown (e.g., see [2]) that if

- The reference trajectory and its derivatives are bounded and small enough.
- Zero dynamics of (23) (i.e., the equilibrium point $\tilde{\eta}_0 = 0$ of the system)

$$\dot{\tilde{\eta}} = q(0, \tilde{\eta}) + P(0, \tilde{\eta})\tilde{u}^e(0, \tilde{\eta}, 0) \quad (24)$$

is exponentially stable.

- $q(\tilde{\xi}, \tilde{\eta}) + P(\tilde{\xi}, \tilde{\eta})\tilde{u}^e(\tilde{\xi}, \tilde{\eta}, v)$ is locally Lipschitz continuous in $\tilde{\xi}, \tilde{\eta}$ then $\lim_{t \rightarrow \infty} e_1^i(t) = 0 \forall i$, and the states $\tilde{\xi}, \tilde{\eta}$ remain bounded.

The controller of (20) is designed for the approximate extended system \sum_e . If we apply this controller to the exact system, we get the system equations in the $(e, \tilde{\eta})$ coordinates given by

$$\begin{aligned} \dot{e}^i &= \bar{A}^i e^i + \epsilon \beta^i(x^e) \tilde{u}^e(x^e) \quad 1 \leq i \leq m \\ \dot{\tilde{\eta}} &= q(\tilde{\xi}, \tilde{\eta}) + P(\tilde{\xi}, \tilde{\eta})\tilde{u}^e(\tilde{\xi}, \tilde{\eta}, v) \end{aligned} \quad (25)$$

where

$$\beta^i = \begin{bmatrix} 0_{1 \times m} \\ \vdots \\ 0_{1 \times m} \\ \beta_{\tilde{\eta}_1^0}^i \\ \vdots \\ \beta_{\tilde{\eta}_i^0}^i \\ \vdots \\ \beta_{\tilde{\eta}_i^0}^i \\ 0_{1 \times m} \end{bmatrix}$$

represents the dynamics that was neglected during the approximate decoupling algorithm. Each β_j^i is $1 \times m$ row vector of functions of x , the first w_0 elements of which are identically zero.

The tracking control law (20) was designed for a system of the form (25) with $\epsilon = 0$. The following theorem shows that it works for the approximate system with nonzero ϵ as well. This theorem is motivated by and is similar to the one for slightly nonminimum phase systems as in [2].

Theorem 3: If

- Zero dynamics of system (25) (i.e., the equilibrium point $\tilde{\eta}_0 = 0$ of (24)) is exponentially stable in a neighborhood U .
- The functions $\beta^i(x^e) \tilde{u}^e(x^e)$ are locally Lipschitz continuous in a neighborhood U with $\beta^i(x_0^e) \tilde{u}^e(x_0^e) = 0 \forall i = 1, \dots, m$.
- $q(\tilde{\xi}, \tilde{\eta}) + P(\tilde{\xi}, \tilde{\eta})\tilde{u}^e(\tilde{\xi}, \tilde{\eta}, v)$ is locally Lipschitz continuous in $\tilde{\xi}, \tilde{\eta}, v$.

Then for ϵ sufficiently small and for desired trajectories with derivatives small enough, the states of system (25) are bounded and the tracking errors satisfy

$$\|e_1^i\| = \|\tilde{\xi}_1^i - y_d\| \leq K\epsilon$$

for some $K < \infty$.

Note: Since we know that f, g, h are smooth functions of x to start with, the functions $\beta^i(x^e) \tilde{u}^e(x^e)$ will be locally Lipschitz so long as the matrix $G_k(x^e)$ is a smooth function of x^e at each iteration of the approximation decoupling algorithm.

Proof: From (22) and the fact that the desired trajectory and its derivatives are bounded (by b_d), we get

$$\|\tilde{\xi}\| \leq \|e\| + b_d. \quad (26)$$

The transformation that transforms \sum_e into $(\tilde{\xi}, \tilde{\eta})$ coordinates is a diffeomorphism, thus there exists $l_x > 0$ such that

$$\|x\| \leq l_x(\|\tilde{\xi}\| + \|\tilde{\eta}\|). \quad (27)$$

As the functions $\beta^i(x^e) \tilde{u}^e(x^e)$ are locally Lipschitz continuous with $\beta^i(x_0^e) \tilde{u}^e(x_0^e) = 0$, there exists a positive constant l_β such that

$$\|2P\beta(x^e) \tilde{u}^e(x^e)\| \leq l_\beta \|x^e\| \quad (28)$$

where $\beta(x^e)$ is the block diagonal matrix with $\beta^i(x^e)$ being its diagonal blocks. Since the zero dynamics

$$\dot{\tilde{\eta}} = q(0, \tilde{\eta}) + P(0, \tilde{\eta})\tilde{u}^e(0, \tilde{\eta}, 0) \quad (29)$$

is exponentially stable, by a converse Lyapunov theorem [22] there exists, $\bar{v}(\tilde{\eta})$ and positive constants k_1, k_2, k_3, k_4 such that

$$k_1 \|\tilde{\eta}\|^2 \leq \bar{v}(\tilde{\eta}) \leq k_2 \|\tilde{\eta}\|^2$$

$$\frac{\partial \bar{v}}{\partial \tilde{\eta}} [q(0, \tilde{\eta}) + P(0, \tilde{\eta})\tilde{u}^e(0, \tilde{\eta}, 0)] \leq -k_3 \|\tilde{\eta}\|^2$$

$$\left\| \frac{\partial \bar{v}}{\partial \tilde{\eta}} \right\| \leq k_4 \|\tilde{\eta}\|.$$

Thus from the exponential stability of zero dynamics and the Lipschitz continuity of $q + Pu^k$, we get

$$\begin{aligned} \dot{v} &= \frac{\partial \bar{v}}{\partial \tilde{\eta}} [q(\tilde{\xi}, \tilde{\eta}) + P(\tilde{\xi}, \tilde{\eta})u^k(\tilde{\xi}, \tilde{\eta}, v)] \\ &= \frac{\partial \bar{v}}{\partial \tilde{\eta}} [q(0, \tilde{\eta}) + P(0, \tilde{\eta})u^k(0, \tilde{\eta}, 0)] \\ &\quad + \frac{\partial \bar{v}}{\partial \tilde{\eta}} [q(\tilde{\xi}, \tilde{\eta}) + P(\tilde{\xi}, \tilde{\eta})u^k(\tilde{\xi}, \tilde{\eta}, v) \\ &\quad - \{q(0, \tilde{\eta}) + P(0, \tilde{\eta})u^k(0, \tilde{\eta}, 0)\}] \\ &\leq -k_3 \|\tilde{\eta}\|^2 + k_4 \|\tilde{\eta}\| l_\eta (\|\tilde{\xi}\| + \|v\|). \end{aligned}$$

To show the states of (25) remain bounded, let

$$V(e, \tilde{\eta}) = e^T \bar{P} e + \psi \bar{v}(\tilde{\eta})$$

be a Lyapunov function for the system (25) where $\bar{P} > 0$ satisfies the following Lyapunov equation

$$\bar{A}^T \bar{P} + \bar{P} \bar{A} = -I$$

and ψ is a positive constant to be specified later. Then

$$\begin{aligned} \dot{V} &= -\|e\|^2 + 2\epsilon e^T \bar{P} \beta(x) u^k(x) + \psi \frac{\partial \bar{v}}{\partial \tilde{\eta}} \dot{\tilde{\eta}} \\ &\leq -\|e\|^2 + \epsilon \|e\| l_\beta \|x\| \\ &\quad + \psi [-k_3 \|\tilde{\eta}\|^2 + k_4 \|\tilde{\eta}\| l_\eta (\|\tilde{\xi}\| + \|v\|)] \\ &\leq -\|e\|^2 + \epsilon \|e\| l_\beta l_x (\|e\| + b_d + \|\tilde{\eta}\|) + \psi \\ &\quad \cdot [-k_3 \|\tilde{\eta}\|^2 + k_4 \|\tilde{\eta}\| l_\eta (\|e\| + b_d + l_v (\|e\| + b_d))] \\ &\leq -\left(\frac{\|e\|}{2} - \epsilon l_\beta l_x b_d\right)^2 + (\epsilon l_\beta l_x b_d)^2 \end{aligned}$$

$$\begin{aligned}
 & - \left(\frac{\|e\|}{2} - (\epsilon l_\beta l_x + \psi k_4 l_\eta (1 + l_v)) \|\tilde{\eta}\| \right)^2 \\
 & + (\epsilon l_\beta l_x + \psi k_4 l_\eta (1 + l_v))^2 \|\tilde{\eta}\|^2 \\
 & - \psi k_3 \left(\frac{\|\tilde{\eta}\|}{2} - \frac{k_4 l_\eta b_d (1 + l_v)}{k_3} \right)^2 \\
 & + \psi \frac{(k_4 l_\eta b_d (1 + l_v))^2}{k_3} \\
 & - \left(\frac{1}{2} - \epsilon l_\beta l_x \right) \|e\|^2 - \frac{3}{4} \psi k_3 \|\tilde{\eta}\|^2 \\
 & \leq - \left(\frac{1}{2} - \epsilon l_\beta l_x \right) \|e\|^2 \\
 & - \left(\frac{3}{4} \psi k_3 - (\epsilon l_\beta l_x + \psi k_4 l_\eta (1 + l_v))^2 \right) \|\tilde{\eta}\|^2 \\
 & + (\epsilon l_\beta l_x b_d)^2 + \psi \frac{(k_4 l_\eta b_d (1 + l_v))^2}{k_3}.
 \end{aligned}$$

Let

$$\tilde{\psi} = \frac{k_3}{4(l_\beta l_x + k_4 l_\eta (1 + l_v))^2}.$$

Then, for all $\psi \leq \tilde{\psi}$ and all $\epsilon \leq \min(\tilde{\psi}, 1/4l_\beta l_x)$, we have

$$\dot{V} \leq -\frac{\|e\|}{4} - \frac{\psi k_3 \|\tilde{\eta}\|^2}{2} + (\epsilon l_\beta l_x b_d)^2 + \psi \frac{(k_4 l_\eta b_d (1 + l_v))^2}{k_3}. \quad (30)$$

Thus $\dot{V} < 0$ whenever $\|\tilde{\eta}\|$ or $\|e\|$ is large. This implies that $\|\tilde{\eta}\|$ and $\|e\|$ and also, $\|\xi\|$ and $\|x\|$ are bounded. The above analysis shows that if we choose the initial condition sufficiently close to x_0^c and b_d sufficiently small, we can guarantee that the states will remain in U . Using the boundedness of x and the continuity of $\beta^i(x)\tilde{u}^c(x)$, we see that

$$\dot{e}^i(x) = \bar{A}^i e^i + \epsilon \beta^i(x) \tilde{u}^c(x)$$

are m SISO exponentially stable linear systems driven by order ϵ input. Thus we conclude that the tracking errors e^i converge to a ball of order ϵ . \square

VI. CONCLUSION

A numerically robust algorithm for input-output decoupling of nonlinear dynamical systems has been proposed. This algorithm provides low gain, practically implementable controllers that do not cancel far off zeros. The use of this algorithm for a slightly nonminimum phase system (i.e., one that has far off right-half plane zeros), results in an overall stable closed-loop system. It is shown that the tracking controllers constructed by using this approximate decoupling algorithm result in bounded tracking with stability. Controllers based on this theory already exist for a few specific examples in the literature and this paper can be thought of as an attempt to formalize the techniques used in those particular examples. Detailed calculations to establish one-to-one mapping between the neglected dynamics and the formal structure at infinity are still to be worked out. The ongoing work on a CAD package called AP_LIN ([23]) based on this approach will help automate the application of

this theory. Although this approximate algorithm is based on the Descusse-Moog dynamic decoupling algorithm, a similar algorithm based on the dynamic extension algorithm (see [1, Chapter 7]) can be worked out in similar fashion.

APPENDIX

EXISTENCE OF AN ANALYTIC MATRIX $G_k(x)$

The proof of existence of $\hat{G}_k(x)$ is given by Descusse and Moog in [6]. Thus we have a matrix $\hat{A}_k(x)$ whose ϵ numerical rank is w_k and the last $m - r_k$ columns are identically zero.

From the definition of ϵ numerical rank of $\hat{A}_k(x)$, it is possible to find a $w_k \times w_k$ minor, say, $\Delta_k(x)$, such that all the singular values of $\Delta_k(x)$ are bigger than ϵ in U . Without loss of generality, we assume that $\Delta_k(x)$ is the block formed by the first w_k rows and the first w_k columns of $\hat{A}_k(x)$, and let $\delta(x)$ represent its determinant.

By definition, any minor of $\hat{A}_k(x)$ having size bigger than w_k , will have at least one singular value smaller than ϵ uniformly in U . Thus the determinant of this minor will be of the order of $\epsilon \times \delta(x)$. Thus we get

$$\det \begin{bmatrix} & & & \vdots & A_{1j}(x) \\ & & & \vdots & \vdots \\ & \Delta_k(x) & & \vdots & \vdots \\ & & & \vdots & A_{w_k j}(x) \\ \dots & \dots & \dots & \dots & \dots \\ A_{i1}(x) & \dots & A_{iw_k}(x) & \vdots & A_{ij}(x) \end{bmatrix} = \epsilon \delta(x)$$

$$\forall i \in \{w_k + 1, \dots, m\}, \quad \forall j \in \{w_k + 1, \dots, r_k\}. \quad (31)$$

Consider the top left $r_k \times r_k$ block of $\hat{A}_k(x)$. We get

$$\delta(x) A_{ij}(x) + \sum_{i=1}^{r_k} \lambda_i(x) A_{ii}(x) = \text{order } \epsilon \times \delta(x),$$

$$\forall i \in \{w_k + 1, \dots, m\}, \quad \forall j \in \{1, \dots, r_k\} \quad (32)$$

where $\lambda_i(x)$ is the cofactor of $A_{ii}(x)$, calculated with respect to the top left $r_k \times r_k$ block of $\hat{A}_k(x)$.

Define the elementary column operation by

$$g_j(x) := \begin{bmatrix} 1 & & & \lambda_1(x) \\ & \ddots & & \vdots \\ & & 1 & \lambda_{r_k}(x) \\ & & & 0 \\ & & & \vdots & 0 \\ & & & 1 & 0 \\ 0 & & & & \delta(x) \\ & & & & 0 \\ & & & & 1 \\ & & & & \vdots \\ & & & & 0 & 1 \end{bmatrix}$$

where $\delta(x)$ is in the j th row and column. The first $r_k - 1$ elements in the j th column of $\hat{A}_k(x)g_j(x)$ will be zero. The r_k^{th} element will be the determinant given by (32), which is

of the order of ϵ . The rest of the elements in this column must be of the order of ϵ , or else there will be a minor of $\hat{A}_k(x)g_k(x)$ having all its singular values more than ϵ and having more than w_k columns and rows. This will contradict the definition of the ϵ numerical rank of a matrix. Thus this particular procedure makes the elements of j th column of the order of ϵ as compared with $\delta(x)$. We can have $r_k - w_k$ matrices of these form making one column of $\hat{A}_k(x)g_i(x)$ small at a time. It is clear that the matrix $\tilde{G}_k(x)$ will thus be nonsingular, square, and an analytic function of x .

Thus $G_k(x) := \hat{G}_k(x)\tilde{G}_k(x)P_k(x)$ is a square invertible matrix of analytic functions of x .

A Generalized Orthonormal Basis for Linear Dynamical Systems

Peter S. C. Heuberger, Paul M. J. Van den Hof, *Member, IEEE*, and Okko H. Bosgra

Abstract—In many areas of signal, system, and control theory, orthogonal functions play an important role in issues of analysis and design. In this paper, it is shown that there exist orthogonal functions that, in a natural way, are generated by stable linear dynamical systems and that compose an orthonormal basis for the signal space ℓ_2^+ . To this end, use is made of balanced realizations of inner transfer functions. The orthogonal functions can be considered as generalizations of, e.g., the pulse functions, Laguerre functions, and Kautz functions, and give rise to an alternative series expansion of rational transfer functions. It is shown how we can exploit these generalized basis functions to increase the speed of convergence in a series expansion, i.e., to obtain a good approximation by retaining only a finite number of expansion coefficients. Consequences for identification of expansion coefficients are analyzed, and a bound is formulated on the error that is made when approximating a system by a finite number of expansion coefficients.

1. INTRODUCTION

CONSIDER a linear time-invariant stable discrete-time system G , represented by its proper transfer function $G(z)$ in the Hilbert space \mathcal{H}_2 , i.e., $G(z)$ is analytic outside the unit circle, $|z| \geq 1$. A general and common representation of $G(z)$ is in terms of its Laurent expansion around $z = \infty$, as

$$G(z) = \sum_{k=0}^{\infty} G_k z^{-k} \quad (1)$$

with $\{G_k\}_{k=0,1,\dots}$ the sequence of Markov parameters.

In constructing this series expansion we have employed a set of orthogonal functions: $\{z^0, z^{-1}, z^{-2}, \dots\}$, where orthogonality is considered in terms of the inner product in \mathcal{H}_2 . In a generalized form we can write (1) as

$$G(z) = \sum_{k=0}^{\infty} L_k f_k(z) \quad (2)$$

with $\{f_k(z)\}_{k=0,1,2,\dots}$ a sequence of orthogonal functions.

There are a number of research areas that deal with the question of either approximating a given system G with a finite number of coefficients in a series expansion as in (2), or (approximately) identifying an unknown system in terms of a finite number of expansion coefficients through

$$\hat{G}(z) = \sum_{k=0}^N L_k f_k(z). \quad (3)$$

The problem that will be analyzed in this paper is the following.

Can we construct a sequence of orthogonal basis functions $\{f_{k,G}(z)\}_{k=0,\dots,\infty}$ with $G \in \mathcal{H}_2$, such that

- to some extent, the basis can be adapted to a linear stable system G to be described, implying that G can be accurately described by only a small number of coefficients in the expansion, and
- the basis allows the construction of an error bound for the approximation of a linear stable system G by a finite length expansion in the basis $f_{k,G}$, i.e., an upper bound on $\|G(z) - \sum_{k=0}^N L_k f_{k,G}(z)\|$ in some prechosen norm, whenever G and \hat{G} do not match exactly.

The use of orthogonal functions with the aim of adapting the system and signal representation to the specific properties of the systems and signals at hand has a long history. The classical work of Lee and Wiener during the 1930's on network synthesis in terms of Laguerre functions [24], [46] is summarized in [25]. Laguerre functions have been used in the 1950's and 1960's to represent transient signals [45], [7]. During the past decades, the use of orthogonal functions has been studied in problems of filter synthesis [22], [30] and for system identification [23], [32], [31], [6] and approximation [35], [36]. In these approaches to system identification, the input and output signals are transformed to a (Laguerre) transformed domain and standard identification techniques are applied to the signals in this domain. Data reduction has been the main motivation in these studies. Identification of continuous-time models with the aid of orthogonal functions is considered in e.g., [38] and [29]. In recent years, a renewed interest in Laguerre functions has emerged. The approximation of (infinite dimensional) systems in terms of Laguerre functions has been considered in [27], [28], [12], [13], and [15]. In the identification of coefficients in finite length series expansions, Laguerre function representations have been considered from a statistical analysis point of view in [43], [42], and [16].

Manuscript received November 17, 1992, revised December 3, 1993. Recommended by Past Associate Editor, B. Pasik-Duncan. This work was supported in part by Shell Research B.V., The Hague, and the Center for Industrial Control Science, The University of Newcastle, Newcastle NSW, Australia.

The use of Laguerre-function-based identification in adaptive control and controller tuning is studied in [47] and [9]. A second-order extension to the basic Laguerre functions using the so called Kautz functions [21] is subject of discussion in [41] and [44].

In this paper we will expand and generalize the orthogonal functions as basis functions for dynamical system representations. Specifically we will generalize the Laguerre functions and Kautz functions to a situation where a higher degree of flexibility is present in the choice of basis functions, and where consequently a smaller error bound as meant in part b) of the problem can be obtained. Laguerre functions are specifically appropriate for accurate modeling of systems with dominant first-order dynamics, whereas Kautz functions are directed toward systems with dominant second-order resonant dynamics. The generalized basis functions, introduced in this paper, will be suited also for systems with a wide range of dominant dynamics, i.e., dominant high frequency and low frequency behavior.

We will restrict attention to the transfer function space \mathcal{H}_2 being equipped with the usual inner product. This choice, rather than the \mathcal{H}_∞ -space where orthogonality is abandoned, is motivated by the fact that our main intended application of these results is in the area of approximate system identification. As the main stream of approaches in system identification is directed toward prediction error methods and the use of least-squares types of identification criteria, [26], the choice of a two-norm is quite straightforward and natural in this respect.

Note that the two problems a) and b) should be treated as a joint problem. One of the (trivial) solutions to problem a) only is the use of a Gram-Schmidt orthogonalization procedure on the impulse response of the system G itself [1]. In that case the system can be described by a series expansion of only one single term. In this situation, however, no results are available for part b) of the problem.

In an identification context, the use of the orthogonal functions as in (1) leads to the so-called finite impulse response (FIR)-model [26]

$$y(t) = \sum_{k=0}^N G_k(\theta) u(t-k) + \varepsilon(t) \quad (4)$$

where $\varepsilon(t)$ is the one-step-ahead prediction error, and $\{y(t), u(t)\}$ are samples of the output, input of the dynamical system to be identified. The identification of the unknown coefficients $\{G_k(\theta)\}_{k=0, \dots, N}$ through least squares minimization of $\varepsilon(t)$ over the time interval is an identification method that has some favorable properties. First, it is a linear regression scheme, which leads to a simple analytical solution; second, it is of the type of output-error-method, which has the advantage that the input/output system $G(z)$ can be estimated consistently whenever the unknown noise disturbance on the output data is uncorrelated with the input signal [26].

It is well known, however, that for moderately damped systems, and/or in situations of high sampling rates, it may take a large value of N , the number coefficients to be estimated, to capture the essential dynamics of the system G into its model.

If we would be able to improve the basis functions in such a way that an accurate description of the model to be estimated can be achieved by a small number of coefficients in a series expansion, then this is beneficial from both aspects of bias and variance of the model estimate.

For the series expansion in (1) with $f_k = z^{-k}$, it is straightforward to show that a system G will have a finite length series expansion if and only if all system poles are at $z = 0$. Moreover, in the scalar case the length of the expansion, i.e., the index of the last nonzero coefficient, equals the total number of poles at $z = 0$.

As a generalized situation, we can consider Laguerre polynomials [37] that are known to generate a sequence of orthogonal functions [14]

$$f_k(z) = \sqrt{1-a^2} z \frac{(1-az)^k}{(z-a)^{k+1}}, \quad |a| < 1. \quad (5)$$

Similar to above, a system G will have a finite length series expansion if and only if all system poles are at $z = a$, with the length of the expansion being equal to the total number of poles at $z = a$.

In dealing with the problem of finding similar results for any general stable dynamical system $G(z)$, we have considered the question of whether a linear system in a natural way gives rise to a set of orthogonal functions. The answer to this question appears to be affirmative. It will be shown that every stable system gives rise to a complete set of orthonormal functions based on input (or output) balanced realizations, or equivalently based on a singular value decomposition of a corresponding Hankel matrix. These generalized orthogonal basis functions will be shown to provide solutions to problems a) and b).

In Section III we will first briefly state the main result of this paper. Next in Section IV it will be shown how inner functions generate two sets of orthonormal functions that are complete in the signal space ℓ_2 . This is the basic ingredient of the main result. Next an interpretation of these results is given in terms of balanced state-space representations. After showing the relations of the new basis functions with existing ones, we will focus on the dynamics that implicitly are involved in the inner functions generating the basis. It will be shown that if the dynamics of a stable system match the dynamics of the inner function that generates the basis, then the representation of this system in terms of this basis becomes extremely simple. Consequences for a related identification and approximation problem are discussed in Section VIII.

Due to space limitations, a complete statistical analysis of the related system identification problems that result from these basis functions can not be given in this paper. A statistical analysis along similar lines as [43] and [44] is presented elsewhere [39].

The proofs of all results are collected in an appendix.

II. PRELIMINARIES

We will use the following notation.

$(\cdot)^T$ Transpose of a matrix.

$(\cdot)^*$	Complex conjugate transpose of a matrix.
$\mathcal{C}^{p \times m}$	Set of complex-valued matrices of dimension $p \times m$.
$\mathbf{R}^{p \times m}$	Real-valued matrix with dimension $p \times m$.
\mathbb{Z}_+	Set of nonnegative integers.
$\ell_2[0, \infty)$	Space of squared summable sequences on the time interval \mathbb{Z}_+ .
$\ell_2^{m \times n}[0, \infty)$	Space of matrix sequences $\{F_k \in \mathcal{C}^{m \times n}\}_{k=0,1,2,\dots}$ such that $\sum_{k=0}^{\infty} \text{tr}(F_k^* F_k)$ is finite.
$\mathcal{H}_2^{p \times m}$	Set of real $p \times m$ matrix functions, analytic for $ z \geq 1$, that are squared integrable on the unit circle.
$\mathcal{RH}_2^{p \times m}$	Set of real rational $p \times m$ matrix functions, analytic for $ z \geq 1$, that are squared integrable on the unit circle.
$\ \cdot\ _2$	Induced 2-norm or spectral norm of a constant matrix, i.e., its maximum singular value.
$\ \cdot\ _{\infty}$	H_{∞} -norm.
$\text{Vec}(\cdot)$	Vector-operation on a matrix, stacking its columns on top of each other.
(\cdot)	Kronecker matrix product.
$\mathcal{H}(G)$	(Block) Hankel matrix related to transfer function $G = \sum_{k=0}^{\infty} G_k z^{-k}$, defined by $\mathcal{H}_{ij}(G) = G_{i+j-1}$ being the (i, j) -block element.
e_i	i th Euclidian basis vector in \mathbf{R}^n .
I_n	$n \times n$ Identity matrix.

In this paper we will consider discrete-time signals and systems. A linear time-invariant finite-dimensional system will be represented by its rational transfer function $G \in \mathcal{RH}_2^{p \times m}$, with m the number of inputs in u , and p the number of outputs in y . State-space realizations will be considered of the form

$$x(k+1) = Ax(k) + Bu(k) \quad (6)$$

$$y(k) = Cx(k) + Du(k) \quad (7)$$

with $A \in \mathcal{C}^{n \times n}$, $B \in \mathcal{C}^{n \times m}$, $C \in \mathcal{C}^{p \times n}$, and $D \in \mathcal{C}^{p \times m}$. (A, B, C, D) is an n -dimensional realization of G if $G(z) = C(zI - A)^{-1}B + D$. A realization is stable if all eigenvalues of A lie strictly within the unit circle. If a realization is stable, the controllability gramian P and observability gramian Q are defined as the solutions to the Lyapunov equations $PA^* + BB^* = P$ and $A^*QA + C^*C = Q$, respectively. A stable realization is called (internally) balanced if $P = Q = \Sigma$, with $\Sigma = \text{diag}(\sigma_1, \dots, \sigma_n)$, $\sigma_1 \geq \dots \geq \sigma_n$, a diagonal matrix with the positive Hankel singular values as diagonal elements. A stable realization is called input balanced if $P = I$, $Q = \Sigma^2$, and output balanced if $P = \Sigma^2$, $Q = I$.

A system $G \in \mathcal{RH}_2^{p \times m}$ is called inner if it satisfies $G^*(z^{-1})G(z) = I$. As G is analytic outside and on the unit circle, it has a Laurent series expansion $\sum_{k=0}^{\infty} G_k z^{-k}$.

III. THE MAIN RESULT

We will start the technical part of this paper by giving the basic result first and then consecutively give the analysis that provides the ingredients for making the result plausible.

Theorem 3.1: Let G be an $m \times m$ inner transfer function with McMillan degree $n > 0$, having a Laurent expansion $G(z) = \sum_{k=0}^{\infty} G_k z^{-k}$ and satisfying $\|G_0\|_2 < 1$, and let (A, B, C, D) be a balanced realization of $G(z)$. Denote

$$V_k(z) = (zI - A)^{-1}BG^k(z). \quad (8)$$

Then the set of functions $\{V_k(z)\}_{k=1, \dots, n, k=0, \dots, \infty}$ constitutes an orthonormal basis of the function space $\mathcal{H}_2^{1 \times m}$.

A direct consequence of this theorem is the following corollary. \square

Corollary 3.2: Let G be an inner function with McMillan degree n as in Theorem 3.1, with a corresponding sequence of basis functions $V_k(z)$. Then for every proper stable transfer function $H \in \mathcal{H}_2^{p \times m}$ there exist unique $D_q \in \mathbf{R}^{p \times m}$, and $L = \{L_k\}_{k=0,1,\dots} \in \ell_2^{p \times n}[0, \infty)$, such that

$$H(z) = D_q + z^{-1} \sum_{k=0}^{\infty} L_k V_k(z). \quad (9)$$

We refer to D_q, L_k as the orthogonal expansion coefficients of $H(z)$. \square

Note that due to the fact that $V_k(z)$ is an $n \times m$ -matrix of transfer functions, the dimension of each L_k is $p \times n$.

IV. ORTHONORMAL FUNCTIONS GENERATED BY INNER TRANSFER FUNCTIONS

In this section we will show that a square and inner transfer function gives rise to an infinite set of orthonormal functions. This derivation is based on the fact that a singular value decomposition of the Hankel matrix associated to a linear system induces a set of left (right) singular vectors that are orthogonal. Considering the left (right) singular vectors as discrete time functions, they are known to be orthogonal in ℓ_2 -sense, thus generating a number of orthogonal functions being equal to the McMillan degree of the corresponding system. We will embed an inner function with McMillan degree n into a sequence of inner functions with McMillan degree kn , for which the left (right) singular vectors of the Hankel matrix span a space with dimension kn . If we let $k \rightarrow \infty$ the set of left (right) singular vectors will yield an infinite number of orthonormal functions, which can be shown to be complete in ℓ_2 .

First we have to recapitulate some properties of inner transfer functions.

Proposition 4.1: Let $G(z)$ be an inner transfer function with a Laurent expansion $G(z) = \sum_{k=0}^{\infty} G_k z^{-k}$. Then

$$\sum_{k=0}^{\infty} G_{k+i}^T G_k = I \quad \text{for } i = 0; \quad (10)$$

$$= 0 \quad \text{for } i > 0. \quad (11)$$

\square

The Hankel matrix of an inner transfer function has some specific properties, reflected in the following two results.

Proposition 4.2: Let $G(z)$ be an inner function with McMillan degree $n > 0$. Then a singular value decomposition (svd) of $\mathcal{H}(G)$ satisfies

$$\mathcal{H}(G) = U_0 V_0^*$$

with $U_0, V_0 \in \mathcal{C}^{\infty \times n}$ unitary,¹ and the pair (U_0, V_0) is unique modulo postmultiplication with a unitary matrix $T \in \mathcal{C}^{n \times n}$. \square

The proposition states that an inner transfer function has all Hankel singular values equal to one. For continuous-time systems, this is proven in [11]. The discrete-time version follows straightforwardly by applying a bilinear transformation.

Proposition 4.3: Let $G(z)$ be a square inner function, having a Laurent expansion $G(z) = \sum_{k=0}^{\infty} G_k z^{-k}$. Denote the block Toeplitz matrices

$$T_v = \begin{bmatrix} G_0 & G_1 & G_2 & \cdots & \cdots \\ 0 & G_0 & G_1 & G_2 & \cdots \\ 0 & 0 & G_0 & G_1 & \cdots \\ \vdots & \vdots & 0 & G_0 & \ddots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}, \quad (12)$$

$$T_u = \begin{bmatrix} G_0 & 0 & 0 & \cdots & \cdots \\ G_1 & G_0 & 0 & \cdots & \cdots \\ G_2 & G_1 & G_0 & \ddots & \cdots \\ \vdots & \vdots & G_1 & G_0 & \cdots \\ \vdots & \vdots & \vdots & \ddots & \ddots \end{bmatrix}. \quad (13)$$

Then

- i) $T_v T_v^T = T_u^T T_u = I$;
- ii) $T_v V_0 = T_u^T U_0 = 0$, for any unitary matrices U_0, V_0 satisfying $U_0 V_0^* = \mathcal{H}(G)$. \square

Lemma 4.4: Let $G(z)$ be a square inner function with McMillan degree n . Then for all $k \in \mathbb{Z}_+$, $G^k(z)$ is an inner function with McMillan degree kn . \square

The result in the lemma is quite straightforward if one realizes that an inner function has all poles within the unit circle, and all zeros outside the circle.

Considering Proposition 4.2, it follows that the rows of V_0^* and the columns of U_0 , are n mutually orthonormal vectors of infinite dimension. Additionally Lemma 4.4 shows that we can construct an inner transfer function with increasing McMillan degree, by repeatedly multiplying the transfer function with itself, and thus implicitly creating an increasing number of orthogonal vectors. The following result shows how we can increase this number of vectors, by embedding the svd of $\mathcal{H}(G)$ into a sequence of svd's of $\mathcal{H}(G^k)$.

Theorem 4.5: Let $G(z)$ be a square inner function with McMillan degree $n > 0$. Then

- a) There exist unitary matrices $U_i, V_i \in \mathcal{C}^{\infty \times n}$, $i = 0, 1, \dots$, such that for every $0 \neq k \in \mathbb{Z}_+$, the matrices

$$\Gamma_k^o = [U_{k-1} \cdots U_1 U_0] \quad \text{and} \quad (14)$$

$$\Gamma_k^c = \begin{bmatrix} V_0^* \\ V_1^* \\ \vdots \\ V_{k-1}^* \end{bmatrix} \quad (15)$$

¹With slight abuse of notation we will use this notation to indicate an operator $\mathcal{C}^n \rightarrow \ell_2[0, \infty)$.

constitute a singular value decomposition of $\mathcal{H}(G^k)$, through

$$\mathcal{H}(G^k) = \Gamma_k^o \Gamma_k^c. \quad (16)$$

- b) The matrix sequence $\{U_i, V_i\}_{i=0,1,\dots}$ is unique up to postmultiplication of each U_i and V_i with one and the same unitary matrix.
- c) Let $G(z)$ have a Laurent expansion $G(z) = \sum_{i=0}^{\infty} G_i z^{-i}$, and consider the block Toeplitz matrices T_u, T_v as in (12), (13) then the matrix sequence $\{U_i, V_i\}_{i=0,1,\dots}$ satisfies

$$V_k^* = V_{k-1}^* T_v \quad (17)$$

$$U_k = T_u U_{k-1} \quad \text{for } k = 1, 2, \dots \quad (18)$$

\square

The theorem shows the construction of orthogonal matrices Γ_k^o, Γ_k^c that have a nesting structure. The suggested svd of $\mathcal{H}(G^k)$ incorporates svd's of $\mathcal{H}(G^i)$ for all $i < k$. In this way orthogonal matrices Γ_k^o and Γ_k^c are constructed with an increasing rank. Note that the restriction on the structure of the consecutive svd's is so strong that, according to b), given a singular value decomposition $\mathcal{H}(G) = U_0 V_0^*$, the matrix sequence $\{U_i, V_i, i = 1, 2, \dots\}$ is uniquely determined. Note also that there is a clear duality between the controllability part Γ_k^c and the observability part Γ_k^o . To keep the exposition and the notation as simple as possible we will further restrict attention to the controllability part of the problem. Dual results exist for the observability part.

Proposition 4.6: Let $G(z)$ be an $m \times m$ inner function with McMillan degree $n > 0$, and consider any sequence of unitary matrices $\{V_i\}_{i=0,1,\dots}$ satisfying (17) in Theorem 4.5. Denote for $k \in \mathbb{Z}_+$

$$V_k(z) = \sum_{i=0}^{\infty} M_k(i) z^{-i}, \quad \text{with } M_k(i) \in \mathcal{C}^{m \times m} \text{ defined by} \quad (19)$$

$$V_k^* = [M_k(0) \ M_k(1) \ M_k(2) \ \cdots].$$

Then

$$V_k(z) = V_0(z) G^k(z).$$

\square

The proposition actually is a z -transform-equivalent of the result in Theorem 4.5. It shows the construction of the controllability matrix Γ_k^c .

In the next stage we show that this controllability matrix generates a sequence of orthogonal functions that is complete in ℓ_2^n .

Theorem 4.7: Let $G(z)$ be an $m \times m$ inner function with McMillan degree $n > 0$, such that $\|G_0\|_2 < 1$; consider a sequence of unitary matrices $\{V_i\}_{i=0,1,\dots}$ as meant in Theorem 4.5. For each $k \in \mathbb{Z}_+$ consider the function $\phi_k : \mathbb{Z}_+ \rightarrow \mathcal{C}^m$ defined by

$$[\phi_k(0) \ \phi_k(1) \ \phi_k(2) \ \cdots] = V_k^*.$$

Then the set of functions $\Psi(G) := \{\phi_k\}_{k=0}^{\infty}$ constitutes an orthonormal basis of the signal space $\ell_2^n[0, \infty)$. \square

Proposition 5.5: Let $G(z)$ be an $m \times m$ inner transfer function with McMillan degree $n > 0$, whose Hankel matrix has an svd $\mathcal{H}(G) = U_0 V_0^*$; let (A, B, C, D) be a minimal balanced realization of G such that $V_0^* = [B \ AB \ A^2 B \ \dots]$. Then the unique sequence of orthogonal matrices $\{\Gamma_k^c\}_{k=1,2,\dots}$ as considered in Theorem 4.5 is determined by

$$\Gamma_k^c = [B_k \ A_k B_k \ A_k^2 B_k \ \dots] \quad (26)$$

with A_k, B_k as defined in (22), (23). \square

The above result shows how a minimal balanced realization of G actually generates the sequence of orthogonal matrices Γ_k^c , the rows of which are the basis functions in our orthonormal basis of ℓ_2^n .

We will show that there exist recursive formulae for constructing the orthogonal functions.

Proposition 5.6: Let G be an inner function, $G \in \mathcal{G}_1$, and consider the assumptions and notation as in Theorem 4.5 and Proposition 5.5. Denote

$$X = BC^* \quad \text{and} \quad (27)$$

P any matrix satisfying

$$PB = BD. \quad (28)$$

Then the elements of Γ_k^c are determined by the following recursive equations

$$M_0(0) = B \quad (29)$$

$$M_k(i+1) = AM_k(i) + \sum_{j=1}^k P^{j-1} X M_{k-j}(i), \quad i \geq 0; \quad (30)$$

$$M_k(0) = PM_{k-1}(0) \quad (31)$$

with Γ_k^c as in (15) with

$$V_k^* = [M_k(0) \ M_k(1) \ M_k(2) \ \dots]$$

as in (19). \square

The recursive equations show how we can simply construct the set of orthogonal functions. Note that the matrix P in (28) is nonunique. The result (29)-(31) however is unique. A straightforward choice for P satisfying (28) is

$$P = BD(B^*B)^{-1}B^*. \quad (32)$$

Note that, as a result of Proposition 5.3, the matrix B^*B is invertible whenever $G \in \mathcal{G}_1$.

The orthogonal functions $\Psi(G)$ generated by an inner function G can be represented in terms of their generating functions $V_k(z)$, as defined in Proposition 4.6. These generating transfer functions can also be realized in terms of a minimal balanced realization of G . This is reflected in the following theorem.

Theorem 5.7: Let G be an inner function, $G \in \mathcal{G}_1$, with a minimal balanced realization (A, B, C, D) . Let this inner function generate an orthonormal basis with corresponding generating functions $V_k(z)$, as defined in Proposition 4.6.

1) Let F be a matrix determined by

$$F = X - PA \quad (33)$$

with X defined in (27) and P any matrix satisfying (28). Then, for $k \in \mathbb{Z}_+$,

- a) $V_k(z) = [(zI - A)^{-1}F(I - zA^*)]^k z(zI - A)^{-1}I$
- b) $V_k(z)$ is unique, i.e., it is not dependent on the specific choice of P in (28).

2) If there exists a matrix R such that $B = RC^*$, then $F = R$ satisfies the conditions of Part 1 of this theorem \square

Now we come to the construction of a series expansion of any stable proper rational transfer function, in terms of the new orthonormal basis.

Theorem 5.8: Let G be an inner function, $G \in \mathcal{G}_1$, with a minimal balanced realization (A, B, C, D) . Let this inner function generate an orthonormal basis with corresponding generating functions $V_k(z)$, as defined in Proposition 4.6. Let $H \in \mathcal{H}_2^{p \times m}$ be any proper and stable transfer function with a minimal realization (A_s, B_s, C_s, D_s) . Then

$$H(z) = D_s + z^{-1} \sum_{k=0}^{\infty} L_k V_k(z) \quad (34)$$

with $L_k \in \mathbb{C}^{p \times n}$ determined by

$$L_k = C_s Q_k \quad (35)$$

$$Q_0 = A_s Q_0 A_s^* + B_s B_s^* \quad (36)$$

$$Q_{i+1} = A_s Q_{i+1} A_s^* + A_s Q_i F^* - Q_i A F^* \quad (37)$$

with F as defined in (33). \square

In Section VII we will show that specific choices of $G(z)$ in relation with $H(z)$, i.e., specific relations between the inner function G producing the orthonormal basis and a transfer function H that should be described in this basis, will lead to very simple representations.

VI. A GENERALIZATION OF CLASSICAL BASIS FUNCTIONS

In this section we show three examples of well-known sets of orthogonal functions that are frequently used in the description of linear time-invariant dynamical systems and that occur as special cases in the framework that is discussed in this paper.

Pulse Functions

Consider the inner function $G(z) = z^{-1}$, $G \in \mathcal{G}_1$. The Hankel matrix of G satisfies

$$\begin{aligned} \mathcal{H}(G) &= \begin{bmatrix} 1 & 0 & \dots & \cdot & 0 \\ 0 & 0 & 0 & \cdot & 0 \\ 0 & 0 & 0 & \cdot & 0 \\ \vdots & \vdots & \cdot & \ddots & \cdot \end{bmatrix} \\ &= \begin{bmatrix} 1 \\ 0 \\ 0 \\ \vdots \end{bmatrix} [1 \ 0 \ 0 \ \dots] = U_0 V_0^*. \end{aligned} \quad (38)$$

As a result $V_0(z) = 1$, and with Proposition 4.6 the generating transfer functions $V_k(z)$ satisfy $V_k(z) = G^k(z) = z^{-k}$, $k = 0, 1, \dots$. The corresponding set of basis functions $\Psi(G)$

determined by $\phi_k(t) = \delta(t - k)$ with $\delta(\tau)$ the Kronecker delta function.

The inner function G can be realized by the minimal balanced realization $(A, B, C, D) = (0, 1, 1, 0)$. The equation $PB = BD$ is satisfied by $P = 0$, and the corresponding result for F is $F = BC = 1$. Applying Theorem 5.8 shows the classical result that $L_k = C_s A_s^k B_s$.

Laguerre Functions

Consider the inner function $G(z) = \frac{1 - az}{z - a}$, with some real-valued a , $|a| < 1$, and denote $\eta = 1 - a^2$. A minimal balanced realization of G is given by $(A, B, C, D) = (a, \sqrt{\eta}, \sqrt{\eta}, -a)$. Equation $PB = BD$ is satisfied by $P = -a$, leading to $F = BC - PA = \eta + a^2 = 1$. Taking account of the fact that for one-dimensional scalar G , $M_k(i) = \phi_k(i)$, it follows from Proposition 5.6 that

$$\phi_0(0) = \sqrt{\eta} \quad (39)$$

$$\phi_k(i+1) = a\phi_k(i) + \eta \sum_{j=1}^k (-a)^{j-1} \phi_{k-j}(i) \quad (40)$$

$$\phi_k(0) = -a\phi_{k-1}(0). \quad (41)$$

These equations exactly match the equations that generate the normalized discrete-time Laguerre polynomials with discount factor a , [14], [32].

The corresponding generating transfer functions $V_k(z)$ can be analyzed with the result of either Proposition 4.6 or Theorem 5.7

$$V_k(z) = \sqrt{\eta} z \frac{(1 - az)^k}{(z - a)^{k+1}}. \quad (42)$$

This exactly fits with the formulation of the generating transfer functions of discrete-time Laguerre polynomials in, e.g., [23].

Kautz Functions

Consider the inner function $G(z) = \frac{-cz^2 + b(c-1)z + 1}{z^2 + b(c-1)z - c}$ with some real-valued b, c satisfying $|c|, |b| < 1$.

A balanced realization of $G(z)$ can be found to be equal to

$$A = \begin{bmatrix} b & \sqrt{(1-b^2)} \\ c\sqrt{(1-b^2)} & -bc \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ \sqrt{(1-c^2)} \end{bmatrix}$$

$$C = [\gamma_2 \quad \gamma_1] \quad D = -c$$

with $\gamma_1 = -b\sqrt{(1-c^2)}$ and $\gamma_2 = \sqrt{(1-c^2)(1-b^2)}$.

With the expression for $V_0(z)$ from Theorem 5.7-a) it follows that

$$z^{-1}V_0(z) = \frac{\sqrt{(1-c^2)}}{z^2 + b(c-1)z - c} \begin{bmatrix} \sqrt{(1-b^2)} \\ z - b \end{bmatrix} \quad (43)$$

which exactly equals $\begin{bmatrix} \psi_2(z, b, c) \\ \psi_1(z, b, c) \end{bmatrix}$ representing the orthogonal Kautz functions, as represented in [41], [44]. Postmultiplication with $G^k(z)$ is equivalent to the situation in the case of Kautz functions.

VII. ORTHONORMAL FUNCTIONS ORIGINATING FROM GENERAL DYNAMICAL SYSTEMS

We have shown that any square inner transfer function $G \in \mathcal{G}_1$ generates an orthonormal basis for the signal space ℓ_2 . One of the reasons for developing this generalized bases was to find out whether we can yield a more suitable representation of a general dynamical system, when the basis within which we describe the system is more or less adapted to the system dynamics. In view of the results presented so far, this aspect relates to the question whether we can construct an inner transfer function generating a basis that incorporates dynamics of a general system to be represented within this basis.

There are several ways of connecting general transfer functions to inner functions, as e.g., inner/outer factorization [10], [5], normalized coprime factorization [8], [40], [33], [4], or inner-unstable factorization [2]. Even if the corresponding inner functions are not square, they can always be embedded in a square inner function [11]. In this paper, however, we will explore a different connection, where a general stable dynamical system with input balanced realization (A, B, C, D) will induce a square inner function through retaining the matrices (A, B) and constructing (C', D) such that (A, B, C', D) is inner. This implies that the poles of the stable dynamical system are retained in the corresponding inner function. The following result shows the existence and construction of such an inner function.

Proposition 7.1: Let (A, B) be the system matrix and input matrix of an input balanced realization of a transfer function $H \in \mathcal{RH}_2^{p \times m}$ with McMillan degree $n > 0$, and with rank $B = m$. Then

a) There exist matrices C', D such that (A, B, C', D) is a minimal balanced realization of a square inner function $G' \in \mathcal{G}_1$.

b) A realization (A, B, C', D) has the property mentioned in a) if and only if

$$C' = UB^*(I_n + A^*)^{-1}(I_n + A) \quad (44)$$

$$D = U[B^*(I_n + A^*)^{-1}B - I_m] \quad (45)$$

with $U \in \mathbb{R}^{m \times m}$ any unitary matrix.

c) For a realization satisfying (44), (45) a valid choice of matrix F satisfying (33) is given by

$$F = [I_n + B(U - I_m)(B^*B)^{-1}B^*](I_n + A)(I_n + A^*)^{-1}. \quad (46)$$

□

In the proposition all inner functions are characterized that can be constructed in the way as described above, by retaining the matrices (A, B) of any given stable system. Note that the extension C', D is not unique. The nonuniqueness is reflected by a possible unitary premultiplication of the inner function. Note also that when choosing $U = I_m$, expression (46) reduces to $F = (I_n + A)(I_n + A^*)^{-1}$.

We will now present a result that is very appealing. It shows that when we want to describe the dynamical system H in terms of the basis that it has generated, as presented in Proposition 7.1, then the series expansion in the new orthogonal basis becomes extremely simple.

Theorem 7.2: Let $H \in \mathcal{RH}_2^{p \times m}$ have an input balanced realization (A_s, B_s, C_s, D_s) , having all controllability indexes > 0 . Let $G \in \mathcal{G}_1$ be a square inner function with minimal balanced realization (A, B, C, D) such that $A = A_s$ and $B = B_s$, generating an orthonormal basis with generating transfer functions $V_k(z)$. Then

$$H(z) = D_s + z^{-1} \sum_{k=0}^{\infty} L_k V_k(z) \quad (47)$$

with

$$L_0 = C_s' \quad \text{and} \quad (48)$$

$$L_k = 0 \quad \text{for } k > 0. \quad (49)$$

Proof: The proof follows by applying Theorem 5.8. With $A = A_s$, $B = B_s$ (36) becomes $Q_0 = A Q_0 A^* + B B^*$. Since (A, B) is input balanced, the solution to this equation is $Q_0 = I$, leading to $L_0 = C_s'$. Substituting $Q_0 = I$ in (37) and using the stability of A shows that $Q_i = 0$ for $i > 0$. \square

The theorem shows that when we use a general stable and proper dynamical system to generate an orthonormal basis as described above, then the system itself has a very simple representation in terms of this basis. It is represented in a series expansion with only two nonzero expansion coefficients, being equal to the system matrices C_s' and D_s .

In the next section we will discuss the results of this paper regarding their relevance to problems of system identification and system approximation.

It has to be stressed that, so far, we have only used the generalized orthonormal basis to study the series expansion of a given stable transfer function. Similar to the case of the pulse functions and Laguerre functions, the presented generalized functions induce a transformation of ℓ_2 -signals to a transform domain, compare e.g., with the z -domain when pulse functions are used. In this transform domain dynamical system equations can be derived, leading to transform pairs of time-domain and orthogonal-domain system representations. In the case of a Laguerre basis, these kinds of transformations actually have been used frequently also in an identification context, by first transforming the measured input/output signals to the Laguerre domain, and consecutively identifying a system in this domain; see e.g., [22], [23], [32], [31].

For the generalized basis, results along these lines have been presented in [18], [19]. An analysis of the system transformations between time domain and generalized transform domain is treated in [19] and [39].

VIII. SYSTEM APPROXIMATION AND IDENTIFICATION

We will now discuss the way in which the introduced orthogonal basis functions provide a solution to problem b) as mentioned in the introduction, i.e., the quantification of an error bound for finite length expansion approximants.

We will present results showing that the speed of convergence in an orthogonal series expansion can be quantified and that an increase of speed is obtained as the dynamics of system and basis approach each other. To formulate these results we need an alternative formulation of Theorem 5.8 in terms of Kronecker products.

Proposition 8.1: Let $H \in \mathcal{RH}_2^{p \times m}$ be a transfer function with an input balanced realization (A_s, B_s, C_s, D_s) , and let (A, B) be an input balanced pair that generates an $m \times 1$ inner transfer function $G \in \mathcal{G}_1$, leading to an orthonormal basis $\Psi(G)$.

Then the orthogonal expansion coefficients L_k satisfying $H(z) = D_s + z^{-1} \sum_{k=0}^{\infty} L_k V_k(z)$ are determined by

$$Vec(L_k) = Z X^k Y \quad (50)$$

with

$$Z = (I \otimes C_s) M^{-1} \quad (51)$$

$$Y = Vec(B_s B^*) \quad (52)$$

$$X = N M^{-1} \quad (53)$$

$$M = I \otimes I - A \otimes A_s \quad (54)$$

$$N = F \otimes A_s - F A^* \otimes I. \quad (55)$$

Note that due to (50) we can consider $Vec(L_k)$ as a sequence of Markov parameters of a dynamical system with a state-space realization given by $(X, Y, Z, 0)$. By examining the eigenvalues of this realization, we create the possibility of drawing some conclusions on the speed of convergence of the series expansion. The following result is taken from [19].

Proposition 8.2: Consider the situation of Proposition 8.1 with $H(z)$ and $G(z)$ having McMillan degree n_s , n , respectively, and $m = 1$. Let μ_i , $i = 1, \dots, n_s$ denote the eigenvalues of A_s , and ρ_j , $j = 1, \dots, n$ denote the eigenvalues of A . The dynamical system $Z(zI - X)^{-1}Y$ has a realization $(X_o, Y_o, Z_o, 0)$ that satisfies

a) X_o has dimension n_s ;

b) X_o has eigenvalues λ_i , $i = 1, \dots, n_s$, that satisfy

$$|\lambda_i| = \prod_{j=1}^n \left| \frac{\mu_i - \rho_j}{1 - \mu_i \rho_j} \right| \quad (56)$$

Since the proof of this proposition is somewhat outside the scope of this paper, the reader is referred to [19].

The above proposition shows that we can draw conclusions on the convergence rate of the sequence of expansion coefficients $\{L_k\}_{k=0}^{\infty}$, when given the eigenvalues of the original system $H(z)$ and the eigenvalues of the inner function $G(z)$ that generates the basis. Note that when the sets of eigenvalues $\{\mu_i\}$, $\{\rho_j\}$ coincide, then $\lambda_i = 0$, for all i , and consequently the sequence $\{L_k\}$ will have a finite number of elements unequal to zero. The above result also enables the determination of an upper bound on the error that is made, when we approximate a given system $H(z)$ through a finite number of its expansion coefficients.

Theorem 8.3: Consider the situation of Proposition 8.2, and denote

$$\hat{H}^N(z) = D_s + z^{-1} \sum_{k=0}^{N-1} L_k V_k(z)$$

and $\lambda := \max_i |\lambda_i|$. Then there exists a finite $c \in \mathbb{R}$ such that for any $\eta \in \mathbb{R}$, $\eta > \lambda$

$$\|H(z) - \hat{H}^N(z)\|_{\infty} \leq c \frac{\eta^{N+1}}{1 - \eta}. \quad (57)$$

Since λ is a measure for the "closeness" of system dynamics and basis dynamics, the above theorem shows that the error that is made when neglecting the tail of a series expansion, becomes smaller as λ becomes smaller. As a result, when restricting to a fixed number of expansion coefficients, the approximation error gets smaller the more accurate the basis dynamics is "adapted" to the system.

In the final part of this paper we will briefly comment on how these results could be employed in an approximate identification framework. As mentioned in the introduction, identification of a finite impulse model (FIR) (4), has some important advantages; however, it fails to be successful when the number of coefficients to be estimated becomes large. This may happen in situations of high sampling rates, moderately damped systems, as well as systems that have dominant dynamics in both the high-frequent and low-frequent region (e.g., multitime-scale systems). An alternative way to attain the advantages of this identification method, is to exploit the model structure

$$y(t) = D(\theta) + \sum_{k=0}^{N-1} L_k(\theta) V_k(q) u(t) + \varepsilon(t) \quad (58)$$

where $\varepsilon(t)$ is the one-step-ahead prediction error, $D(\theta)$, $L_k(\theta)$ the parameterized expansion coefficients, and with $V_k(z)$ representing an appropriately chosen basis.

Note that this model structure can simply be written as

$$y(t) = D(\theta) + \sum_{k=0}^{N-1} L_k(\theta) u_k(t) + \varepsilon(t) \quad (59)$$

where $u_k(t)$ can simply be calculated by applying $u(t)$ to the known-filters $V_k(q)$, compare Fig. 1.

Identifying θ through least squares optimization of $\varepsilon(t)$ over the time interval, is a similar problem as in the case of a FIR-model. With appropriately chosen basis functions, however, the convergence rate of the series expansion can become extremely fast; with only a few coefficients to be estimated a very accurate approximate model can be obtained. This is of course interesting and appealing from both aspects of bias (accurate approximation is possible) and variance (few parameters to be estimated from data). An analysis of bias and variance errors in these identification schemes is presented in [39].

Additionally, when comparing these "orthogonal FIR" model structures with nonlinearly parameterized model structure as e.g., a Box Jenkins or ARMAX model ([26]), we avoid problems of possible occurrence of local (nonglobal) minima in the quadratic identification criterion. Moreover, the freedom in the choice of basis functions allows the useful use of "a priori information" concerning the system dynamics.

Very often an identification experimenter has a rough-knowledge about the dynamics of the system under consideration, e.g., from previous experiments or from physical insight on the process dynamics. It would be favorable to exploit

this knowledge in an identification procedure. The method suggested above, shows that this a priori knowledge can be exploited in terms of the basis functions that are chosen. When we have rough-knowledge about the poles of the system, we can construct basis functions that are based on this set of poles. The more accurate the poles are, i.e., the more accurate our a priori information is, the better we can adapt the basis functions to the system dynamics. As a result, see Theorem 8.3, the estimated model can become more accurate when restricting to a prespecified number of coefficients to be estimated.

Effectively the identification problem now reflects the identification of the mismatch between the system under consideration and the knowledge that already was available, represented in the basis functions. This actually is very appealing, as the a priori information simplifies the identification procedure. Note that in the way described above, the *a priori* information does not have to be exact, i.e., it is not of the type of fixing *a priori* a constraint on the model parameters, as e.g., the steady-state gain. The information can be uncertain. The only result is that the more accurate it is, the more simple the system representation will be.

This discussion also motivates the use of an iterative scheme, where the identification of parameters θ is performed iteratively, using the model that is estimated in step $i-1$ for constructing the basis functions for step i . An example of such an iterative scheme has been shown in [19].

One remark that has to be made in this respect, is a remark on the model order of a system represented by a finite number of expansion coefficients. The McMillan degree of this system, as in the case of an FIR-representation, will generally be large. This results from the following observation.

Proposition 8.4 Consider the transfer function

$$\hat{H}^N(z) = \hat{D} + \sum_{k=0}^{N-1} L_k V_k(z)$$

with $V_k(z)$ the generating transfer functions of an orthonormal basis $\Psi(G)$, where the inner function $G \in \mathcal{G}_1$ has a minimal balanced realization (A, B, C, D) with dimension n . Then $\hat{H}^N(z)$ has a state-space realization $(A_{N-1}, B_{N-1}, K, \hat{D})$, with A_{N-1}, B_{N-1} defined in (22), (23), and $K = [\hat{L}_0 \ L_1 \ \hat{L}_2 \ \cdots \ L_{N-1}]$. \square

The proof of this proposition follows by inspection.

With \hat{L}_i being the result of an unconstrained optimization in an identification procedure, the state-space dimension of the model will generically be equal to Nn . Consequently, if one wants to represent the model again in a traditional state-space form of low dimension, a model reduction procedure will have to be used to arrive at a reduced dimension. This also motivates a further analysis of the realization problem in terms of orthogonal expansion coefficients $\{L_k\}$.

IX. CONCLUSIONS

We have developed a theory on orthogonal functions as basis functions for general linear time-invariant stable systems. The basic ingredient is that every square inner transfer function in

a very natural way induces two sets of orthogonal functions that form a basis of the signal space ℓ_2 . The ordinary pulse functions and the classical Laguerre and Kautz polynomials are special cases in this theory of inner functions.

With this concept we have explored the connection between a general dynamical system and an inner function, by letting the inner function be determined through a specified set of poles. An important property of the resulting orthonormal functions is that they—to some extent—incorporate the dynamic behavior of the underlying system. We have developed a theory on these system based orthogonal functions, both on an input-output level and in terms of balanced state-space realizations. Furthermore we have shown how the alternative basis can be fruitfully used in problems of system approximation and identification, leading to simplified identification schemes, in which *a priori* knowledge about the process dynamics can be utilized by incorporating the information into the basis.

APPENDIX

Lemma A1: Let $G(z)$, $F(z)$, and $R(z)$ be stable transfer functions with Laurent expansions $G(z) = \sum_{k=0}^{\infty} G_k z^{-k}$, $F(z) = \sum_{k=0}^{\infty} F_k z^{-k}$, and $R(z) = \sum_{k=0}^{\infty} R_k z^{-k}$. Then $R(z) = F(z)G(z)$ if and only if

$$[R_0 \ R_1 \ R_2 \ \dots] = [F_0 \ F_1 \ F_2 \ \dots] T_v \quad (\text{A.1})$$

with T_v as defined in (12). \square

Proof: The equality $R(z) = (\sum_{k=0}^{\infty} F_k z^{-k}) (\sum_{k=0}^{\infty} G_k z^{-k})$ is equivalent to $\sum_{k=0}^{\infty} R_k z^{-k} = \sum_{k=0}^{\infty} [\sum_{i=0}^k F_i G_{k-i}] z^{-k}$, and to $R_k = \sum_{i=0}^k F_i G_{k-i}$, which exactly matches (A.1). \square

Lemma A2 [11]: Given matrices $X \in \mathbb{C}^{n \times m}$, $Y \in \mathbb{C}^{n \times r}$, $r \geq m$, with $XX^* = YY^*$; then there exists a $W \in \mathbb{C}^{m \times r}$ such that $Y = XW$ and $WW^* = I$. \square

Lemma A3: Let $\binom{n}{k} = \frac{n!}{k!(n-k)!}$. Then $\binom{n+1}{k} = \binom{n}{k} + \binom{n}{k-1}$ and $\sum_{i=0}^t \binom{k+i}{k} = \binom{k+t+1}{k+1}$. \square

Proof: By simple calculation. \square

Lemma A4: Let $G(z)$ be a square inner function such that $\|G_0\| < 1$, with $\|\cdot\|$ any induced matrix norm. Let G^k have a Laurent expansion $G^k(z) = \sum_{i=0}^{\infty} G_i^{(k)} z^{-i}$. Then $\|G_i^{(k)}\| \leq \binom{k+i-1}{k-1} \|G_0\|^{k-i}$ for $0 \leq i \leq k-1$. \square

Proof: The proof will be given by induction. For $k=1$, validity is trivial. Suppose that the statement holds true for $k \leq n$. Now we consider two cases.

i) Consider $G_i^{(n+1)}$, where $i < n$

$$\begin{aligned} G_i^{(n+1)} &= G_0 G_i^{(n)} + G_1 G_{i-1}^{(n)} + \dots + G_i G_0^{(n)}; \\ \|G_i^{(n+1)}\| &\leq \|G_0\| \|G_i^{(n)}\| + \|G_1 G_{i-1}^{(n)}\| + \dots + \|G_i G_0^{(n)}\| \\ &\leq \|G_0\| \binom{n+i-1}{n-1} \|G_0\|^{n-i} + \\ &\quad + \binom{n+i-2}{n-1} \|G_0\|^{n-i+1} + \\ &\quad + \dots + \binom{n}{n-1} \|G_0\|^{n-1} + \|G_0\|^n \end{aligned} \quad (\text{A.2})$$

$$\begin{aligned} &\leq \|G_0\|^{n+1-i} \sum_{j=0}^i \binom{n-1+j}{n-1} \\ &= \|G_0\|^{n+1-i} \binom{n+i}{n} \quad \text{by Lemma A3.} \end{aligned} \quad (\text{A.3})$$

ii) Consider the case $i = n$

$$G_n^{(n+1)} = G_0 G_n^{(n)} + G_1 G_{n-1}^{(n)} + \dots + G_n G_0^{(n)}; \quad (\text{A.4})$$

$$\begin{aligned} \|G_n^{(n+1)}\| &\leq \|G_0\| + \|G_n^{(n)}\| + \dots + \|G_1^{(n)}\| + \|G_0^{(n)}\| \\ &\leq \|G_0\| \left[1 + \binom{2n-1}{n-1} + \binom{2n-3}{n-1} + \dots + \binom{n}{n-1} + 1 \right] \\ &= \|G_0\| \left[1 + \binom{2n-1}{n} \right] \\ &\leq \|G_0\| \left[\binom{2n-1}{n-1} + \binom{2n-1}{n} \right] = \\ &= \|G_0\| \binom{2n}{n}. \end{aligned}$$

We have shown that $\|G_i^{(n+1)}\| \leq \|G_0\|^{n+1-i} \binom{n+i}{n}$ for $i \leq n$, which proves the result. \square

Lemma A5: Let $G(z)$ be an $m \times m$ inner function such that $\|G_0\| < 1$, with $\|\cdot\|$ any induced matrix norm. Let G^k have a Laurent expansion $G^k(z) = \sum_{i=0}^{\infty} G_i^{(k)} z^{-i}$, and Hankel matrix $\Pi_k := \mathcal{H}(G^k)$. Then for all i

$$\lim_{k \rightarrow \infty} \max_j \|(\Pi_k^* \Pi_k)_{ij} - \delta_{ij}\| = 0.$$

Proof: Consider $R_k(i) = \sum_{t=0}^i \|G_t^{(k)}\|$. With Lemma A4 it follows that $R_k(i) \leq$

$$\begin{aligned} \sum_{t=0}^i \binom{k+t-1}{k-1} \|G_0\|^{k-t} &\leq \left[\sum_{t=0}^i \binom{k+t-1}{k-1} \right] \|G_0\|^{k-i} \\ &= \binom{k+i}{k} \|G_0\|^{k-i} \leq (k+1)^i \|G_0\|^{k-i}. \end{aligned}$$

Since $\|G_0\| < 1$, this implies that $R_k(i) \rightarrow 0$ for $k \rightarrow \infty$.

Now consider the (i, j) -block element of $\Pi_k^* \Pi_k$ with $j \geq i$. $(\Pi_k^* \Pi_k)_{ij} = \sum_{s=0}^{\infty} (G_{i+s}^{(k)})^* G_{j+s}^{(k)} = \delta_{ij} I_m - \sum_{s=0}^{i-1} (G_s^{(k)})^* G_{s+j-i}^{(k)}$. Consequently $\|(\Pi_k^* \Pi_k)_{ij} - \delta_{ij} I_m\| = \|\sum_{s=0}^{i-1} (G_s^{(k)})^* G_{s+j-i}^{(k)}\| \leq \sum_{s=0}^{i-1} \|G_s^{(k)}\| = R_k(i-1) \rightarrow 0$ for $k \rightarrow \infty$.

For $j < i$ it holds that $R_k(j-1) < R_k(i-1)$, which implies that for all j , $\|(\Pi_k^* \Pi_k)_{ij} - \delta_{ij}\| \leq R_k(i-1)$. \square

Proof of Proposition 4.1: Denote $L_i = \sum_{k=0}^{\infty} G_{k+i}^T G_k$ for $i \in \mathbb{Z}$, with $G_j := 0$, $j < 0$. Then $G^T(z^{-1}) G(z) = \sum_{i=-\infty}^{\infty} G_i^T z^i \sum_{k=0}^{\infty} G_k z^{-k}$. This expression equals $\sum_{j=-\infty}^{\infty} (\sum_{k=0}^{\infty} G_{k+j}^T G_k) z^j = \sum_{j=-\infty}^{\infty} L_j z^j$. Since G is inner, $G^T(z^{-1}) G(z) = I$, and evaluation of the former expression for $j \geq 0$ proves the result.

Proof of Proposition 4.3: Part i) follows directly from Proposition 4.1. For Part ii), consider $T_v(\mathcal{H}(G))^*$. Applying Proposition 4.1, shows that $T_v(\mathcal{H}(G))^* = 0$, which implies

that $T_v V_0 U_0^* = 0$ and $T_v V_0 U_0^* U_0 = 0$, leading to $T_v V_0 = 0$. The proof for T_u follows analogously, employing the fact that $G^T(z)$ is inner too. \square

Proof of Lemma 4.4: If G is inner, then for any $k > 1$, $(G^k)^T(z^{-1}) G^k(z) = (G^{k-1})^T(z^{-1}) G^T(z^{-1}) G(z) G^{k-1}(z) = (G^{k-1})^T(z^{-1}) G^{k-1}(z)$, and by induction it follows that G^k is inner. A proof for the McMillan degree of G^k is contained in the proof of Proposition 5.4. \square

Proof of Theorem 4.5:

Part A: A constructive proof will be given in three steps.

- i) The choices for U_j and V_j^* as in (17), (18) lead to matrices Γ_k^o and Γ_k^c in (14), (15), that are unitary;
- ii) The constructed matrix $\Gamma_k^o \Gamma_k^c$ has a block Hankel structure;
- iii) $\Gamma_k^o \Gamma_k^c = \mathcal{H}(G^k)$.

Proofs:

- i) Note that the (i, j) -block-element of $\Gamma_k^o (\Gamma_k^c)^*$ equals $V_0^* T_v^{i-1} (T_v^*)^{j-1} V_0$. With Proposition 4.3 it follows that this equals I for $i = j$, and zero elsewhere.
- ii) This proof will be given by complete induction. For $k = 1$ the statement is true by definition. Assume that it holds for $k - 1$, i.e., $\Pi_{k-1} := \Gamma_{k-1}^o \Gamma_{k-1}^c$ is a Hankel matrix. We have to show that Π_k is a Hankel matrix too, with $\Pi_k = [U_{k-1} \quad \Gamma_{k-1}^o] \begin{bmatrix} \Gamma_{k-1}^c \\ V_{k-1}^* \end{bmatrix}$.

The Markov parameters of the system $G^{k-1}(z)$ will be denoted by H_0, H_1, H_2, \dots .

With U_j and V_j^* chosen as in (17), (18), it follows that

$$\Pi_k = [T_u \Gamma_{k-1}^o \quad U_0] \begin{bmatrix} \Gamma_{k-1}^c \\ V_{k-1}^* \end{bmatrix}$$

showing that $\Pi_k = T_u \Pi_{k-1} + U_0 V_0^* T_v^{k-1}$.

The matrix Π_k has a block Hankel structure if and only if $S \Pi_k = \Pi_k S^*$, with

$$S = \begin{bmatrix} 0 & I & 0 & 0 & \dots \\ 0 & 0 & I & 0 & \dots \\ \vdots & \vdots & 0 & \ddots & \vdots \end{bmatrix}.$$

Evaluation of $S \Pi_k$ shows that $S \Pi_k = S T_u \Pi_{k-1} + S U_0 V_0^* T_v^{k-1} =$

$$= \begin{bmatrix} G_1 \\ G_2 \\ \vdots \end{bmatrix} \Pi_{k-1} + \begin{bmatrix} G_2 & G_3 & \dots \\ G_3 & G_4 & \dots \\ \vdots & \vdots & \ddots \end{bmatrix} T_v^{k-1} \quad (\text{A.5})$$

$$= \begin{bmatrix} G_1 \\ G_2 \\ \vdots \end{bmatrix} \begin{bmatrix} H_1 & H_2 & H_3 & \dots \\ \Pi_{k-1} S^* & & & \end{bmatrix} + \begin{bmatrix} G_2 & G_3 & \dots \\ G_3 & G_4 & \dots \\ \vdots & \vdots & \ddots \end{bmatrix} T_v^{k-1} \\ = T_u \Pi_{k-1} S^* + \begin{bmatrix} G_1 & G_2 & \dots \\ G_2 & G_3 & \dots \\ \vdots & \vdots & \ddots \end{bmatrix} \begin{bmatrix} H_1 & H_2 & H_3 & \dots \\ & T_v^{k-1} & & \end{bmatrix}.$$

(A.6)

From Lemma A1 we can deduct that the i th block row of T_v^{k-1} corresponds to the Markov parameters of the transfer function $z^{-i+1} G^{k-1}(z)$. So

$$T_v^{k-1} = \begin{bmatrix} H_0 & H_1 & H_2 & \dots \\ 0 & H_0 & H_1 & \dots \\ \vdots & 0 & H_0 & \dots \\ \vdots & \vdots & \ddots & \ddots \end{bmatrix}.$$

As a result (A.6) can be written as

$$S \Pi_k = T_u \Pi_{k-1} S^* + U_0 V_0^* T_v^{k-1} S^* = \Pi_k S^*$$

which proves that Π_k is a block Hankel matrix.

- iii) The proof follows by induction, similarly as in step ii). Consider the first block row of $\Pi_k = \Gamma_k^o \Gamma_k^c$. This equals

$$G_0 [H_1 \quad H_2 \quad \dots] + [G_1 \quad G_2 \quad \dots] T_v^{k-1}.$$

Lemma A1 shows that this is equivalent to

$$G_0 [H_1 \quad H_2 \quad \dots] + [W_0 \quad W_1 \quad \dots]$$

where W_i is such that

$$\sum_{k=0}^{\infty} W_k z^{-k} = \left[\sum_{j=0}^{\infty} G_{j+1} z^{-j} \right] G^{k-1}(z) = \left[\sum_{j=0}^{\infty} G_{j+1} z^{-j} \right] \left[\sum_{i=0}^{\infty} H_i z^{-i} \right].$$

Hence the first block row of Π_k corresponds to the Markov parameters of $\left[\sum_{j=0}^{\infty} G_{j+1} z^{-j} \right] \left[\sum_{i=0}^{\infty} H_i z^{-i} \right] = G^k(z)$.

Part B: Since $\Pi_k = [U_{k-1} \quad \Gamma_{k-1}^o] \begin{bmatrix} \Gamma_{k-1}^c \\ V_{k-1}^* \end{bmatrix}$ is an svd of Π_k , it follows that $U_0^* \Pi_k = V_{k-1}^*$, and $\Pi_k V_0 = U_{k-1}$ which shows the uniqueness of U_{k-1} and V_{k-1} for a given Γ_{k-1}^o and Γ_{k-1}^c . Since U_0, V_0 are unique up to unitary postmultiplication, this holds for the whole sequence of matrices $\{U_i, V_i\}_{i=0,1,\dots}$.

Part C: The proof is given by construction in part a). \square

Proof of Proposition 4.6: With $V_k^* = V_{k-1}^* T_v$ the result follows immediately from Lemma A1. \square

Proof of Theorem 4.7: The result of the theorem follows if the set of basis functions is complete in ℓ_2 , i.e., if for any $x \in \ell_2[0, \infty)$, the following implication holds

$$(\langle \phi_k, x \rangle = 0 \text{ for all } k) \Rightarrow x = 0$$

with $\langle \cdot, \cdot \rangle$ the inner product in ℓ_2 .

If $\langle \phi_k, x \rangle = 0$ for all k , then $(\Gamma_k^c)^* \Gamma_k^c y = 0$ for all k , with $y := [x(0) \ x(1) \ \dots]^*$. Consider the i th row of this equation: $[(\Gamma_k^c)^* \Gamma_k^c]_{i*} y = 0$ for all k , with $[(\Gamma_k^c)^* \Gamma_k^c]_{i*}$ the i th row of the corresponding matrix, then

$$\|[(\Gamma_k^c)^* \Gamma_k^c]_{i*} - e_i^*\| y \leq \|[(\Gamma_k^c)^* \Gamma_k^c]_{i*} - e_i^*\| \cdot \|y\|.$$

Since, $(\Gamma_k^c)^* \Gamma_k^c = (\mathcal{H}(G^k))^* \mathcal{H}(G^k)$, it follows from Lemma A5 that $\lim_{k \rightarrow \infty} \|[(\Gamma_k^c)^* \Gamma_k^c]_{i*} - e_i^*\| = 0$, which implies that $y_i = 0$. \square

Proof of Corollary 4.10: Part a) follows directly from the completeness of the basis. For part b), consider the i th row of $H(z) - D$, with $D = \lim_{z \rightarrow \infty} H(z)$, and $H(z) - D$ written as $\sum_{k=1}^{\infty} h^T(k) z^{-k}$, with $h(k) \in \mathbb{R}^m$.

Consider the scalar time series $\{w(t)\}_{t=0,1,\dots}$ defined by

$$[w(0) \ w(1) \ w(2) \ \dots] = [h^T(1) \ h^T(2) \ \dots].$$

Applying part a) delivers $w(t) = \sum_{k=0}^{\infty} W_k^T \phi_k(t)$, with $W_k \in \mathbb{R}^n$, $\phi_k(t) \in \mathbb{R}^n$. As a result $h^T(j+1) = \sum_{k=0}^{\infty} W_k^T [\phi_k(mj+1) \ \dots \ \phi_k(m(j+1))]$.

In the notation of Proposition 4.6 this leads to $h^T(j+1) = \sum_{k=0}^{\infty} W_k^T M_k(j)$. Consequently $\sum_{i=1}^{\infty} h^T(i) z^{-i} = \sum_{i=1}^{\infty} \sum_{k=0}^{\infty} W_k^T M_k(i-1) z^{-i} = z^{-1} \sum_{k=0}^{\infty} W_k^T V_k(z)$. Since this applies to each row of $H(z) - D$, this proves the result.

Proof of Lemma 5.1: From Proposition 4.2 it follows that for the realization of an inner function, the controllability and observability grammians have to satisfy $PQ = I$, while stability requires that $P, Q \geq 0$. In a balanced realization $P = Q$ and diagonal, which implies $P = Q = I$. \square

Proof of Proposition 5.2:

$$\begin{aligned} G^T(z^{-1})G(z) &= [B^*(z^{-1}I - A^*)^{-1}C^* + D^*] \\ &\quad \cdot [C(zI - A)^{-1}B + D] \\ &= B^*(z^{-1}I - A^*)^{-1}C^*C(zI - A)^{-1}B + \\ &\quad + D^*C(zI - A)^{-1}B \\ &\quad + B^*(z^{-1}I - A^*)^{-1}C^*D + D^*D. \quad (\text{A.7}) \end{aligned}$$

Using $A^*A + C^*C = I$, we can rewrite the first term of the right-hand side by employing $I - A^*A = A^*(zI - A) + (z^{-1}I - A^*)A + (z^{-1}I - A^*)(zI - A)$.

Substitution of this in (A.7) shows that

$$\begin{aligned} G^T(z^{-1})G(z) &= (D^*C + B^*A)(zI - A)^{-1}B \\ &\quad + B^*(z^{-1}I - A^*)^{-1}(C^*D + A^*B) \\ &\quad + B^*B + D^*D. \end{aligned}$$

Since (A, B) is a controllable pair, it follows that $G^T(z^{-1})G(z) = I$ if and only if $B^*B + D^*D = I$ and $D^*C + B^*A = 0$. \square

Proof of Proposition 5.3: Using Proposition 5.2, and its dual version, it follows that $DD^* + CC^* = D^*D + B^*B = I$. Now $\|D\|_2 < 1$ is equivalent to the smallest singular value of B^*B being greater than zero which is equivalent to $\text{rank } B = m$. The result for $\text{rank } C$ follows analogously. \square

Proof of Proposition 5.4: We use complete induction on k to prove this proposition. Note that we can write

$$\begin{aligned} A_k &= \begin{bmatrix} A_{k-1} & 0 \\ BC_{k-1} & A \end{bmatrix} & B_k &= \begin{bmatrix} B_{k-1} \\ BD^{k-1} \end{bmatrix} \\ C_k &= [DC_{k-1} \ C] \end{aligned}$$

with $(A_1, B_1, C_1, D_1) = (A, B, C, D)$. Validity of the statement for (A_1, B_1, C_1, D_1) is straightforward. Assuming validity for $k-1$, we have to show that the statement holds for k . First we show that (A_k, B_k, C_k, D_k) is indeed a realization of $G^k(z)$

$$\begin{aligned} C_k(zI - A_k)^{-1}B_k + D_k &= [DC_{k-1} \ C] \cdot \\ &\quad \begin{bmatrix} (zI - A_{k-1})^{-1} & 0 \\ (zI - A)^{-1}BC_{k-1}(zI - A_{k-1})^{-1} & (zI - A)^{-1} \end{bmatrix} \\ &\quad \cdot \begin{bmatrix} B_{k-1} \\ BD^{k-1} \end{bmatrix} + D^k \\ &= [DC_{k-1} + C(zI - A)^{-1}BC_{k-1}](zI - A_{k-1})^{-1}B_{k-1} + \\ &\quad + C(zI - A)^{-1}BD^{k-1} + D^k \\ &= [D + C(zI - A)^{-1}B]C_{k-1}(zI - A_{k-1})^{-1}B_{k-1} + \\ &\quad + [C(zI - A)^{-1}B + D]D^{k-1} \\ &= [D + C(zI - A)^{-1}B][C_{k-1}(zI - A_{k-1})^{-1}B_{k-1} + D_{k-1}] \\ &= G(z)G^{k-1}(z) = G^k(z). \end{aligned}$$

Balancedness of the realization (A_k, B_k, C_k) can be shown by evaluating: $A_k A_k^* + B_k B_k^*$. For brevity of notation, we will write $(A_{k-1}, B_{k-1}, C_{k-1}, D_{k-1}) = (A, B, C, D)$

$$\begin{aligned} A_k A_k^* + B_k B_k^* &= \\ &\quad \begin{bmatrix} AA^* + BB^* & AC^*B^* + BD^*B^* \\ BCA^* + BDB^* & BCC^*B + AA^* + BDD^*B^* \end{bmatrix} \\ &= \begin{bmatrix} AA^* + BB^* & (AC^* + BD^*)B^* \\ B(CA^* + DB^*) & B(CC^* + DD^*)B^* + AA^* \end{bmatrix}. \end{aligned}$$

Employing Proposition 5.2 together with $AA^* + BB^* = I$ shows that the above expression equals the identity matrix. In a similar way, using the dual forms, it can be shown that $A_k^* A_k + C_k^* C_k = I$, which proves that the realization is balanced and minimal. \square

Proof of Proposition 5.5: Since $V_0^* = [B \ AB \ A^2B \ \dots]$ and $\mathcal{H}(G) = U_0 V_0^*$ is an svd, it follows that $U_0^* = [C^* \ A^*C^* \ \dots]$. Similarly it holds for any k that $\mathcal{H}(G^k) = \Gamma_k^o \Gamma_k^c$ is an svd, with $(\Gamma_k^o)^* = [C_k^* \ A_k^*C_k^* \ \dots]$. Since Γ_k^o and Γ_k^c satisfy the recursion property of Theorem 4.5-a), the given solution has to be the unique one. \square

Proof of Proposition 5.6: With $X = BC$ and P any matrix satisfying $PB = BD$, the matrices A_k, B_k as in Proposition 5.4 will take the form

$$\begin{aligned} A_k &= \begin{bmatrix} A & 0 & \dots & 0 \\ X & A & 0 & 0 \\ PX & X & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ P^{k-2}X & P^{k-1}X & \dots & X & A \end{bmatrix} \text{ and} \\ B_k &= \begin{bmatrix} B \\ PB \\ P^2B \\ \vdots \\ P^{k-1}B \end{bmatrix}. \end{aligned}$$

we can write

$$A_k^j B_k = \begin{bmatrix} M_0(j) \\ M_1(j) \\ \vdots \\ M_{k-1}(j) \end{bmatrix} = A_k(A_k^{j-1} B_k) = \\ = A_k \begin{bmatrix} M_0(j-1) \\ M_1(j-1) \\ \vdots \\ M_{k-1}(j-1) \end{bmatrix}.$$

With the above representation of A_k this leads to the recursive relation (30). Relations (29), (31) follow directly from B_k . \square

Proof of Theorem 5.7: 1-a). Using Proposition 4.6 we have to show that

$$z(zI - A)^{-1} B[D + C(zI - A)^{-1} B]^k = \\ = [(zI - A)^{-1} F(I - zA^*)]^k z(zI - A)^{-1} B.$$

Note that it is sufficient to show that this holds for $k = 1$, since successive application of the equality for $k = 1$ shows the result for any k . The equality for $k = 1$ is equivalent to

$$\{B[D + C(zI - A)^{-1} B] = F(I - zA^*)(zI - A)^{-1} B\} \\ \Leftrightarrow \{BD + BC(zI - A)^{-1} B = BC(zI - A)^{-1} B + \\ - PA(zI - A)^{-1} B - zFA^*(zI - A)^{-1} B\}, \\ \Leftrightarrow \{BD = -PA(zI - A)^{-1} B - zFA^*(zI - A)^{-1} B\}.$$

With $PB = BD$ it suffices to show that

$$P = -PA(zI - A)^{-1} - zFA^*(zI - A)^{-1}.$$

This is equivalent to $\{P(zI - A) = -PA - zFA^*\} \Leftrightarrow \{P = -FA^*\} \Leftrightarrow \{P = -BCA^* + PAA^*\} \Leftrightarrow \{P = BDB^* + P - PBB^*\} \Leftrightarrow \{PBB^* = BDB^*\}$ which is known to be true since $PB = BD$.

1-b) This follows directly from Proposition 4.6.

2) Take $P = -RA^*$. Then $PB = -RA^*B$, which with Proposition 5.2-i) equals RC^*D . With $B = RC^*$ it follows that $PB = BD$ and thus this choice of P satisfies (28).

Now it has to be shown that for this P , $BC - PA = R$. This follows from $BC - PA = BC + RA^*A = BC + R(I - C^*C) = BC + R - BC = R$. \square

Proof of Theorem 5.8: Denote the infinite-dimensional matrices $B_\infty := B_k$, $k \rightarrow \infty$, and $A_\infty := A_k$, $k \rightarrow \infty$. Then we can rewrite (34) as

$$[C_s B_s \ C_s A_s B_s \ C_s A_s^2 B_s \ \dots] = \\ = [L_0 \ L_1 \ \dots][B_\infty \ A_\infty B_\infty \ A_\infty^2 B_\infty \ \dots]. \quad (A.8)$$

Because of the orthonormality of $[B_\infty \ A_\infty B_\infty \ \dots]$ postmultiplication of (A.8) with $[B_\infty \ A_\infty B_\infty \ \dots]^*$ provides

$$[C_s B_s \ C_s A_s B_s \ \dots][B_\infty \ A_\infty B_\infty \ \dots]^* = [L_0 \ L_1 \ L_2 \ \dots]$$

leading to $[L_0 \ L_1 \ L_2 \ \dots] = \sum_{k=0}^{\infty} C_s A_s^k B_s B_\infty^* (A_\infty^*)^k$.

We define

$$Q := [Q_0 \ Q_1 \ Q_2 \ \dots] = \sum_{k=0}^{\infty} A_s^k B_s B_\infty^* (A_\infty^*)^k \quad (A.9)$$

and as a result, $L_k = C_s Q_k$, which equals (35).

Based on (A.9) we can write $A_s Q A_\infty^* = Q - B_s B_\infty^*$. With $X = BC$ and P any matrix satisfying $PB = BD$, this leads to

$$A_s [Q_0 \ Q_1 \ Q_2 \ \dots] \begin{bmatrix} A^* & X^* & X^* P^* & \dots & \dots \\ 0 & A^* & X^* & X^* P^* & \dots \\ 0 & 0 & A^* & X^* & \dots \\ \vdots & \vdots & 0 & A^* & \ddots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix} \\ = [Q_0 \ Q_1 \ Q_2 \ \dots] - B_s [B^* \ B^* P^* \ B^* (P^*)^2 \ \dots].$$

The first element of this equation shows $A_s Q_0 A^* = Q_0 - B_s B^*$, which equals (36). The i th element leads to

$$A_s [Q_i A^* + \sum_{j=1}^i Q_{i-j} X^* (P^*)^{j-1}] = Q_i - B_s B^* (P^*)^i. \quad (A.10)$$

Postmultiplication with P^* gives

$$A_s [Q_i A^* P^* + \sum_{j=1}^i Q_{i-j} X^* (P^*)^j] = Q_i P^* - B_s B^* (P^*)^{i+1}. \quad (A.11)$$

Writing (A.10) for $i \rightarrow i+1$, shows that

$$A_s [Q_{i+1} A^* + \sum_{j=1}^{i+1} Q_{i-j+1} X^* (P^*)^{j-1}] = Q_{i+1} - B_s B^* (P^*)^{i+1} \quad (A.12)$$

and subtracting (A.11) from (A.12) delivers

$$A_s Q_{i+1} A^* - A_s Q_i [A^* P^* - X^*] = Q_{i+1} - Q_i P^*. \quad (A.13)$$

Note that $P = P(AA^* + BB^*) = PAA^* + BDB^* = PAA^* - BCA^* = -FA^*$, and since $F = X - PA$, (A.13) leads to (37). \square

Proof of Proposition 7.1: Part a) A similar result for continuous-time systems is proven in [11]. The discrete-time version follows by applying a bilinear transformation, as is shown in [19].

Part b) The proof is based on an equivalence relation as employed in [11], based on the bilinear transformation. If (A_d, B_d, C_d, D_d) is a balanced realization of a square discrete-time system G_d , then (A_c, B_c, C_c, D_c) is a (continuous-time) balanced realization of a continuous-time system G_c , where

$$A_c = [A_d - I][A_d + I]^{-1} \quad A_d = [I + A_c][I - A_c]^{-1} \\ B_c = \sqrt{2}[A_d + I]^{-1} B_d \quad B_d = \sqrt{2}[I - A_c]^{-1} B_c \\ C_c = \sqrt{2} C_d [A_d + I]^{-1} \quad C_d = \sqrt{2} C_c [I - A_c]^{-1} \\ D_c = D_d - C_d [A_d + I]^{-1} B_d \quad D_d = D_c + C_c [I - A_c]^{-1} B_c.$$

Furthermore G_d is inner if and only if G_c is inner. From [11] it follows that G_c is inner if and only if the following conditions are satisfied:

- 1) $A_c + A_c^* + B_c B_c^* = A_c + A_c^* + C_c^* C_c = 0$
- 2) $D_c D_c^* = D_c^* D_c = I$
- 3) $D_c^* C_c + B_c^* = D_c B_c^* + C = 0$.

Given A_d, B_d we can construct A_c, B_c with the equations above, additionally choosing $C_c := B_c^*$, $D_c := -I$ it follows that (A_c, B_c, C_c, D_c) is a balanced realization of an inner function.

Now transforming the continuous-time realization back to the discrete-time domain, with the expressions for C_d, D_d

as given before and employing the relation $(I - A_c)^{-1} = \frac{1}{2}(I + A_d)$, shows that

$$C_d = B_d^*(A_d^* + I)^{-1}(A_d + I) \quad (A.14)$$

$$D_d = B_d^*(A_d^* + I)^{-1}B_d - I \quad (A.15)$$

which completes the balanced realization (A_d, B_d, C_d, D_d) .

Using the fact that B_d and C_d have full rank, Proposition 5.2 now implies that premultiplication of C_d and D_d with any unitary matrix U characterizes the intended class of balanced realizations.

Part c) Consider a realization (A, B, C, D) satisfying (44), (45) with $U = I$. For $\bar{F} = [I + A][I + A^*]^{-1}$ it follows immediate that $\bar{F}C^* = B$, and the result follows with Theorem 5.7-2).

Denote $F(\lambda, U) = [\lambda I + B(U - \lambda I)(B^*B)^{-1}B^*]\bar{F}$, with U a unitary matrix and $\lambda \in \mathcal{C}$. Then by substitution it can be verified that $F(\lambda, U)C^*U^* = B$. This means that for any $\tilde{C} = UC$ we have constructed a λ -family $F(\lambda, U)$ that satisfies $F(\lambda, U)\tilde{C}^* = B$. Again with Theorem 5.7-2) and choosing $\lambda = 1$ this proves the result. \square

Proof of Proposition 8.1: This result follows directly from rewriting the Lyapunov equations in Theorem 5.8 in terms of Kronecker products: see [3], [19]. \square

Proof of Theorem 8.3: Consider a single scalar entry of the rational matrix function $W(z) = Z_o(zI - X_o)^{-1}Y_o$, written as $w(z) = \sum_{k=1}^{\infty} w_k z^{-k}$. Then $w(z)$ is convergent for $|z| > \lambda$. Consequently, according to basic theory of power series, see e.g., [20], as employed also in [17], there exists an $\alpha \in \mathbb{R}$ such that for each $\eta > \lambda$, $|w_k \eta^{-k}| \leq \alpha$, leading to $|w_k| \leq \alpha \eta^k$. Since this holds for any entry of $W(z)$, and $W(z) = \sum_{k=1}^{\infty} \text{Vec}(L_{k-1})z^{-k}$, there exist scalars α_{ij} such that $|L_k(i, j)| \leq \alpha_{ij} \eta^{k+1}$, with $L_k(i, j)$ being the (i, j) -entry in L_k . Denoting $E(z) := H(z) - \hat{H}^N(z) = \sum_{k=N}^{\infty} L_k V_k(z)$, it follows that $\|E(z)\|_{\infty} \leq \|\sum_{k=N}^{\infty} L_k V_k(z)\|_{\infty} \leq \|V_0(z)\|_{\infty} \sum_{k=N}^{\infty} \|L_k\|_{\infty}$.

Using the above upper bound for $|L_k(i, j)|$ together with the well-known relation between the ∞ -norm and the Frobenius norm, $\|\cdot\|_{\infty} \leq \|\cdot\|_F$, it follows that

$$\|L_k\|_{\infty} \leq \eta^{k+1} \sqrt{\sum_{i,j} \alpha_{ij}^2}. \quad (A.16)$$

Substituting this latter upper bound in the derived upper bound for $\|E(z)\|_{\infty}$, the result of the theorem follows with $c = \|V_0(z)\|_{\infty} \sqrt{\sum_{i,j} \alpha_{ij}^2}$. \square

Peter S. C. Heuberger was born in Maastricht, The Netherlands, in 1957. He obtained the M.Sc. degree in Mathematics from the Groningen State University in 1983 and the Ph.D. degree in 1991 from Delft University of Technology.

From 1983 until 1990 he was a Research Assistant in the Mechanical Engineering Systems and Control Group at Delft University of Technology. Since 1991, he has been a staff member of the Dutch National Institute of Public Health and Environmental Protection in Bilthoven, The Netherlands, dealing

with modeling and calibration of environmental systems. His main research interests are in issues of system identification and model reduction.

Paul M. J. Van den Hof (S'85-M'88) was born in Maastricht, The Netherlands, in 1957. He obtained the M.Sc. and Ph.D. degrees both from the Department of Electrical Engineering, Eindhoven University of Technology, The Netherlands, in 1982 and 1989, respectively.

From 1986 to 1990 he was an Assistant Professor in the Mechanical Engineering Systems and Control Group at Delft University of Technology, The Netherlands. Since 1991 he has been working in this same group as an Associate Professor. In 1992 he has held a short term visiting position at the Centre for Industrial Control Science, The University of Newcastle, NSW, Australia. His research interests are in issues of system identification, parameterization, and the interplay between identification and robust control design, with applications in mechanical servo systems and industrial process control systems.

Dr. Van den Hof is an Associate Editor of *Automatica*. For his M.Sc. thesis he received the 1983 Control Systems Award (*Regeltechniekprijs*) of the Royal Dutch Institute of Engineers (KIVI).

Okko H. Bosgra was born in Groningen, The Netherlands, in 1944. He obtained the M.Sc. degree in mechanical engineering from Delft University of Technology in 1968.

From 1981-1985 he held a Professorship in the Department of Physics at the Agricultural University of Wageningen, The Netherlands. Since 1986 he is a Full Professor in control engineering, heading the Mechanical Engineering Systems and Control Group of Delft University of Technology, The Netherlands. His current research interests are in the

theory of robust identification and control design and their application to industrial problems in the process control field and in the field of mechanical servo motion control.

Prof. Bosgra is a member of the EUCA (European Union Control Association) Governing Board, a founding member of the Dutch Systems and Control Theory Network, and an Editor-At-Large of the new *European Journal of Control*.

H_∞ Control via Measurement Feedback for General Nonlinear Systems

Alberto Isidori, *Fellow, IEEE*, and Wei Kang, *Member, IEEE*

Abstract—This paper shows how the problem of (local) disturbance attenuation via measurement feedback, with internal stability, can be solved for a nonlinear system of rather general structure. The solution of the problem is shown to be related to the existence of solutions of a pair of Hamilton–Jacobi inequalities in n independent variables, which are associated with state-feedback and, respectively, output-injection design. The results of the paper extend a number of recent achievements in this area.

1. INTRODUCTION

THE development of a systematic analysis of the nonlinear equivalent of the H_∞ (sub)optimal control problem was initiated by the important contributions of Ball–Helton [2], Basar–Bernhard [4], and Van der Schaft [10]. In particular, [10] has shown that the solution of the problem in question in the case of full information configuration, that is when the set of measured variables which are available for feedback includes the state of the controlled plant and the exogenous disturbance input, can be determined from the solution of a Hamilton–Jacobi equation, which is the nonlinear version of the Riccati equation considered in analysis of the H_∞ (sub)optimal control problem for linear systems. More recent contributions to this area of research are the works [11], [6], [3], and [7]. In particular, [6] presents a set of sufficient conditions for the solution of the problem of (local) disturbance attenuation in the case of measurement feedback, that is when the set of measured variables is just a function of the state of the plant and of the disturbance input. The paper [3], among many other important contributions, discusses a number of issues related to the necessity of the (sufficient) conditions proposed in [10] and [6]. The paper [7] considers, as the paper [6] does, systems modeled by equations which are affine in both control and disturbance inputs, and shows that, if a local solution is sought, the sufficient conditions given in [6] can be simplified and turned into conditions involving two Hamilton–Jacobi inequalities in n independent variables, associated with the design of a “state-feedback” and, respectively, of an “output-injection gain.”

In the present paper we study the H_∞ (sub)optimal control problem for systems modeled by equations which are not necessarily affine in the inputs, a more general class, nonlinear systems already considered in [3] (which discusses necessary conditions and a separation principle in the case of measurement feedback) and in [12] (which discusses the case of state feedback). More precisely, we present a (more general) necessary condition for the existence of a solution to the problem in the case of measurement feedback and we show that, if this condition is strengthened in a suitable way, then the construction of a feedback law yielding local disturbance attenuation with internal stability becomes possible. The analysis of the necessity extends the results of [3] while the analysis of the sufficiency extends the results of [7].

Consider a nonlinear system modeled by equations of the form

$$\begin{aligned} \dot{x} &= F(x, w, u) \\ z &= Z(x, u) \\ y &= Y(x, w). \end{aligned} \quad (1)$$

The first equation of this system describes a plant with state x , defined on a neighborhood X of the origin in \mathbb{R}^n with control input $u \in \mathbb{R}^m$ and subject to a set of exogenous input variables $w \in \mathbb{R}^r$ which includes disturbances (to be rejected) and/or references (to be tracked). The second equation defines a penalty variable $z \in \mathbb{R}^s$, which may include a tracking error, as well as a cost of the input u needed to achieve the prescribed control goal. The third equation defines a set of measured variables $y \in \mathbb{R}^p$, which are functions of the state plant x and the exogenous input w . The mappings $F(x, w, u)$, $Z(x, u)$, and $Y(x, w)$ are smooth mappings (i.e., mappings of class C^k for some sufficiently large k) defined in a neighborhood of the origin in $\mathbb{R}^n \times \mathbb{R}^r \times \mathbb{R}^m$. We assume also that $F(0, 0, 0) = 0$, $Z(0, 0) = 0$ and $Y(0, 0) = 0$.

The control action to (1) is to be provided by a controller which processes the measured variable y and generates the appropriate control input u , and is modeled by equations of the form

$$\begin{aligned} \dot{\xi} &= \eta(\xi, y) \\ u &= \theta(\xi, y) \end{aligned} \quad (2)$$

in which ξ is defined on a neighborhood Ξ of the origin in \mathbb{R} and $\eta: \Xi \times \mathbb{R}^p \rightarrow \mathbb{R}^n$, $\theta: \Xi \times \mathbb{R}^p \rightarrow \mathbb{R}^m$ are smooth functions satisfying $\eta(0, 0) = 0$ and $\theta(0, 0) = 0$.

The purpose of the control is twofold: to achieve closed-loop stability and to attenuate the influence of the exogenous input w on the penalty variable z . Following numerous authors (see

IEEE Log Number 9408275.

e.g., [13], [5], [3], [11]) the property of disturbance attenuation in a nonlinear system can be characterized in the following way. A nonlinear system

$$\begin{aligned}\dot{x} &= f(x, u) \\ y &= h(x)\end{aligned}\quad (3)$$

is said to be locally dissipative near $(x, u) = (0, 0)$, with respect to a given supply rate $s(u, y)$, if there exists a smooth function $V(x)$, which is nonnegative and vanishes at $x = 0$, such that

$$\frac{\partial V}{\partial x} f(x, u) + s(u, h(x)) \leq 0 \quad (4)$$

for all (x, u) in a neighborhood of $(0, 0)$ (note that there is some abuse of terminology in this definition: following [13], one should say that a system is "dissipative," with respect to the supply rate $s(x, y)$, if the integral version of the inequality (4) holds, which would not require $V(x)$ to be differentiable).

If (3) is locally asymptotically stable (at the equilibrium $x = 0$) and locally dissipative with respect to the supply rate $s(u, y) = \gamma^2 \|u\|^2 - \|y\|^2$, then its output response to any sufficiently small input, from the initial state $x(0) = 0$, satisfies

$$0 \leq V(x(t)) \leq \int_0^t (\gamma^2 \|u(s)\|^2 - \|y(s)\|^2) ds$$

for all $t > 0$. As a consequence (3) has an L_2 gain which is less than or equal to γ (see [5]).

In what follows, we address the problem of finding a controller which renders the closed-loop system (1)–(2) locally asymptotically stable [at the equilibrium $(x, \xi) = (0, 0)$] and locally dissipative with respect to the supply rate $s(w, z) = \gamma^2 \|w\|^2 - \|z\|^2$. This problem will be referred to as the problem of local disturbance attenuation with internal stability.

II. DISTURBANCE ATTENUATION VIA STATE FEEDBACK

As pointed out by various authors (see, e.g., [2], [4]), the problem of finding a feedback law of the form $u = \alpha(x)$ rendering the closed-loop system

$$\begin{aligned}\dot{x} &= F(x, w, \alpha(x)) \\ z &= Z(x, \alpha(x))\end{aligned}\quad (5)$$

(locally) dissipative with respect to the supply rate $s(w, z) = \gamma^2 \|w\|^2 - \|z\|^2$, can be cast as a two player, zero sum, differential game, in which the minimizing player controls the input u and the maximizing player controls the input w .

The Hamiltonian function associated with the game in question in the present case is a function $H: \mathbb{R}^n \times \mathbb{R}^n \times \mathbb{R}^r \times \mathbb{R}^m \rightarrow \mathbb{R}$ defined as

$$H(x, p, w, u) = p^T F(x, w, u) + \|Z(x, u)\|^2 - \gamma^2 \|w\|^2.$$

Suppose plant (1) satisfies the following hypothesis.

Assumption A1: The penalty map $Z(x, u)$ is such that the matrix

$$D_1 = \frac{\partial Z}{\partial u}(0, 0)$$

has rank m .

Then, it is easy to see that, in a neighborhood of the point $(x, p, w, u) = (0, 0, 0, 0)$, the function $H(x, p, w, u)$ has unique local saddle point in (w, u) for each (x, p) . More precisely, there exists unique smooth functions $w_*(x, p)$ and $u_*(x, p)$, defined in a neighborhood of $(0, 0)$, satisfying

$$\begin{aligned}\frac{\partial H}{\partial w}(x, p, w_*(x, p), u_*(x, p)) &= 0, \\ \frac{\partial H}{\partial u}(x, p, w_*(x, p), u_*(x, p)) &= 0, \\ w_*(0, 0) &= 0, \quad u_*(0, 0) = 0\end{aligned}$$

and such that

$$\begin{aligned}H(x, p, w, u_*(x, p)) &\leq H(x, p, w_*(x, p), u_*(x, p)) \\ &\leq H(x, p, w_*(x, p), u)\end{aligned}\quad (6)$$

for each (x, p, w, u) in a neighborhood of $(x, p, w, u) = (0, 0, 0, 0)$. The existence of these functions and (6) can easily be deduced from the observation that $H(x, p, w, u)$, viewed as a function of (w, u) , has a Hessian matrix which, at $(x, p, w, u) = (0, 0, 0, 0)$, is equal to

$$\begin{pmatrix} -2\gamma^2 I & 0 \\ 0 & 2D_1^T D_1 \end{pmatrix}$$

where $D_1^T D_1$ is positive definite by hypothesis.

Let now $V: \mathbb{R}^n \rightarrow \mathbb{R}$ be a smooth function, defined in a neighborhood U of $x = 0$ and such that $V(0) = 0$ and $V_x(0) = 0$, set

$$H_*(x, p) = H(x, p, w_*(x, p), u_*(x, p))$$

$$\alpha_1(x) = w_*(x, V_x^T(x)), \quad \alpha_2(x) = u_*(x, V_x^T(x)) \quad (7)$$

and observe that (6) implies in particular

$$H(x, V_x^T(x), w, \alpha_2(x)) \leq H_*(x, V_x^T(x)).$$

Now, suppose the function $V(x)$ is nonnegative (in which case $V(0) = 0$ implies $V_x(0) = 0$) and renders the inequality

$$H_*(x, V_x^T(x)) \leq 0 \quad (8)$$

satisfied for each x in a neighborhood of zero. Then, set $\alpha(x) = \alpha_2(x)$ in (5). This yields a closed-loop system satisfying

$$V_x(x)F(x, w, \alpha_2(x)) + \|Z(x, \alpha_2(x))\|^2 - \gamma^2 \|w\|^2 \leq 0$$

that is a system which, in a neighborhood of $(x, w) = (0, 0)$, has the required dissipativity property.

Inequality (8) is called a Hamilton–Jacobi–Isaacs inequality. If $V(x)$ is positive definite and appropriate additional hypotheses are satisfied, it can be proven that the feedback law $u = \alpha_2(x)$ is also locally asymptotically stabilizing. These additional hypotheses may take different forms. For instance, as shown in [7] for the case of affine nonlinear systems, one may simply assume that the function $V(x)$ satisfies a strict inequality, i.e., that the left-hand side of (8) is negative for each $x \neq 0$. Or, one may assume that the plant (1) has a suitable "detectability" property. In what follows we describe this second choice.

Assumption A2 Any bounded trajectory $x(t)$ of the system

$$\dot{x}(t) = F(x(t), 0, u(t))$$

satisfying

$$Z(x(t), u(t)) = 0$$

for all $t > 0$, is such that $\lim_{t \rightarrow \infty} x(t) = 0$

Remark Note that this assumption is the nonlinear version of the hypothesis that the system with input u and output z (and $w = 0$) has no finite transmission zeros on the imaginary axis \square

In fact, we have the following result (whose proof, pretty similar to the proof of a corresponding result for affine systems given in [7], is omitted)

Proposition II 1 Consider the system (1) and suppose Assumptions A1 and A2 hold. Suppose there exists a smooth positive definite function $V(r)$, locally defined in a neighborhood of $r = 0$ and such that $V(0) = 0$, which satisfies the Hamilton-Jacobi-Isaacs inequality (8). Then, the feedback law $u = \alpha_2(x)$ solves the problem of local disturbance attenuation with internal stability.

Remark Recalling the interpretation of the problem as a two players, zero sum, differential game, the previous arguments show that if there exists a function $V(r)$ which renders $H_*(r, V_r^T(r)) = 0$, the strategy $u = \alpha_2(r)$ is the best strategy for the minimizing player and the strategy $w = \alpha_1(r)$ is the best strategy for the maximizing player. Since in the present setup, w is a disturbance, the latter can be interpreted as the worst possible disturbance affecting the system \square

III. DISTURBANCE ATTENUATION VIA MEASUREMENT FEEDBACK

A. Preliminaries

If the state x of the plant is not available for measurement then the feedback law proposed in the previous section cannot be directly implemented. Motivated by the results obtained in [7] for affine systems, we consider then a controller in which the feedback law $\alpha_2(x)$ is replaced by a law of the form $\alpha_2(\xi)$, where ξ is an "estimate" of x provided by an appropriate auxiliary dynamics. The latter consists of a copy of the dynamics of x corrected by a term proportional to the error which is induced by the estimation on the measured variable y , that is a system described by an equation of the form

$$\dot{\xi} = F(\xi, w, u) + G(\xi)(y - Y(\xi, w)) \quad (9)$$

where the matrix $G(\xi)$, which will be called the output injection gain, is a matrix to be determined.

Since w is not directly available either, we substitute its actual value by the worst possible one, which, as seen in the previous section, at each time t is a function of the value of the state of the plant at this time and has the expression

$w_*(t) = \alpha_1(x(t))$. Thus, in (9) we set $u = \alpha_2(\xi)$ and $w = \alpha_1(\xi)$. This yields a dynamic feedback law of the form

$$\begin{aligned} \dot{\xi} &= F(\xi, \alpha_1(\xi), \alpha_2(\xi)) + G(\xi)(y - Y(\xi, \alpha_1(\xi))) \\ u &= \alpha_2(\xi) \end{aligned} \quad (10)$$

For convenience, we represent the corresponding closed loop system as

$$\dot{x}' = F'(x', w), \quad z = Z'(x') \quad (11)$$

with x' and $F'(x', w)$, as shown at the bottom of the page and $Z'(x') = Z(x, \alpha_2(\xi))$

As before, we try to render this system locally dissipative with respect to the appropriate supply rate, i.e., we seek the existence of a smooth nonnegative function $U(x')$ such that

$$U_{x'} F'(x', w) + \|Z'(x')\|^2 - \gamma^2 \|w\|^2 \leq 0 \quad \text{for all } w \quad (12)$$

In addition, we want the closed-loop system to be locally asymptotically stable. In this respect, it is quite easy to show that if the above dissipation inequality holds and some appropriate conditions are satisfied the closed loop system (11) has an asymptotically stable equilibrium at $x' = 0$. In fact, the following result holds.

Lemma III 1 Consider system (11) and suppose the following

- i) Assumptions A1 and A2 hold
- ii) the system

$$\dot{\xi} = F(\xi, \alpha_1(\xi), 0) - G(\xi)Y(\xi, \alpha_1(\xi)) \quad (13)$$

has a locally asymptotically stable equilibrium at $\xi = 0$,

iii) there exists a smooth function $U(x')$, vanishing at $x' = 0$ and positive for $x' \neq 0$, which satisfies the inequality (12) for $w = 0$.

Then $F'(x', 0)$ has a locally asymptotically stable equilibrium at $x' = 0$.

Proof The positive definite function $U(x')$ satisfies

$$\frac{dU(x'(t))}{dt} \leq -\|Z(x', \alpha_2(\xi))\|^2 < 0$$

and this shows that the closed-loop system is stable at $x' = 0$. To prove asymptotic stability, consider any trajectory $x'(t)$ of $x' = F'(x', 0)$ yielding $U(x'(t)) = 0$ for all $t > 0$. Then the previous inequality implies that

$$Z(x(t), \alpha_2(\xi(t))) = 0 \quad \text{for all } t \geq 0$$

From Assumption A2, we conclude that $\lim_{t \rightarrow \infty} x(t) = 0$. Moreover, Assumption A1 implies that there is a unique smooth function $u = u(x)$, defined in a neighborhood of $x = 0$ such that

$$Z(x, u(x)) = 0 \quad \text{and} \quad u(0) = 0$$

Therefore, $\lim_{t \rightarrow \infty} \tau(t) = 0$ and $Z(x(t), \alpha_2(\xi(t))) = 0$ implies $\lim_{t \rightarrow \infty} \alpha_2(\xi(t)) = 0$

$$x' = \begin{pmatrix} x \\ \xi \end{pmatrix}, \quad F'(x', w) = \begin{pmatrix} F(x, w, \alpha_2(\xi)) \\ F(\xi, \alpha_1(\xi), \alpha_2(\xi)) + G(\xi)Y(x, w) - G(\xi)Y(\xi, \alpha_1(\xi)) \end{pmatrix}$$

This shows that the ω -limit set of the trajectory in question entirely contained into the set

$$\mathcal{M} = \{(r, \xi) \mid r = 0, \alpha_2(\xi) = 0\}$$

any initial condition in this set produces a trajectory in which $r(t) = 0$, while $\xi(t)$, which is necessarily a trajectory of (13), is such that $\lim_{t \rightarrow \infty} \xi(t) = 0$ by hypothesis. Thus, by LaSalle's invariance principle, we conclude that $r^* = 0$ is an asymptotically stable equilibrium of $F^e(r^*, 0)$. \square

In view of this results we see that if the gain matrix $G(\xi)$ is such that

a) the inequality (12) holds for some positive definite function $U^e(r^*)$, and

b) system (13) has a locally asymptotically stable equilibrium at $\xi = 0$, then the feedback law (10) solves the problem of disturbance attenuation (with local asymptotic stability). In the next two subsections, we discuss the problem of how to find a matrix $G(\xi)$ such that these two properties hold

B A Necessary Condition

To (partially) motivate the condition that, in the next subsection, will be used to find an expression of the output injection $G(\xi)$ in the feedback law (10), we first describe a necessary condition for the solution of the problem of disturbance attenuation via measurement feedback.

Consider the Hamiltonian function $K: \mathbb{R}^n \times \mathbb{R}^n \times \mathbb{R}^p \times \mathbb{R}^p \rightarrow \mathbb{R}$ defined as

$$K(r, p, w, y) + p^T F(r, u, 0) - y^T Y(r, u) + \|Z(r, 0)\|^2 - \gamma^2 \|w\|^2 \quad (14)$$

and suppose the plant (1) satisfies the following hypothesis

Assumption A3 The measurement map $Y(r, w)$ is such that the matrix

$$D_2 = \frac{\partial Y}{\partial w}(0, 0)$$

has rank p

Since

$$\left(\frac{\partial^2 K(r, p, w, y)}{\partial w^2} \right)_{(r, p, w, y) = (0, 0, 0, 0)} = -2\gamma^2 I$$

there exists a smooth function $w(r, p, y)$, defined in a neighborhood of $(0, 0, 0)$ such that

$$\left(\frac{\partial K(r, p, w, y)}{\partial w} \right)_{w=w(r, p, y)} = 0 \quad w(0, 0, 0) = 0$$

Moreover, it is also easy to check that

$$\left(\frac{\partial^2 K(r, p, w(r, p, y), y)}{\partial y^2} \right)_{(r, p, y) = (0, 0, 0)} = \frac{1}{2\gamma^2} D_2 D_2^T$$

thus, there exists a smooth function $y_*(r, p)$, defined in a neighborhood of $(0, 0)$ such that

$$\left(\frac{\partial K(r, p, \hat{w}(r, p, y), y)}{\partial y} \right)_{y=y_*(r, p)} = 0 \quad y_*(0, 0) = 0$$

By construction,

$$K(r, p, w, y) \leq K(r, p, w(r, p, y), y) \quad (15)$$

for all (r, p, w, y) in a neighborhood of $(0, 0, 0, 0)$ and

$$K(r, p, \hat{w}(r, p, y), y) \geq K(r, p, w(r, p, y_*(r, p)), y_*(r, p)) \quad (16)$$

for all (r, p, y) in a neighborhood of $(0, 0, 0)$

Finally, set

$$w_{**}(r, p) = w(r, p, y_*(r, p))$$

The functions $w_{**}(r, p)$ and $y_*(r, p)$ thus defined can be used to express a necessary condition for the existence of solutions to the problem of disturbance attenuation via measurement feedback

Theorem III.1 Consider system (1) and suppose Assumption A3 holds. Suppose the problem of local disturbance attenuation is solved by the feedback law

$$\xi = \eta(\xi, y) \quad u = \theta(\xi)$$

and let $U(r, \xi)$ be a positive definite smooth function satisfying

$$(U_\xi(r, \xi) - U_\xi(r, \xi)) \begin{pmatrix} F(r, w, \theta(\xi)) \\ \eta(\xi, Y(r, u)) \end{pmatrix} + \|Z(r, \theta(\xi))\|^2 - \gamma^2 \|w\|^2 < 0 \quad (17)$$

for all (r, ξ, w) in a neighborhood of $(0, 0, 0)$. Then the positive definite function $W(r) = U(r, 0)$ satisfies

$$K(r, W_r^T(r), w_{**}(r, W_r^{-1}(r)), y_*(r, W_r^{-1}(r))) < 0 \quad (18)$$

for each r in a neighborhood of zero

Proof Set $\xi = 0$ in (17) to obtain

$$W_r(r)I(r, w, 0) + U_\xi(r, 0)\eta(0, Y(r, u)) + \|Z(r, 0)\|^2 - \gamma^2 \|u\|^2 \leq 0$$

Since the function $\eta(0, y)$ vanishes at $y = 0$, there exists a vector of smooth functions $P(r, y)$ such that $U_\xi(r, 0)\eta(0, y) = P^T(r, y)y$ and therefore

$$W_r(r)I(r, w, 0) + P^T(r, Y(r, u))Y(r, w) + \|Z(r, 0)\|^2 - \gamma^2 \|u\|^2 \leq 0$$

Choosing $w = w(r, W_r^{-1}(r), y)$, the latter yields

$$K(r, W_r^T(r), w(r, W_r^{-1}(r), y), P(r, Y(r, w(r, W_r^{-1}(r), y)))) \leq 0$$

Now, let $y(r)$ denote the unique solution of

$$y(r) = P(r, Y(r, w(r, W_r^{-1}(r), y(r)))) \quad y(0) = 0$$

and set $y = y(r)$ into the previous inequality, to obtain

$$K(r, W_r^T(r), w(r, W_r^{-1}(r), y(r)), y(r)) \leq 0$$

At this point, (16) shows that $K(r, W_r^T(r), u(r, W_r^{-1}(r), y_*(r, W_r^{-1}(r)))) \leq 0$ and the result follows. \square

Remark In the case of a system in which $I(r, w, 0)$ and $Y(r, w)$ are affine in w , condition (18) reduces to the necessary condition $IAY^T I(r) \leq 0$ of [3]. We observe, however, that the latter was proven under the hypothesis that $\eta(\xi, y)$ is affine in y , while this hypothesis is not required in the proof of (18). On the other hand, (18) is only locally valid while the necessary condition of [3] is globally valid. \square

C. The Design of the Output Injection Gain

In this subsection we show that, under appropriate hypotheses, the feedback gain can be determined from the solution of an inequality involving the Hamiltonian function $K(x, p, w, y)$ introduced in the previous subsection. The inequality in question is somewhat stronger than the inequality (18), whose necessity was proven in the previous subsection, and has the following form

$$K(x, W_x^T(x), w_{**}(x, W_x^T(x)), y_*(x, W_x^T(x))) - H_*(x, V_x^T) < 0. \quad (19)$$

As a matter of fact, we can prove the following result.

Theorem III.2: Consider the system (1) and suppose:

- i) Assumptions A1, A2, and A3 hold,
- ii) inequality (8) has a smooth solution $V(x)$, defined in a neighborhood of $x = 0$, vanishing at $x = 0$ and positive for $x \neq 0$,
- iii) inequality (19) has a smooth solution $W(x)$, defined in a neighborhood of $x = 0$, vanishing at $x = 0$ and positive for $x \neq 0$,
- iv) $W(x) - V(x) > 0$ for all $x \neq 0$,
- v) the Hessian matrix of

$$K(x, W_x^T(x), w_{**}(x, W_x^T(x)), y_*(x, W_x^T(x))) - H_*(x, V_x^T)$$

is nonsingular at $x = 0$ and the equation

$$(W_x(x) - V_x(x))G(x) = y_*^T(x, W_x^T(x)) \quad (20)$$

has a smooth solution $G(x)$.

Then, the problem of local disturbance attenuation with internal stability is solved by the output feedback

$$\begin{aligned} \dot{\xi} &= F(\xi, \alpha_1(\xi), \alpha_2(\xi)) - G(\xi)Y(\xi, \alpha_1(\xi)) + G(\xi)y \\ u &= \alpha_2(\xi) \end{aligned}$$

with $\alpha_1(x)$, $\alpha_2(x)$, and $G(x)$ chosen as in (7) and (20).

Proof: Set $Q(x) = W(x) - V(x)$ and define

$$S(x, w) = Q_x[F(x, w, 0) - G(x)Y(x, w)] + H(x, V_x^T, w, 0) - H_*(x, V_x^T).$$

Then, it is easy to check that

$$\begin{aligned} S(x, w) &= W_x F(x, w, 0) - y_*^T(x, W_x^T)Y(x, w) \\ &\quad - V_x F(x, w, 0) + H(x, V_x^T, w, 0) \\ &\quad - H_*(x, V_x^T) \\ &= W_x F(x, w, 0) - y_*^T(x, W_x^T)Y(x, w) \\ &\quad + \|Z(x, 0)\|^2 - \gamma^2 \|w\|^2 - H_*(x, V_x^T) \\ &= K(x, W_x^T, w, y_*(x, W_x^T)) - H_*(x, V_x^T) \\ &\leq K(x, W_x^T, w_{**}(x, W_x^T), y_*(x, W_x^T)) \\ &\quad - H_*(x, V_x^T) \\ &= x^T M(x)x \end{aligned}$$

where $M(x)$ is a matrix of smooth functions, which is negative definite at $x = 0$.

Now set $U(x^e) = Q(x - \xi) + V(x)$. It can be proven that the function thus defined is such that the two conditions a) and

b) indicated at the end of Section III-A hold, if $G(x)$ is chosen as in (20). As far as condition a) is concerned, observe that

$$\begin{aligned} U_{x^e} F(x^e, w) &+ \|Z^e(x^e)\|^2 - \gamma^2 \|w\|^2 \\ &= Q_x(x - \xi)[F(x, w, \alpha_2(\xi)) - F(\xi, \alpha_1(\xi), \alpha_2(\xi)) \\ &\quad - G(\xi)Y(x, w) + G(\xi)Y(\xi, \alpha_1(\xi))] \\ &\quad + V_x F(x, w, \alpha_2(\xi)) + \|Z(x, \alpha_2(\xi))\|^2 - \gamma^2 \|w\|^2 \\ &\leq Q_x(x - \xi)[F(x, w, \alpha_2(\xi)) - F(\xi, \alpha_1(\xi), \alpha_2(\xi)) \\ &\quad - G(\xi)Y(x, w) + G(\xi)Y(\xi, \alpha_1(\xi))] \\ &\quad + H(x, V_x^T, w, \alpha_2(\xi)) - H_*(x, V_x^T). \end{aligned}$$

Let $L(x, \xi, w)$ denote the expression on the right-hand side of this inequality. It is easy to see that, in a neighborhood of $(x, \xi) = (0, 0, 0)$, there exists a (unique) function $\tilde{w}(x, \xi)$ such that

$$\left(\frac{\partial L(x, \xi, w)}{\partial w} \right)_{w=\tilde{w}(x, \xi)} = 0, \quad \tilde{w}(0, 0) = 0$$

and

$$L(x, \xi, w) \leq L(x, \xi, \tilde{w}(x, \xi))$$

for all (x, ξ, w) in a neighborhood of $(0, 0, 0)$. Thus, in this neighborhood,

$$U_{x^e} F(x^e, w) + \|Z^e(x^e)\|^2 - \gamma^2 \|w\|^2 \leq L(x, \xi, \tilde{w}(x, \xi)).$$

Moreover, it is also possible to show, by means of somewhat lengthy calculations (omitted for reasons of space), that

$$L(x, \xi, \tilde{w}(x, \xi)) = (x - \xi)^T R(x, \xi)(x - \xi) \quad (21)$$

where $R(x, \xi)$, a matrix of smooth functions, is such that $R(0, 0) = M(0)$. Thus $R(x, \xi)$ is negative definite in a neighborhood of $(0, 0)$ and the result [namely, property a)] follows.

To prove that condition b) holds, it suffices to set $w = \alpha_1(x)$ in the definition of $S(x, w)$, to conclude that

$$0 > S(x, \alpha_1(x)) \geq Q_x(F(x, \alpha_1(x), 0) - G(x)Y(x, \alpha_1(x)))$$

thus showing that $Q(x)$ is a Lyapunov function for (13). \square

Remark: The output injection gain $G(x)$ is implicitly defined by means of (20). Obviously, the existence of a smooth solution $G(x)$ of this equation depends on how $W_x(x) - V_x(x)$ and $y_*(x, W_x^T(x))$, which both vanish at $x = 0$, tend to zero as $x \rightarrow 0$. If, for instance, the function $W(x) - V(x)$ has a Hessian matrix which is nonsingular at $x = 0$, then a smooth solution of (20) always exists. In this case, in fact

$$W_x(x) - V_x(x) = x^T R_1(x)$$

where $R_1(x)$ is a matrix which is nonsingular for each x in a neighborhood of $x = 0$. The right-hand side of (20) can be given a similar expression, say

$$y_*^T(x, W_x^T(x)) = x^T L(x)$$

and the equation in question is indeed solved by $G(x) = R_1^{-1}(x)L(x)$. \square

Remark: It may be useful to stress that the proof of Theorem III.2, as far as property a) is concerned, does not just consist of straightforward "second-order" arguments. It

in this respect, the result cannot be viewed as direct consequence of the corresponding result which is known to hold for linear systems. As a matter of fact, the maximum of $\|F(x^e, w) + \|Z^e(x^e)\|^2 - \gamma^2 \|w\|^2$ in w [that is, the function $L(x, \xi, \tilde{w}(x, \xi))$] is a function of (x, ξ) whose second-order terms vanish at $x = \xi$. In other words, the maximum in w of the left-hand side of (12) has a "second-order" approximation which is only semidefinite, and this does not suffice to conclude that (12) holds. The required conclusion is reached only after a stronger relation like (21) is shown, which clearly is not just a property of second-order terms. \square

IV. AN EXAMPLE

In the previous sections, we have shown how to construct a feedback law which solves the problem of disturbance attenuation, using the solutions $V(x)$ and $W(x)$ of the pair of Hamilton–Jacobi–Isaacs inequalities (8)–(19). In this section we illustrate, with the help of an example, how the problem of determining actual solutions of these inequalities can be addressed. The first thing to observe, in this respect, is that—except for some special classes of systems (like, for instance, the systems in which $F(x, w, u)$, $H(x, u)$ and $Y(x, w)$ are affine in w and u)—the inequalities in question are only implicitly defined [because so are the functions $w_*(x)$, $u_*(x)$, $w_{**}(x)$, $y_*(x)$ which characterize the left-hand sides of (8)–(19)]. Thus, the only feasible practical way to implement the results established so far is to try to estimate the solutions of these inequalities by means of appropriate numerical methods.

To this end, we recall that the problem of determining polynomial approximations (of some prescribed degree) for the solution of a Hamilton–Jacobi equation has been addressed and solved by Albrecht in [1] and Lukes in [9]. The results described in these papers were developed for the specific case of the Hamilton–Jacobi equation arising in nonlinear optimal control, but indeed hold (as, e.g., observed in [11]) also in the more general case of the Hamilton–Jacobi–Isaacs equation of a nonlinear differential game, thus also for the inequalities (8) and (19).

The approach in question can be briefly described as follows. Suppose one is interested in the determination of a positive definite function $V: \mathbb{R}^n \rightarrow \mathbb{R}$, defined in a neighborhood of $x = 0$ and vanishing at $x = 0$, such that

$$H(x, V_x^T(x), w_*(x, V_x^T(x)), u_*(x, V_x^T(x))) = \phi(x) \quad (22)$$

for some negative semidefinite or negative definite analytic function $\phi(x)$. Suppose $V(x)$ is analytic and set

$$\begin{aligned} V(x) &= \sum_{d=1}^{\infty} V^{[d+1]}(x) \\ w_*(x) &= w_*(x, V_x^T(x)) = \sum_{d=1}^{\infty} w_*^{[d]}(x) \\ u_*(x) &= u_*(x, V_x^T(x)) = \sum_{d=1}^{\infty} u_*^{[d]}(x) \\ \phi(x) &= \sum_{d=3}^{\infty} \phi^{[d]}(x) \end{aligned}$$

in which the superscript "[d]" means that a function or the components of a vector are homogeneous polynomials of degree d .

Following [1] and [9], it is possible to show that, for any $d > 1$, $V^{[d+1]}(x)$ and $w_*^{[d]}(x)$, $u_*^{[d]}(x)$ depend only on $V^{[2]}(x)$, $w_*^{[1]}(x)$, $u_*^{[1]}(x)$, \dots , $V^{[d]}(x)$, $w_*^{[d-1]}(x)$, $u_*^{[d-1]}(x)$. The function $V^{[2]}(x)$ is determined by a Riccati equation, involving the parameters which characterize the linear approximation of the plant at the equilibrium $(x, u, w) = (0, 0, 0)$, while $V^{[d+1]}(x)$, for $d > 1$, is determined by a linear equation (called homological equation) which involves the parameters of $V^{[2]}(x)$, $w_*^{[1]}(x)$, $u_*^{[1]}(x)$, \dots , $V^{[d]}(x)$, $w_*^{[d-1]}(x)$, $u_*^{[d-1]}(x)$ (see [9], [11], and [8] for more details).

Thus, it is not difficult to setup up a recursive procedure yielding, after d stages, a polynomial approximation of order $d+1$ for $V(x)$ and a polynomial approximation of order d for $u_*(x)$. Note also that the function $\phi(x)$ on the right-hand side of (22) is quite an arbitrary function (the only requirement being its sign-definiteness) and, thus, the extra degrees of freedom associated with the choice of this function can be exploited to the purpose of simplifying the entire solution process.

In the following (elementary) example we show how the solution of a Hamilton–Jacobi inequality can be achieved via polynomial approximations. This example may also help, in our opinion, to dissipate the impression that the analysis of the problem of "local" disturbance attenuation with internal stability relies solely on "first order" arguments. Consider the system

$$\begin{pmatrix} \dot{x} \\ \dot{y} \end{pmatrix} = \begin{pmatrix} xy \\ x^2 + w + u \end{pmatrix}, \quad z = \begin{pmatrix} y - x^2 \\ u \end{pmatrix}.$$

It is easily seen (by means of simple arguments which are omitted for reasons of space) that for any linear feedback law $u = ax + by$, the equilibrium point $(x, y) = (0, 0)$ of the corresponding closed-loop system (with $w = 0$) is unstable. Thus, in particular, the problem of local disturbance attenuation with internal stability cannot be solved by means of a linear state feedback law. The problem in question, however, can be solved by means of a nonlinear state feedback, as shown hereafter.

The Hamilton–Jacobi inequality (8) assumes in this case the form

$$V_x xy + V_y x^2 + y^2 - 2x^2 y + x^4 + \frac{1}{4} \lambda V_y^2 \leq 0 \quad (23)$$

where $\lambda = (1/\gamma^2) - 1$.

Set

$$V(x, y) = V^{[2]}(x, y) + V^{[3]}(x, y)$$

with

$$\begin{aligned} V^{[2]}(x, y) &= ax^2 + by^2 \\ V^{[3]}(x, y) &= cx^2 y + dx y^2 + ex^3 + fy^3. \end{aligned}$$

In the notation introduced before, we obtain on the left-hand side of the Hamilton–Jacobi inequality (23) a function of (x, y) of the form

$$\phi(x, y) = \Phi^{[2]}(x, y) + \Phi^{[3]}(x, y) +$$

in which

$$\Phi^{[2]}(x, y) = (1 + b^2\lambda)y^2$$

$$\Phi^{[3]}(x, y) = (2a + 2b - 2 + \lambda bc)x^2y + 2\lambda bdx y^2 + 3\lambda bfy^3$$

Since $\phi(x, y)$ is required to be sign-definite, we impose $\Phi^{[3]}(x, y) = 0$, i.e., we impose the following constraints on the parameters which characterize $V(x, y)$

$$a = 1 - b - \frac{\lambda}{2}bc, \quad d = f = 0$$

Moreover, to obtain simpler expressions, we set $c = 0$. As a result, we obtain

$$V(x) = ax^2 + by^2 + cx^2y$$

$$\phi(x, y) = (1 + b^2\lambda)y^2 + \left(\frac{\lambda}{4}c^2 + c + 1\right)x^4 + 2cx^2y^2$$

The function $V(x, y)$ is positive definite, and the function $\phi(x, y)$ is negative definite, in a neighborhood of the origin, if the following constraints hold

$$a > 0, \quad b > 0, \quad 1 + b^2\lambda < 0, \quad \left(\frac{\lambda}{4}c^2 + c + 1\right) < 0$$

For any $\lambda < 0$, i.e., for any $\gamma > 1$, these conditions can indeed be satisfied by suitable (sufficiently large) choices of $b > 0$ and $c > 0$. The positive definite function $V(x, y)$ thus found satisfies the strict version Hamilton–Jacobi–Isaacs inequality (8). Thus, according to the results described before, the corresponding feedback law

$$u = \alpha(x) = -\frac{1}{2}V_y = -by - \frac{c}{2}x^2$$

locally asymptotically stabilizes the equilibrium of the corresponding closed-loop system and renders its L_2 gain less than or equal to γ .

Perturbation Bounds for Root-Clustering of Linear Systems in a Specified Second Order Subregion

W. Bakker, J. S. Luo, and A. Johnson

Abstract—Sufficient bounds for structured and unstructured uncertainties for root-clustering in a specified second order subregion of the complex plane, for both continuous-time and discrete-time systems, are given using the Generalized Lyapunov Theory. Furthermore, for unstructured uncertainties, a still less conservative result is obtained by shifting the center or focus of the subregion along the real axis to the origin and by applying root-clustering to the “shifted eigenvalue” system matrix, which is obtained by shifting the eigenvalues of the system matrix correspondingly.

I. INTRODUCTION

We study the problem of how to guarantee the location of the eigenvalues of a perturbed system matrix in a specified (symmetric) second-order subregion of the complex plane. The perturbation may be structured or unstructured. The subregions discussed are, in the continuous-time case, subregions of the left-half complex plane (LHP) and in the discrete-time case subregions of the unit disk (UD) centered at the origin. Recently, Abdul-Wahab [1] and [2] discussed second-order subregions for discrete-time and continuous time systems, but the results have turned out to be erroneous. The errors have been pointed out by Yedavalli [3] for the continuous-time case and by Bakker and Luo [4] for the discrete-time case. More recently, Yedavalli [5] obtained results for first and second-order subregions using Generalized Lyapunov Theory presented by Gutman and Jury [6].

Conservatism of the paper of Yedavalli [5] is reduced in several ways. First, the norms used to compute the bound are taken at a later stage compared to the bounds of Yedavalli. Next, an important result is, for unstructured uncertainties, that the bound can be improved for subregions with center or focus at $(\alpha, 0)$. This improved bound is obtained by shifting the center or focus of the subregion along the real axis to the origin and computing the bound for the “shifted eigenvalue” matrix. Generally, a large α yields a large improvement. Finally, from Luo *et al.* [7] we are motivated to use the square root of positive definite matrix $Q (= S^T S)$ in the Lyapunov equations; the result can be improved by choosing the S -matrix appropriately. Using a personal computer, the optimal S -matrix can be found by an optimization program in Matlab (e.g., `fminu.m` [9]).

This paper is organized as follows. In Section II the robust stability analysis for state-space models of continuous- and discrete-time systems using the Generalized Lyapunov Theory [6] is described. In Section III we introduce bounds for both continuous and discrete-time systems with unstructured uncertainties. A motivation for “shifting”

is given, followed by the “shifting theorem.” In Section IV, bounds for structured uncertainties are given. For both cases, the bounds can be improved by optimization programs. In Section V, the results are illustrated with examples, followed by two general remarks. We end the paper with conclusions in Section VI.

II. GENERALIZED LYAPUNOV ROOT-CLUSTERING THEORY

Let the perturbed continuous-time system be represented by

$$\dot{\mathbf{x}}(t) = (A + E)\mathbf{x}(t) \quad (2.1a)$$

and let the perturbed discrete-time system be represented by

$$\mathbf{x}(k+1) = (A + E)\mathbf{x}(k) \quad (2.1b)$$

where the state vector is $\mathbf{x}(t)$ or $\mathbf{x}(k) \in \mathbb{R}^n$, the time-invariant system matrix $A \in \mathbb{R}^{n \times n}$ and the perturbation matrix $E \in \mathbb{R}^{n \times n}$. If the structure of the perturbation is known, the substitution

$$E = \sum_{i=1}^m \epsilon_i E_i \quad (2.2)$$

is made. Here ϵ_i ($i = 1, 2, \dots, m$) are time-invariant uncertain parameters which are assumed to lie in the interval around zero ($\epsilon_i \in [-\epsilon, \epsilon]$ where $\epsilon > 0$) and E_i ($i = 1, 2, \dots, m$) are constant matrices determined by the structure of the parameter uncertainties.

Any symmetric second order subregion in the complex plane ($(s$ or $z) = x + iy$) is described by (x, y) satisfying the inequality [6]

$$\Omega_2 = \{(x, y): \gamma_{00} + \gamma_{10}x + \gamma_{20}x^2 + \gamma_{02}y^2 < 0\} \quad (2.3)$$

where γ_{ij} is a real coefficient (note the difference with the boldfaced state vector \mathbf{x} and the real coordinate x). It is clear that this region is symmetrical with respect to the x axis. This inequality describes for example circles, ellipses, left parabolas, etc. Let us now define, as in [6]

$$\begin{aligned} c_{00} &= \gamma_{00}, & c_{10} &= c_{01} = \frac{1}{2}\gamma_{10}, & c_{11} &= \frac{1}{2}(\gamma_{20} + \gamma_{02}), \\ c_{20} &= c_{02} = \frac{1}{4}(\gamma_{20} - \gamma_{02}) \end{aligned} \quad (2.4)$$

so we can present the Lyapunov criterion for root-clustering in a specified second-order subregion Ω_2 [6]: Let $\gamma_{20} + \gamma_{02} \geq 0$ in (2.3) and let the coefficients c_{pq} be given by (2.4). If and only if for a given positive definite Hermitian matrix Q the following generalized Lyapunov equation (GLE)

$$c_{00}P + c_{10}(A^T P + PA) + c_{11}A^T P A + c_{20}((A^T)^2 P + PA^2) = -Q \quad (2.5)$$

has a positive definite solution P , then all the eigenvalues of the nonperturbed system [$E = 0$ in (2.1)] are located inside the defined subregion (2.3). Equation (2.5) can be solved using the Kronecker product; for a detailed description, see [6].

III. PERTURBATION BOUNDS FOR UNSTRUCTURED UNCERTAINTIES

In this section new stability robustness bounds for systems with unstructured uncertainties based on the Generalized Lyapunov Root-Clustering Theory presented in Section II are given. It is shown that "shifting," for a large class of subregions, yields improved bounds. These results are organized in the "shifting theorem."

In the next theorem we give less conservative bounds on the norm of the perturbation matrix E so that the eigenvalues are located in the specified subregion. There is no knowledge assumed about the structure of the perturbation.

Theorem 3.1: Suppose

- 1) The perturbed system is described by (2.1).
- 2) The eigenvalues of the nonperturbed system matrix A are located inside a subregion Ω_2 defined by (2.3).
- 3) S^T and S are full rank (invertible) matrices satisfying $Q = S^T S$.
- 4) P is a symmetric positive definite matrix defined by (2.5).

Then the perturbed system matrix $A + E$ has all the eigenvalues located in the subregion Ω_2 described by (2.3), if

$$\|E\| < \mu = \frac{b}{2a} \left(-1 + \sqrt{1 + \frac{4a}{b^2}} \right) \quad (3.1)$$

with

$$a \equiv |c_{11}| \|P\| \|S^{-1}\|^2 + 2|c_{20}| \|S^{-1}\| \|PS^{-1}\| \quad (3.1a)$$

$$\begin{aligned} b \equiv & 2|c_{10}| \|S^{-1}\| \|PS^{-1}\| + 2|c_{11}| \|S^{-1}\| \|PAS^{-1}\| \\ & + 2|c_{20}| \|S^{-1} A^T\| \|PS^{-1}\| \\ & + 2|c_{20}| \|S^{-1}\| \|A^T P S^{-1}\| \end{aligned} \quad (3.1b)$$

and where $\|A\|$ = the spectral norm of the matrix A (the largest singular value of A).

Proof: See Appendix.

Remark 3.1: For first-order subregions, $c_{11} = c_{20} = 0$ (2.3) and (2.4). In that case the upper bound (3.1) is obtained from (A.2) with $\alpha = 0$ to be $\mu = 1/b$.

Shifting of Subregions

The bound μ depends on the matrices A , P , and S and on the coefficients that describe the subregion. Consider the role of the system matrix in the bound (summarized in Fact 1). Of interest are subregions of the form

$$\Omega_2 = \{(x, y): ((x - \alpha)/v)^f + (y/w)^g - u < 0\} \quad (3.2)$$

where $(\alpha, v, w, u) \in \mathbf{R}$ and $v > 0$, $u > 0$; $f = 1, 2$, and $g = 0, 2$. Examples are a circle, a left-parabola, an ellipse, a vertical strip, etc. The eigenvalues of system matrix A have to be located in this subregion. Next, for convenience, restrict the subregion to be a circular subregion of the LHP, with center $(\alpha, 0)$ and radius 1 satisfying $\alpha < -1$, $f = 2 = g$, $u = 1 = v = w$ in (3.2) (for other subregions similar arguments hold). Then the eigenvalues of the matrix A have to be located within a distance 1 from $(\alpha, 0)$ and therefore satisfy

$$(\alpha - 1) < \operatorname{Re}(\lambda(A)) < (\alpha + 1).$$

Because $\alpha < -1 \Leftrightarrow \alpha + 1 < 0$, taking norms

$$|\operatorname{Re}(\lambda(A))| > |\alpha + 1|.$$

From [20]

$$\begin{aligned} \|A\| &\geq |\lambda(A)| = (\operatorname{Re}(\lambda(A))^2 + \operatorname{Im}(\lambda(A))^2)^{1/2} \\ &\geq |\operatorname{Re}(\lambda(A))| > |\alpha + 1|. \end{aligned} \quad (3.3)$$

Fact 1: The coefficients c_{11} and c_{20} and the solution for P (2.5) (see Remark 3.2), used in the bound (3.1a), are not affected by shifting.

Fact 2: From (3.3), $\|A\| > |\alpha + 1|$. This implies, with Fact 1, that when $S = I$ at least the third term in (3.1b) is multiplied by a factor larger than $|\alpha + 1|$. Thus when α is small ($\alpha \ll -1$), $|\alpha + 1|$ is large and consequently that $\|A\|$ is large. So a large α causes a large b . For subregions as a left-parabola or a vertical strip, with center or focus at $(\alpha, 0)$, similar inequalities hold.

Fact 3: The value of a is unaffected by shifting (follows from Fact 1).

Fact 4: When b becomes large (a unaffected) then the bound becomes small (i.e., very conservative). This is even more obvious when, with $b \gg a$, a Taylor series expansion is used for the square root in (3.1): $\mu \approx 1/b$.

We have shown that the bound is conservative when subregions with center or focus at $(\alpha, 0)$, α sufficiently large, are considered. In the next theorem, it is shown that it is possible to shift the subregions (3.2) from $(\alpha, 0)$ to $(0, 0)$ and to compute the bound for the "shifted eigenvalue" system matrix with Theorem 3.1. With the facts are given above, the improvement of the bound should be clear.

Theorem 3.2 "Shifting Theorem": Root-clustering in a subregion Ω_2 (3.2) of the complex plane for a system matrix A is equivalent to root-clustering in a shifted subregion $\hat{\Omega}_2$ (3.4) of the complex plane for a "shifted eigenvalue" system matrix \hat{A} , where

$$\hat{\Omega}_2 = \{(\hat{x}, \hat{y}): (\hat{x}/v)^f + (\hat{y}/w)^g - u < 0\} \quad (3.4a)$$

$$\hat{x} = x - \alpha \quad (3.4b)$$

$$\hat{A} = A - \alpha I. \quad (3.4c)$$

Proof. Using (3.4c)

$$\lambda(A + E) = \lambda(A + \alpha I + E) = \lambda(\hat{A} + E) + \alpha$$

and for the real coordinate of the subregion, with (3.4b)

$$\hat{x} = x - \alpha.$$

Thus, the bound on the perturbation E can be computed for the shifted subregion and "shifted eigenvalue" system matrix, being valid for the original subregion and system matrix.

Remark 3.2: Theorem 3.2 can also be proved using the General Lyapunov Equation; that is, when (3.4c) is substituted in the GLE of the shifted subregion (with coefficients (2.4) for this shifted subregion) after some standard manipulations it can be shown that for subregions that can be shifted the solution P of the GLE of the shifted subregion equals the solution P of the GLE of the original subregion.

Remark 3.3: For convenience and motivated by fact that the coefficient c_{10} becomes zero in the bound (see (3.1b) and Fact 4) the subregion is shifted along the real axis to the origin. For some very specific cases, the best bound is not obtained by shifting exactly to the origin. In that case, one can find the "optimal shift" along the real axis which yields the best bound.

Remark 3.4: The result (3.1) is a function of S . In [7] it is shown that for similar cases an optimization (maximization) of $\mu(a(S), b(S))$ reduces conservatism. This can be done with the program fminu.m in Matlab [9]. The power of this method will be illustrated with examples in Section V.

Table I shows the results of this section for some second order subregions. When the regions satisfy (3.2), the parameters holding for the shifted subregions are presented.

TABLE 1

RESULTS FOR DIFFERENT SUBREGIONS. c_{pq} IS FOUND WITH (2.4) AND (2.3). THE EIGENVALUES ARE LOCATED IN THE SUBREGION Ω_1 (2.3) OR Ω_2 (2.4) IN THEOREM 3.1 WITH a AND b AS BELOW IS SATISFIED. THE EQUATIONS AFTER THE '~' ARE OBTAINED FROM THE SHIFTED SUBREGION (THEOREM 3.2)

IV. PERTURBATION BOUNDS FOR STRUCTURED UNCERTAINTIES

For structured uncertainties it is possible to obtain less conservative results. In the next theorem we obtain a perturbation bound for this case.

Theorem 4.1 The same assumptions as in Theorem 3.1 (1)-(4) are made. The system is given by (2.1) with the perturbation as in (2.2). The eigenvalues of the perturbed system are located in the described subregion (2.3) if

$$|\epsilon| < \mu = \frac{b}{2a} \left(-1 + \sqrt{1 + \frac{4a}{b}} \right) \quad (4.1)$$

where

$$a \equiv \left\| \sum_{i,j} \sum_i |P_{ij}^*| \right\|, \quad b \equiv \left\| \sum_{i=1}^n |P_i^*| \right\|$$

$$P_{ij}^* \equiv S^{-1} P_j S^{-1}, \quad P_i^* \equiv S^{-1} P S^{-1}$$

$$I \equiv c_{11}(F_i^T P E_i + F_j^T P E_i) + c_{20}((F_i E_j)^T P + P E_i E_j + (F_j F_i)^T P + P F_j F_i)$$

$$\equiv c_{10}(E^T P + P E) + c_{11}(F_i^T P A + A^T P F_i) + c_{20}((E_i A)^T P + P E_i A + (A F_i)^T P + P A F_i)$$

where $|A| = \{|a_{ij}|\}$, with $A = \{a_{ij}\}$ a $n \times n$ matrix.

Proof. See Appendix.

Remark 4.1 For first order subregions, (4.1) becomes $\mu = 1/b$ (Remark 3.1).

Remark 4.2 Optimization of $\mu(a(S), b(S))$ in (4.1) reduces conservatism (see Remark 3.4).

Similar to Section III, it is possible to work out this general result for different subregions. This is done in Table II.

V. EXAMPLES FOR DIFFERENT SECOND ORDER SUBREGIONS

Root Clustering in a Circle with Unstructured Uncertainties

The result will now be illustrated with an example. We take the same plant matrix as Yedavalli [5]

$$A = \begin{bmatrix} -4 & 3 & -0.1 \\ 0 & 2 & -3.1 \end{bmatrix} \quad (5.1)$$

with eigenvalues $\lambda_1 = -1.2$, $\lambda_2 = -3.5$. The circular subregion is defined with $\alpha = -1$, $\beta = 1$, $\gamma = 1$, $\delta = 2$ in (3.2). First, taking $Q = S = I$, (3.1) gives the upper perturbation bound

$$\mu_{S=I} = 0.0370$$

where the result in [5] is $\mu_{S=I} = 0.0341$. This is an improvement of 8.5%.

Secondly, we shift the center of circle to the origin (Theorem 3.2) and apply our root clustering Theorem 3.1 for the system matrix A in the subregion Ω_2 (3.4a). This gives

$$A = \begin{bmatrix} -0.3 & -0.1 \\ 0.2 & 0.6 \end{bmatrix}$$

with eigenvalues $\lambda_1(A) = -0.2$, $\lambda_2(A) = 0.5$. The upper bound on $\|E\|$ becomes

$$\mu_{S=I} = 0.3782$$

Comparing the result $\mu_{S=I}$ to $\mu_{S=I}$ [5] we see that the bound is improved by 1009%.

Thirdly, for the shifted subregion Ω_2 and the "shifted eigenvalue" matrix A , optimizing S gives the solutions with (2.5)

$$S = \begin{bmatrix} 0.9013 & 0.0723 \\ 0.0760 & 0.8494 \end{bmatrix}, \quad P = \begin{bmatrix} 0.9098 & 0.2981 \\ 0.2981 & 1.1395 \end{bmatrix}$$

With (3.1) this gives

$$\mu_{S=S_{opt}} = 0.3865$$

Comparing $\mu_{S=S_{opt}}$ and $\mu_{S=I}$ an improvement of 2.2% is achieved.

TABLE II
RESULTS FOR DIFFERENT SUBREGIONS: c_{pq} IS FOUND WITH (2.4) AND (2.3). THE EIGENVALUES ARE LOCATED IN THE SUBREGION Ω_2 IF THE CONDITIONS IN THEOREM 4.1 WITH P_i AND P_i AS BELOW ARE SATISFIED

Subregion	$\Omega_2 = (x, y)$:	c_{00}	c_{10}	c_{11}	c_{20}	P_0	P_1
circle	$(x-\alpha)^2 + y^2 - r^2 < 0$	$\alpha^2 - r^2$	$-\alpha$	1	0	$E_1^T P E_1 + E_1^T P E_1$	$-\alpha(E_1^T P + P E_1) + (E_1^T P A + A^T P E_1)$
parabola	$-4\alpha x + 4px + y^2 < 0$	$-4p\alpha$	$2p$	$\frac{1}{2}$	$-\frac{1}{4}$	$\frac{1}{2}(E_1^T P E_1 + E_1^T P E_1)$ $-\frac{1}{4}(E_1^T E_1^T P + P E_1 E_1 + E_1^T E_1^T P + P E_1 E_1)$	$2p(E_1^T P + P E_1) + \frac{1}{2}(E_1^T P A + A^T P E_1)$ $-\frac{1}{4}(A^T E_1^T P + P E_1 A + E_1^T A^T P + P A E_1)$
ellipse	$((x-\alpha)/v)^2 + (y/w)^2 - 1 < 0$	$(\alpha/v)^2 - 1$	$-\alpha v^{-2}$	$\frac{1}{2}(v^2 + w^2)$	$\frac{1}{4}(v^2 - w^2)$	$\frac{1}{2}(v^2 + w^2)(E_1^T P E_1 + E_1^T P E_1)$ $+\frac{1}{4}(v^2 - w^2)(E_1^T E_1^T P + P E_1 E_1 + E_1^T E_1^T P + P E_1 E_1)$	$-\alpha v^{-2}(E_1^T P + P E_1) + \frac{1}{2}(v^2 + w^2)(E_1^T P A + A^T P E_1)$ $+\frac{1}{4}(v^2 - w^2)(A^T E_1^T P + P E_1 A + E_1^T A^T P + P A E_1)$
Vertical strip	$(x-\alpha)^2 - \beta^2 < 0$	$\alpha^2 - \beta^2$	$-\alpha$	$\frac{1}{2}$	$\frac{1}{4}$	$\frac{1}{2}(E_1^T P E_1 + E_1^T P E_1)$ $+\frac{1}{4}(E_1^T E_1^T P + P E_1 E_1 + E_1^T E_1^T P + P E_1 E_1)$	$-\alpha(E_1^T P + P E_1) + \frac{1}{2}(E_1^T P A + A^T P E_1)$ $+\frac{1}{4}(A^T E_1^T P + P E_1 A + E_1^T A^T P + P A E_1)$
Ride quality [6]	1. $\rho_1^2 < x^2 + y^2$ 2. $x^2 + y^2 < \rho_2^2$ 3. $-w^2 + y^2 < 0$	ρ_1^2 $-\rho_2^2$ $-w^2$	0 0 0	-1 1 $\frac{1}{2}$	0 0 $-\frac{1}{4}$	$-(E_1^T P E_1 + E_1^T P E_1)$ $E_1^T P E_1 + E_1^T P E_1$ $\frac{1}{2}(E_1^T P E_1 + E_1^T P E_1)$ $-\frac{1}{4}(E_1^T E_1^T P + P E_1 E_1 + E_1^T E_1^T P + P E_1 E_1)$	$-(E_1^T P A + A^T P E_1)$ $E_1^T P A + A^T P E_1$ $\frac{1}{2}(E_1^T P A + A^T P E_1)$ $-\frac{1}{4}(A^T E_1^T P + P E_1 A + E_1^T A^T P + P A E_1)$

Root-Clustering in an Ellipse with Structured Uncertainties

Consider the system and perturbation matrices

$$A = \begin{bmatrix} -0.1 & 0.6 \\ -0.4 & 1 \end{bmatrix}, \quad E_1 = \begin{bmatrix} 1 & 0 \\ 1 & 0 \end{bmatrix}, \quad E_2 = \begin{bmatrix} 0 & 1 \\ 0 & 1 \end{bmatrix}.$$

With $\lambda_1(A) = 0.2$, $\lambda_2(A) = 0.7$. Taking the ellipsoidal subregion with $\alpha = 0.4$, $v = 0.5$, $w = 0.4$, then the eigenvalues λ_1 and λ_2 are located in this subregion. The bound on ϵ_1 and ϵ_2 , μ , can be computed directly with $Q = S = I$ ((4.1) and Table I)

$$\mu_{\epsilon, S=I} = 0.0395.$$

Using the method proposed in [5], taking $Q = I$, we obtain the perturbation bound

$$\mu_{\epsilon, yrd} = 0.0072.$$

Comparing the bounds $\mu_{\epsilon, S=I}$ with $\mu_{\epsilon, yrd}$ we see that our bound gives an improvement of 449%. A still less conservative result can be obtained by optimizing. The optimal S matrix and the solution for P (2.5) become

$$S = \begin{bmatrix} 0.9144 & -0.4853 \\ -0.8012 & 1.0582 \end{bmatrix}, \quad P = \begin{bmatrix} 1.8312 & -1.6732 \\ -1.6732 & 1.8692 \end{bmatrix}.$$

The error bound then becomes

$$\mu_{\epsilon, S=S_{opt}} = 0.1098.$$

Comparing the bounds $\mu_{\epsilon, S=S_{opt}}$ with $\mu_{\epsilon, S=I}$ we see that optimization gives an improvement of 178%. Optimizing the Q matrix and using the method of Yedavalli, the same bound as $\mu_{\epsilon, yrd}$ is obtained.

The results of this example are illustrated in Fig. 1, where the location of the roots in the ellipsoidal subregion of the unit disk, with the maximum perturbation ($\lambda(A \pm \mu(E_1 + E_2))$), are shown.

Regarding this plot, it is important to note that the roots marked with a "x" are, in general, not the outermost points of a root locus determined by varying ϵ from $-\mu$ to μ in $\lambda(A \pm \epsilon(E_1 + E_2))$.

General Remarks

Remark 5.1: In remarks 3.4 and 4.1, comment is given about the optimal S matrix. This S matrix can be obtained with use of

Fig. 1. Root-clustering in the ellipsoidal subregion of the unit disk. The roots of the nonperturbed system are denoted by "o", the roots of the system with the maximum perturbation bound $\mu_{\epsilon, S=I}$ are denoted by "+" and the roots with the bound $\mu_{\epsilon, S=S_{opt}}$ are denoted by "x."

MATLABTM programs for the optimization toolbox [9]. Furthermore, note that the optimal S matrix is not unique. For example, when $\hat{S} = \alpha S$ is substituted, the solution of \hat{P} with (2.5) becomes (where $\hat{Q} = \alpha^2 Q = \alpha^2 S^T S$) $\hat{P} = \alpha^2 P$. Clearly, the bound [(3.1) or (4.1)] obtained for P and S equals the bound obtained for \hat{P} and \hat{S} .

Remark 5.2: It is important to note that the bounds derived are valid for *time-invariant* uncertainties. In the theorems given, however, only the location of the eigenvalues is guaranteed to remain in a specified subregion; this is true for each value of the uncertainty that satisfies the bound. So, when the bound is satisfied, at each time instant, by the *time-varying* uncertainties, then the eigenvalues remain in the subregion. For these time-varying uncertainties, however, this does not guarantee a certain corresponding performance. In engineering practice we are interested in performance; hence we presented bounds that guarantee, beside root-clustering in a subregion, also a corresponding performance.

VI. CONCLUSIONS

In this paper some improved bounds for robust performance of linear systems are obtained. Systems with structured and unstructured uncertainties are treated. For each case, optimization yields better results. For unstructured uncertainties, with shifting of the subregion and the system matrix, a less conservative result is obtained. We have presented our results for various different subregions in the form of tables. With the method proposed it is possible to determine admissible uncertainties of the system to guarantee, for time invariant uncertainties, a certain performance.

APPENDIX

Proof of Theorem 3.1: Recall the Lyapunov root-clustering criterion of Section II. From assumption (2) it follows that there exist a positive definite solution P of the GLE (2.5). If the GLE of the perturbed system matrix $A + E$ has a positive definite "solution" Q_1 for that solution P then the eigenvalues of the perturbed system matrix are located in the specified subregion. Thus, the eigenvalues of the perturbed system are located in Ω_2 if

$$\begin{aligned} c_{00}P + c_{10}((A + E)^T P + P(A + E)) \\ + c_{11}(A + E)^T P(A + E) + c_{20}(((A + E)^T)^2 P \\ + P(A + E)^2) = -Q_1 < 0. \end{aligned}$$

See also Yedavalli [5]. Substitution of (2.5) gives

$$\begin{aligned} &\Leftrightarrow c_{10}(E^T P + PE) + c_{11}(E^T P A + A^T P E + E^T P E) \\ &\quad + c_{20}((A^T E^T + E^T A^T + (E^T)^2)P \\ &\quad + c_{20}P(AE + EA + E^2) - Q < 0 \\ &\Leftrightarrow c_{10}S^{-1}(E^T P + PE)S^{-1} \\ &\quad + c_{11}S^{-1}(E^T P A + A^T P E + E^T P E)S^{-1} \\ &\quad + c_{20}S^{-1}((A^T E^T + E^T A^T + (E^T)^2)PS^{-1} \\ &\quad + c_{20}S^{-1}P(AE + EA + E^2)S^{-1} - S^{-1}S^T S S^{-1} < 0 \\ &\Leftrightarrow c_{10}S^{-1}E^T P S^{-1} + c_{10}S^{-1}P E S^{-1} + c_{11}S^{-1}E^T P A S^{-1} \\ &\quad + c_{11}S^{-1}A^T P E S^{-1} + c_{11}S^{-1}E^T P E S^{-1} \\ &\quad + c_{20}S^{-1}A^T E^T P S^{-1} + c_{20}S^{-1}E^T A^T P S^{-1} \\ &\quad + c_{20}S^{-1}(E^T)^2 P S^{-1} + c_{20}S^{-1}P A E S^{-1} \\ &\quad + c_{20}S^{-1}P E A S^{-1} + c_{20}S^{-1}P E^2 S^{-1} - I < 0. \quad (A.1) \end{aligned}$$

The left side of (A.1) is a Hermitian matrix. A Hermitian matrix has the property that all the eigenvalues (λ_k) are real and that it is negative definite if and only if all its eigenvalues are negative. Further, from [10], the property $\lambda_k(A - I) < 0 \Leftrightarrow \lambda_k(A) - 1 < 0 \Leftrightarrow \|A\| - 1 < 0$ and $\|A\| + \|B\| > \|A + B\|$, with $\|A\| =$ the spectral norm of the matrix A (the largest singular value of A), gives

$$\begin{aligned} &\|c_{10}S^{-1}E^T P S^{-1}\| + \|c_{10}S^{-1}P E S^{-1}\| + \|c_{11}S^{-1}E^T P A S^{-1}\| \\ &\quad + \|c_{11}S^{-1}A^T P E S^{-1}\| + \|c_{11}S^{-1}E^T P E S^{-1}\| \\ &\quad + \|c_{20}S^{-1}A^T E^T P S^{-1}\| + \|c_{20}S^{-1}E^T A^T P S^{-1}\| \\ &\quad + \|c_{20}S^{-1}(E^T)^2 P S^{-1}\| + \|c_{20}S^{-1}P A E S^{-1}\| \\ &\quad + \|c_{20}S^{-1}P E A S^{-1}\| + \|c_{20}S^{-1}P E^2 S^{-1}\| - 1 < 0 \\ &\approx 2\|c_{10}S^{-1}P\|\|E\|\|S^{-1}\| + 2\|c_{11}S^{-1}\|\|E^T\|\|P A S^{-1}\| \\ &\quad + \|c_{11}S^{-1}\|\|E^T\|\|P\|\|E\|\|S^{-1}\| \\ &\quad + 2\|c_{20}S^{-1}A^T\|\|E^T\|\|P S^{-1}\| + 2\|c_{20}S^{-1}\|\|E^T\|\|A^T P S^{-1}\| \\ &\quad + 2\|c_{20}S^{-1}\|\|(E^T)^2\|\|P S^{-1}\| - 1 < 0 \end{aligned}$$

$$\begin{aligned} &\Leftrightarrow (|c_{11}|\|P\|\|S^{-1}\|^2 + 2|c_{20}|\|S^{-1}\|\|P S^{-1}\|)\|E\| \\ &\quad + (2|c_{10}|\|S^{-1}\|\|P S^{-1}\| + 2|c_{11}|\|S^{-1}\|\|P A S^{-1}\| \\ &\quad + 2|c_{20}|\|S^{-1}\|A\|\|P S^{-1}\| \\ &\quad + 2|c_{20}|\|S^{-1}\|\|A^T P S^{-1}\|)\|E\| - 1 < 0 \end{aligned}$$

$$\Leftrightarrow a\|E\|^2 + b\|E\| - 1 < 0 \quad (A.2)$$

with

$$\begin{aligned} a &\equiv |c_{11}|\|P\|\|S^{-1}\|^2 + 2|c_{20}|\|S^{-1}\|\|P S^{-1}\| \\ b &\equiv 2|c_{10}|\|S^{-1}\|\|P S^{-1}\| + 2|c_{11}|\|S^{-1}\|\|P A S^{-1}\| \\ &\quad + 2|c_{20}|\|S^{-1}\|A\|\|P S^{-1}\| + \|S^{-1}\|\|A^T P S^{-1}\| \end{aligned}$$

$$\Leftrightarrow \|E\| < -\frac{b}{2a} + \frac{1}{2a} \cdot \sqrt{b^2 + 4a}.$$

□

Proof of Theorem 4.1: The first part of the proof is the same as the proof of Theorem 3.1. We continue with (A.1)

$$\begin{aligned} &\Leftrightarrow S^{-1}\{c_{10}(E^T P + PE) + c_{11}(E^T P A + A^T P E) \\ &\quad + c_{20}((E A)^T P + (A E)^T P + P(AE + EA)) \\ &\quad + c_{11}E^T P E + c_{20}((E^T)^2 P + P E^T)\}S^{-1} - I < 0. \quad (A.3) \end{aligned}$$

Now the substitution $E \rightarrow \sum_{i=1}^m \epsilon_i E_i$ is made (2.2). Abbreviating

$$P_i^* \equiv S^{-1} P_i S^{-1}; \quad P_{ij}^* \equiv S^{-1} P_{ij} S^{-1}$$

$$\begin{aligned} P_i &\equiv c_{10}(E_i^T P + P E_i) + c_{11}(E_i^T P A + A^T P E_i) \\ &\quad + c_{20}((E_i A)^T P + P E_i A + (A E_i)^T P + P A E_i) \\ P_{ij} &\equiv c_{11}(E_i^T P E_j + E_j^T P E_i) \\ &\quad + c_{20}((E_i E_j)^T P + P E_i E_j + (E_j E_i)^T P + P E_j E_i) \end{aligned}$$

$$\Leftrightarrow \sum_{i=1}^m \epsilon_i P_i^* + \sum_{i=1}^m \sum_{j=1}^m \epsilon_i \epsilon_j P_{ij}^* - I < 0.$$

The left side of this inequality is a Hermitian matrix. From [10], the property

$$\lambda_k(A - I) < 0 \Leftrightarrow \lambda_k(A) - 1 < 0 \Leftrightarrow \|A\| - 1 < 0 \text{ gives}$$

$$\Leftrightarrow \left\| \sum_{i=1}^m \epsilon_i P_i^* + \sum_{i=1}^m \sum_{j=1}^m \epsilon_i \epsilon_j P_{ij}^* \right\| - 1 < 0$$

$$\Leftrightarrow \left\| \sum_{i=1}^m \epsilon_i P_i^* \right\| + \left\| \sum_{i=1}^m \sum_{j=1}^m \epsilon_i \epsilon_j P_{ij}^* \right\| - 1 < 0$$

$$\Leftrightarrow \epsilon \left\| \sum_{i=1}^m |P_i^*| \right\| + \epsilon^2 \left\| \sum_{i=1}^m \sum_{j=1}^m |P_{ij}^*| \right\| - 1 < 0$$

$$\Leftrightarrow a\epsilon^2 + b\epsilon - 1 < 0 \quad (A.4)$$

$$\text{with } a \equiv \left\| \sum_{i=1}^m \sum_{j=1}^m |P_{ij}^*| \right\|, \quad b \equiv \left\| \sum_{i=1}^m |P_i^*| \right\|$$

$$|\epsilon| < -\frac{b}{2a} + \frac{1}{2a} \cdot \sqrt{b^2 + 4a}$$

and where $|A| = \{|a_{ij}|\}$, with $A = \{a_{ij}\}$, a $n \times n$ matrix.

Comments on "Strictly Positive Real Transfer Functions Revisited"

H. J. Marquez and C. J. Damaren

Abstract—In the above paper,¹ the distinction between weak and strong strictly positive real (SPR) functions was addressed, and the feedback interconnection of a weak SPR system and a passive one was shown to be stable. The purpose of this note is to show that the proof of this lemma is actually incorrect.

1 INTRODUCTION

The concepts of passivity and strict positive realness have been an important area of research for the last three decades. These investigations have brought a better understanding of these ideas and their applications, but also an ever increasing mismatch in the terminology adopted by different authors. The most widely accepted definitions of passivity and strict passivity are the following [1]. Define a real inner product $\langle \cdot, \cdot \rangle_T$ by

$$\langle \cdot, \cdot \rangle_T = \int_0^T \dot{\cdot}^T(t) \dot{\cdot}(t) dt \quad (1)$$

and let L_{2e}^n be the space of all functions $\dot{\cdot}: R^+ \rightarrow R^n$ which satisfy $\|\dot{\cdot}\|_2^2 = \langle \dot{\cdot}, \dot{\cdot} \rangle_T < \infty$, $\forall T \in R^+$ (R^+ is the set of positive real numbers).

Passivity $H: L_{2e}^n \rightarrow L_{2e}^n$ is said to be passive if there exists $\beta \in R$ such that

$$\langle \dot{\cdot}, H\dot{\cdot} \rangle_T \geq \beta \quad \forall \dot{\cdot} \in L_{2e}^n, \quad \forall T \in R^+ \quad (2)$$

Fig 1 The feedback system S .

Strict Passivity $H: L_{2e}^n \rightarrow L_{2e}^n$ is said to be strictly passive if there exists $\delta > 0$, and $\beta \in R$ such that

$$\langle \dot{\cdot}, H\dot{\cdot} \rangle_T \geq \delta \|\dot{\cdot}\|_2^2 + \beta, \quad \forall \dot{\cdot} \in L_{2e}^n, \quad \forall T \in R^+ \quad (3)$$

For linear systems these definitions are closely related to the concept of strictly positive real (SPR). See the above paper¹ for the definitions of weak and strong SPR. From these definitions, it is straightforward that a linear time-invariant system whose transfer function is (weak or strong) SPR is passive but, in general, not strictly passive. For example the system $H(s) = k/(s+a)$, $k > 0$, and $a > 0$ is SPR (and so passive), however, it is not strictly passive since $\text{Re}[H(j\omega)] \rightarrow 0$ as $\omega \rightarrow \infty$, and therefore no δ can be found to satisfy (3). The main problem with this result is that it renders the passivity theorem nearly inapplicable for linear systems, since only biproper or improper linear systems can be strictly passive.

Motivated by this observation the authors¹ considered the class of systems which satisfy the inequality (6b)¹

$$\frac{\int_0^\infty \dot{y}^T u dt + \beta}{\int_0^\infty \dot{u}^T u dt} > 0 \quad (4)$$

where $\dot{y} = H\dot{u}$, and (4) is valid for all inputs u such that $\|\dot{u}\|_2/\|u\|_2 < \infty$. This class of systems was shown to be equivalent to those which are weak SPR and played a central role in Lemma 1. There, it was claimed that the feedback interconnection of a passive system and one that satisfies inequality (4) (see Fig 1¹) is stable. The intention of this note is to show that the proof of Lemma 1¹ is not valid. We notice here that the condition $\|\dot{u}\|_2/\|u\|_2 < \infty$ is not used in the proof of Lemma 1, and therefore in the remainder of this note it is disregarded.

Using our notation, (4) can be rewritten as

$$\frac{\langle \dot{u}, H\dot{u} \rangle_T + \beta}{\langle \dot{u}, \dot{u} \rangle_T} > 0 \quad (5)$$

A number of comments must be made concerning this definition. In the first place, it is incomplete since for expression (4) to be well defined, it is necessary for the function u to belong to the space L_2^1 . This is an important point. In fact, this issue renders incorrect the proof of Lemma 1¹. Notice that in the proof of Lemma 1¹ it is necessary to consider precisely the case where u is not in L_2 . Yet more appropriate is to use extended spaces and rewrite (4) as

$$\lim_{T \rightarrow \infty} \frac{\langle \dot{u}, H\dot{u} \rangle_T + \beta}{\langle \dot{u}, \dot{u} \rangle_T} > 0, \quad \forall \dot{u} \in L_{2e}^n \quad (6)$$

We now analyze the proof of Lemma 1 (Appendix II¹). Since $u_1 = -\dot{y}$ and $y_1 = u$ (refer to Fig 1¹)

$$\frac{\langle \dot{u}, H\dot{u} \rangle_T + \beta}{\langle \dot{u}, \dot{u} \rangle_T} + \frac{\langle \dot{u}_1, H_1 \dot{u}_1 \rangle_T + \beta_1}{\langle \dot{u}_1, \dot{u}_1 \rangle_T} = \frac{\beta + \beta_1}{\langle \dot{u}, \dot{u} \rangle_T} \quad (7)$$

Here H_1 is passive, and therefore the second term on the left hand side of (7) is greater than or equal to zero, while H satisfies

inequality (6). To show stability, the authors reason by contradiction as follows: assume that $u \notin L_2$, and take limits on both sides of (7) as $T \rightarrow \infty$. In this case, the right-hand side tends toward zero and therefore, the left-hand side also tends toward zero. Hence the authors conclude that there is a contradiction since, by (6), the left-hand side is actually greater than zero. Therefore it must be true that $u \in L_2$.

This reasoning is fallacious, however, unless condition (6) is strengthened by requiring that the following be satisfied

$$\inf_{u \in L_2} \left[\lim_{T \rightarrow \infty} \frac{\langle u, Hu \rangle_T + \beta}{\langle u, u \rangle_T} \right] \geq \delta > 0 \quad (8)$$

In other words, there are only two possibilities of interest in (7)

$$1) \quad \inf_{u \in L_2} \left[\lim_{T \rightarrow \infty} \frac{\langle u, Hu \rangle_T + \beta}{\langle u, u \rangle_T} \right] \geq \delta > 0 \quad (9)$$

If this is the case then indeed there is a contradiction in (7). Condition (9), however, implies that the system is strictly passive and therefore Lemma 1 becomes a restatement of the passivity theorem (see, for example, [1]) i.e., it says nothing about weak SPR functions.

$$2) \quad \inf_{u \in L_2} \left[\lim_{T \rightarrow \infty} \frac{\langle u, Hu \rangle_T + \beta}{\langle u, u \rangle_T} \right] = 0 \quad (10)$$

In this case there is no contradiction in (7) since the left-hand side also tends toward zero for some function u without violating condition (6) (in the same way $1/n^2 \rightarrow 0$ as $n \rightarrow \infty$, for all $p \in R^+$ ≥ 1).

As a final remark we make the following observations, which emphasize the distinction between weak and strong SPR. It is relatively easy to show that the feedback combination of a (possibly nonlinear) passive plant and a strong SPR compensator is stable. The result can be proved by defining the loop transformation shown in Fig. 1 and noting that it does not alter the stability properties of the original system. It is then straightforward to show that for small enough $\epsilon > 0$, the system $H'_1 = (1 - H_1)^{-1}H_1$ is passive while $H' = H + 1$ is strictly passive and therefore stability follows from the passivity theorem.

The case of a weak SPR system is, however, very different as shown in the following example.

Example 1 Consider the linear time-invariant system $H(s) = (s+c)/[(s+a)(s+b)]$ and let $H'(s) = H(s)/[1-\epsilon H(s)]$. We have

$$\begin{aligned} H'(j\omega) + H'(-j\omega) \\ = 2 \frac{(abc - \epsilon c^2) + \omega^2(a+b-\epsilon-\epsilon)}{(ab - \epsilon c - \omega^2)^2 + (a+b-\epsilon-\epsilon)^2} > 0 \end{aligned} \quad (11)$$

if and only if

$$abc - \epsilon c^2 > 0 \quad a+b-\epsilon-\epsilon > 0 \quad (12)$$

if $a+b > \epsilon$, we can always find an $\epsilon > 0$ that satisfies (12). If, however, $a+b = \epsilon$ (i.e., when $H(s)$ is weak SPR), no such $\epsilon > 0$ exists.

II. CONCLUSIONS

The proof of Lemma 1¹ is incorrect. Since this note does not prove that the feedback interconnection of a passive plant and a weak SPR controller is stable, we conclude that it remains an open question.

On Interval Polynomials with No Zeros in the Unit Disc

V. Blondel

Abstract—We give a necessary condition for an interval polynomial to have no zeros in the closed unit disc. The condition is expressed in terms of the two first intervals.

The stability analysis of polynomials subject to structured uncertainty has received considerable attention this last decade (see [2] for an historical overview, references related to this contribution include [1], [3], [5], [8], and [9]).

In this note we give a necessary condition for an interval polynomial

$$P = \{a_0 + a_1z + \dots + a_nz^n \mid \underline{a}_i \leq a_i \leq \bar{a}_i\}$$

to be D -stable, i.e., such that all members of P have no roots in the closed unit disc. Our condition is expressed in terms of the two first intervals only.

In a corollary we show that if $\underline{a}_0 < \bar{a}_0/2$ and $\underline{a}_1 < \bar{a}_1/9$ then P cannot be D -stable.

The results presented here are easy consequences of a little known theorem on analytic functions.

Landau's Theorem Assume that the function f is analytic in the open unit disc $|z| < 1$ and that $f(z) \neq 0, 1$ for all $|z| < 1$. Then

$$|f'(0)| \leq 2|f(0)|(|\log|f(0)|| + 4)$$

where 4 is a constant which can be taken equal to 4.4.

For a proof of this theorem (which is sometime referred to as Landau-Carathéodory theorem) see for example Hille [4, p. 221]. The best possible bound for 4 was given in 1981 by Jenkins [6], it is equal to $4\pi/\Gamma(1/4) = 4.37$.

We now prove our theorem.

Theorem Let $P = \{a_0 + a_1z + \dots + a_nz^n \mid \underline{a}_i \leq a_i \leq \bar{a}_i\}$ be an interval D -stable polynomial and assume that $\bar{a}_0 > \underline{a}_0 > 0$. Then

$$|a_1| \leq 2\underline{a}_0 \left(\log^+ \frac{\underline{a}_0}{\bar{a}_0 - \underline{a}_0} + 1 \right)$$

where $\log^+ t = \max(0, \log t)$.

Proof Define $a_i^* \in [\underline{a}_i, \bar{a}_i]$ by $a_0^* = \min(2\underline{a}_0, \bar{a}_0)$ and choose an arbitrary set of coefficients $a_i^* \in [\underline{a}_i, \bar{a}_i]$ ($i = 2, \dots, n$). Consider the polynomial $p(z)$ defined by

$$p(z) = \frac{1}{\underline{a}_0 - a_0^*} (\underline{a}_0 + a_1z + a_2^*z^2 + \dots + a_n^*z^n)$$

It is easy to see that $p(z)$ never takes the value zero or one in the open unit disc. Indeed

$$p(z) = 0 \Leftrightarrow \underline{a}_0 + \bar{a}_1z + a_2^*z^2 + \dots + a_n^*z^n = 0$$

and

$$p(z) = 1 \Leftrightarrow a_0^* + \bar{a}_1z + a_2^*z^2 + \dots + a_n^*z^n = 0$$

Manuscript received November 4, 1993; revised June 25, 1994.

The author is with the Division of Optimization and Systems Theory, Department of Mathematics, Royal Institute of Technology (KTH), S-100 44 Stockholm, Sweden.

IEEE Log Number 9408547.

These two polynomials belong to P , hence $p(z) \neq 0, 1$ when $|z| < 1$. Applying Landau's theorem on $p(z)$ we obtain

$$\left| \frac{\bar{a}_1}{a_0 - a_0^*} \right| \leq 2 \left| \frac{a_0}{a_0 - a_0^*} \right| \left(\left| \log \left| \frac{a_0}{a_0 - a_0^*} \right| \right| + 4.4 \right).$$

Since $a_0^* > a_0 > 0$ we get

$$|\bar{a}_1| \leq 2a_0 \left(\left| \log \frac{a_0}{a_0^* - a_0} \right| + 4.4 \right)$$

The coefficient a_0^* is defined by $a_0^* = \min(2a_0, \bar{a}_0)$. If $2a_0 \leq \bar{a}_0$ then $a_0^* = 2a_0$ and

$$|\bar{a}_1| \leq 2a_0 4.4 = 2a_0 \left(\log^+ \frac{a_0}{\bar{a}_0 - a_0} + 4.4 \right)$$

whereas if $2a_0 > \bar{a}_0$ then $a_0^* = \bar{a}_0$ and

$$|\bar{a}_1| \leq 2a_0 \left(\left| \log \frac{a_0}{a_0^* - a_0} \right| + 4.4 \right) = 2a_0 \left(\log^+ \frac{a_0}{\bar{a}_0 - a_0} + 4.4 \right).$$

The theorem is thus proved

Remarks

- 1) A corresponding theorem can be derived for other stability regions. For Schur stability (no roots outside the open unit disc) we obtain a necessary condition for the stability of interval polynomials with uncertainty in the highest order coefficient.
- 2) It is clear from the proof of theorem that, if $p_1(z) = \alpha + a_1 z + a_2 z^2 + \dots + a_n z^n$ and $p_2(z) = \beta + a_1 z + a_2 z^2 + \dots + a_n z^n$ are both D -stable polynomials, then

$$|\alpha| \leq 2|\beta| \left(\left| \log \left| \frac{\alpha}{\beta} \right| \right| + 4.4 \right)$$

This inequality can be used to derive bounds for other structured uncertainties descriptions.

Corollary Let $P = \{\alpha_0 + a_1 z + \dots + a_n z^n \mid \underline{a}_i \leq a_i \leq \bar{a}_i\}$ be an interval polynomial and assume that $0 < 2\underline{a}_0 < \bar{a}_0$ and $\underline{a}_0 < \bar{a}_1$. Then P cannot be D -stable.

Proof Assume by contradiction that P is D -stable. Since $2\underline{a}_0 \leq \bar{a}_0$, the theorem gives $|\bar{a}_1| \leq 2\underline{a}_0 4.4 = 8.8\underline{a}_0$. But this is a contradiction since $\underline{a}_0 < \bar{a}_1$. The result is thus proved.

The Logical Control of an Elevator

Derek N. Dyck and Peter E. Caines

Abstract—This paper presents a detailed example of the design of a logical feedback controller for finite state machines. In this approach, the control objectives and associated control actions are formulated as a set of axioms each of the form X implies Y , where X asserts that i) the current state satisfies a set of conditions and ii) the control action y will steer the current state towards a given target state; Y asserts that the next control input will take the value y . An automatic theorem prover establishes which of the assertions X is true, and then the corresponding control y is applied. The main advantages of this system are its flexibility (changing the control law is accomplished through changing only the axioms) and the fact that, by the design of the system, control actions will provably achieve the control objectives. The illustrative design problem presented in this paper is that of the logical specification and logical feedback control of an elevator.

I. INTRODUCTION

The COCOLOG system (from Conditional Observer and Controller LOGic) [1], [2] is a logical system for the state estimation and control of finite state machines. In this approach, the control objectives are formulated as axioms (i.e., necessarily true logical formulas) which relate the current state to a target state. The axioms are each of the form X implies Y , where X asserts that i) the current state satisfies a set of conditions and ii) the control action y will steer the current state towards a given target state; Y asserts that the next control input will take the value y . An automatic theorem prover establishes which of the assertions X is true, and then the corresponding control y is applied. The main advantages of this system are its flexibility (changing the control law is accomplished through changing only the axioms) and the fact that, by the design of the system, control actions will provably achieve the control objectives.

This paper applies the COCOLOG system to an idealized version of an elevator control problem. Section II describes the state, dynamics and control of the elevator. Sections III-V briefly outline the COCOLOG system and present a new logical framework specific to the control of an elevator. Sections VI and VII present the results of computer simulations using an Automatic Theorem Prover (due to Mackling, see [3]) and the conclusions which can be drawn from these results.

II. THE ELEVATOR CONTROL EXAMPLE

The logical control of an elevator is a good example with which to illustrate the operation of the COCOLOG system because it shares with many other discrete event systems the features of i) simplicity of dynamics, ii) combinatorial complexity of state description, and iii) great variety of possible control strategies and resulting trajectories. This section describes the basic set-up of the elevator control problem.

A. The State

The elevator control problem studied in this paper consists of a single elevator in a building with five floors, numbered zero to four. The elevator can handle up to three demands, with the

Manuscript received March 29, 1994. This work was supported in part by NSERC Grant GP001329 and NCE IRIS Project B5.

The authors are with the Department of Electrical Engineering, McGill University, Montréal, Québec, Canada H3A 2A7.
IEEE Log Number 9408548.

TABLE I
ELEVATOR STATE VARIABLES AND THEIR VALUES FOR THE INITIAL STATE OF THE EXAMPLE TRAJECTORY

Current Floor = 2		
Location ₀ = 1	Location ₁ = 2	Location ₂ = 3
Destination ₀ = 2	Destination ₁ = 0	Destination ₂ = 4
Frustration ₀ = 3	Frustration ₁ = 2	Frustration ₂ = 1

demands numbered zero to two. A demand is characterized by the demand state which is given by a triple consisting of a location, a declared destination, and a frustration level. To simplify the state representation, a frustration level of zero is used to indicate an inactive demand. Table I contains the complete set of state variables and their values for the initial state of the example to be presented later.

2. System Dynamics

The dynamics of the elevator are quite simple. At each time step, the elevator either moves up or down one floor, or stays at the same floor, according to the control input. This means the elevator effectively stops at every floor it passes. New arrivals are treated as disturbance inputs: when a person enters the world of the elevator, he or she immediately announces a destination and starts with a frustration of one. The frustration is then incremented at each time step until the individual reaches his or her destination. It is assumed that there are never more demands arriving than the maximum number of demands allowed by the system (if there are, these demands are simply ignored until an active demand is satisfied).

Any person at the same floor as the elevator moves with the elevator (that is, the elevator takes on everybody at each floor it arrives at, even if they are traveling in the opposite direction). When a person's location becomes equal to his or her destination, that person immediately leaves the world of the elevator. That is, when the location and destination of a demand become equal, the frustration of the demand is set to zero, indicating an inactive demand.

The example presented in this paper involves satisfying the active demands in the sense that the controlled trajectory of the elevator results in a state in which the location and destination of each active demand are equal, and the elevator is at rest. This formulation is easily extended to the case where new demands occur at random instants and enter the system if fewer than three demands are active at that instant (see, e.g., [3]).

C. Control Law

The control problem for an elevator may be viewed as a disturbance rejection control problem. The basic objective is to empty the elevator, though other goals may temporarily or permanently override this one. The basic control law must therefore guarantee that in the absence of disturbances and overrides the elevator empties in finite time. Our control strategy for the basic control problem is that of prioritizing persons with a high frustration level.

The simple control law which satisfies these objectives is the control law "Max first" which always attends to the person with the highest frustration level. That is, at each time step, the person with the highest frustration is selected and referred to as Max. If Max is not in the elevator, the elevator moves up or down in the direction of Max's location. If Max is in the elevator, the elevator moves in the direction of Max's destination. Since the dynamics guarantee that Max will be selected when the elevator reaches Max's floor, this control law

satisfies the basic objective of emptying the elevator in finite time in the absence of fresh inputs (i.e., new demands or overrides).

To illustrate the basic COCOLOG property of flexibility with respect to control objectives, two override control objectives are added. In the first, the fourth floor of the building is designated as a hospital, and it is assumed that any person whose destination is the fourth floor is an emergency case who takes priority over all other persons in the world of the elevator. In the second, the objective is changed altogether in case of a fire: as is common practice, when the fire alarm is triggered, the elevator stops at the nearest floor (so that people can take the stairs to safety). In our control strategy the fire objective overrides the hospital emergency objective.

The ease with which these control objectives can be added to the basic control law illustrates the power of the COCOLOG approach to control. It should be emphasized that the "Max first" basic control law is not designed to be an optimal one, but rather one which is simple enough to clearly illustrate its implementation using COCOLOG. It is to be noted that logic control laws of the type: "serve the most frustrated customer first" treat large sets of states as equivalent, since the states of the demands not being served are ignored. Consequently, the logic control law described here succeeds in handling a system in which the number of possible states is estimated at 10 million.

III. COCOLOG

The COCOLOG system is a family of first-order logical theories. The theories provide a logical system for describing and reasoning about the state estimation and control of a given finite input-state-output machine. The COCOLOG system consists of a family of theories because at each time step a new theory is generated, since some axioms are used to describe the inputs and observed outputs of the system (or the next state in the case of complete state observation). More formally, at each discrete time instant k , the k th first order logical theory Th_k is used to determine the next control input $U(k)$ through a set of Conditional Control Axioms (CCA's) with Th_k . The CCA's imply certain values for the control input when certain conditions C_k^m are fulfilled. In logical syntax, the CCA's are of the form

$$C_k^m \rightarrow (U(k) = u^m).$$

This formula, in English, would read: "If formula C_k^m in theory k is true, then this implies that the control input at time step k is equal to the constant u^m ."

In COCOLOG, the control input $U(k)$ is assigned a particular value u^m if a proof exists, in Th_k , of the predicate $U(k) = u^m$. Since each CCA_k^m is an axiom, a sufficient condition for this to hold is the existence of a proof of C_k^m in Th_k . We observe that for finite machines in general, and the elevator example in particular, a finite model (in the technical sense of model theory, see [2] and [7]) for any theory is readily constructed. This establishes the consistency of COCOLOG theories in general and ELCOLOG (see below) in particular.

A. Markovian Fragment

The family of theories in a COCOLOG all have in common a subset of the axioms which are the same in all theories; these axioms are, by definition, the axioms in Th_0 . The transition from theory Th_{k-1} to Th_k is governed by meta-level rules of inference, which cannot be represented within these theories. In the general case, each theory Th_k follows from Th_{k-1} by the addition of axioms, for example the axiom which asserts the equality of the output at time instant k to the observed output value. In practice, however, it is very expensive (in terms of proof time on an automatic theorem prover) to keep increasing the number of axioms as the system evolves over time. An alternative is to restrict the set of axioms to a moving window which only includes the most recent additions to the axioms in Th_0 . This is a so called Markovian fragment of COCOLOG theory, which is described in more detail in [4]. It can be shown that, provided certain conditions are satisfied, the Markovian fragment has the same power to make control decisions as the original COCOLOG (this is the principal mathematical result of [4]).

The rest of this section focuses on the application of COCOLOG to the special case of the elevator control example. More details of the operation of COCOLOG in the general case can be found in [2], [5], and [6].

B. Markovian Fragments for the Elevator Control Example

In the case of the elevator control example, the Markovian fragment is implemented by effectively starting from a new initial state at each time step. Each theory Th_k therefore consists only of the axioms in Th_0 together with a set of axioms which describe the state at time instant k . In the general case, the state description axioms would in fact describe the current state estimate (CSE) set of possible current states which satisfy the predicate CSE_k . However, since the elevator system has full state output, i.e., complete state observation, the current state is known exactly, and hence CSE_k is satisfied only by a single state value.

Our axiomatic formulation of the elevator system does not contain a complete axiomatization of the system state transition function. Although this approach reduces the expressibility of our syntax, this approach has several advantages at both the logical and the implementation level:

- 1) A complete logical model of the system is not used in the elevator example to reason about the behavior of the controlled elevator. This reduction of the axioms to a subset of the Markovian fragment increases the efficiency of the logic controller. We note that the actual (computed) state transition of the system (occurring at each control action) is realized outside the ATP program. This is consistent with our ontological assumption that the controlled dynamical system is an entity distinct from the logic controller and the theories it carries.
- 2) Whenever the system undergoes exogenous disturbance inputs (in our case new passengers and their destinations) the resulting state value is efficiently accepted into the flow of COCOLOG theories. This is because the complete state observation hypothesis implies the new state value is immediately available to the COCOLOG controller.
- 3) Since the current state is treated as an initial state within each theory, the time index can be dropped altogether within each theory. (This would not be possible, however, if a model of the dynamics of the system is used to predict the state of the system at future time instants.) This results in a significant simplification of the conditional control axiom set.

The logic resulting from our restrictions of a complete Markovian fragment specification is sufficiently different from COCOLOG that

it warrants the distinct name ELCOLOG (for ELevator COntroller LOGic). The next section presents the language of ELCOLOG.

IV. THE ELEVATOR CONTROLLER LOGIC ELCOLOG

ELCOLOG is a first order logic which is used in elevator control to prove or disprove control formulas, given a specified state. Associated with any logic is a syntax and a semantic interpretation. The syntax is a set of symbols and the rules for formulating formulas. The semantics is the meaning attached to these symbols.

A. The Language of ELCOLOG

The ELCOLOG language consists of constant symbols, variable symbols, function symbols, and predicate symbols, as well as the punctuation symbols "(", ")", ",", and ".". The precise syntactic rules governing formulas can be found in any logic text, e.g., [7]. This section gives an informal description of the syntax, and a semantic interpretation.

Constant Symbol Set:

The symbols representing zero and the first four positive integers:
0 1 2 3 4

The Skolem constants (used in place of existentially quantified variables): **Vic** **Max**

Vic is the index to the demand of the person whose destination is the hospital, in the case of an emergency (i.e., the victim), and **Max** is the index to the demand of the person with the maximum frustration level.

Variable Symbol Set:

General variables: **a b c**

Variables used for indexing the location, destination, and frustration: **m n**

The indexing variables may only assume values in the constant symbol set: {0, 1, 2, **Vic**, **Max**}. Normally, this restriction would imply the use of types to constrain the semantics and to increase the efficiency of the ATP. However, in our simple example this is instead accomplished through the use of domain predicates, which are added to the relevant logical axioms to restrict their application to instantiations obeying this rule.

Function Symbol Set:

The following are the state projection functions. They are all implicit functions of the time index k . Note that arg is an index and must be one of {**Vic**, **Max**, 0, 1, 2, **m**, **n**}.

- Pn** - the position of the elevator (at the current time instant).
- Pl(arg)** - the location of the person associated with demand #arg.
- Pd(arg)** - the destination of the person associated with demand #arg.
- Pf(arg)** - the frustration of the person associated with demand #arg.

And the input at this time step is also an implicit function of the time index k :

- U** - the control input.

Predicate Symbol Set:

Logical operators:

- $\neg \text{arg}$ - True iff arg is not true.
- $\text{arg}_1 \wedge \text{arg}_2$ - True iff both arg_1 and arg_2 are true.
- $\text{arg}_1 \vee \text{arg}_2$ - True iff either arg_1 or arg_2 is true.
- $\text{arg}_1 \rightarrow \text{arg}_2$ - True iff arg_2 is true whenever arg_1 is true

Arithmetic relations:

- $\text{arg}_1 = \text{arg}_2$ - True iff arg_1 and arg_2 are equal.
- $\text{arg}_1 < \text{arg}_2$ - True iff arg_1 is strictly less than arg_2 .

Predicates, with the state as an implicit argument, used in the conditional control axioms:

- Fire** - True iff the fire alarm is on.
- Emergency** - True iff someone's destination is the fourth floor (the hospital).

To reduce the clutter of parentheses, the following operator precedence is used, listed from highest to lowest: $=$, $<$, \neg , \wedge , \vee , \rightarrow .

B Rules of Inference

Rules of inference determine how new formulas can be derived from a set of formulas (some of which will be axioms) while preserving truth in the process (that is, if all the formulas in the set are true, then the new formula is also true). Formally, for ELCOLOG to be a logic, it is required that the rules of inference be defined so that proofs of formulas can be constructed. For this formal requirement, the two rules of inference used in ELCOLOG are Modus Ponens and the Generalization rule. Stated in English, Modus Ponens is simply: "If A is true, and A implies B is true, then B is true," where A and B are formulas. The Generalization rule is: "If A is true, then A is true for all v ," where v is a variable, and A is a formula in which v is free (i.e., is not governed by a universal or existential quantifier). Also, along with these two rules, several Logical Axiom Schemata are also defined. In these details ELCOLOG is identical to COCOLOG (see [2]), so they will not be repeated here.

V. AXIOMATIC THEORY OF ELCOLOG

As in COCOLOG, the axioms in Th_0 include all the axioms except the axioms describing the current state. The complete set of axioms in Th_k is given in Appendix I. The axioms in Th_0 divide naturally into number relation axioms, control axioms, and override control axioms. The set of axioms in Th_k is formed by adding the current state axioms.

A Number Relation Axioms

The number relation axioms define the domain of positive integers, and also define the properties of the equality and inequality predicates. To make automatic theorem proving tractable, the arithmetic axioms also include several theorems. In particular, included as "oracle information" are the properties of the "less than" predicate ($<$) for all pairs of integers in the domain.

B Control Axioms

The control axioms are built around the simple control law, described in Section II-C, which attends to the person with the highest destination level. These axioms are in the form of Conditional Control Axioms in COCOLOG

$$C^m \rightarrow U = u^m.$$

- first of these is the axiom which expresses the law
- put if all demands are inactive:

$$Pf(\text{Max}) = 0 \rightarrow U = 0.$$

- other axioms in this form are the following.

Go down if Max is waiting at a floor below the elevator:

$$\neg(Pf(\text{Max}) = 0) \wedge Pl(\text{Max}) < Pn \rightarrow U = 1$$

Go down if Max is in the elevator and wanting to go down:

$$\neg(Pf(\text{Max}) = 0) \wedge Pl(\text{Max}) = Pn \wedge Pd(\text{Max}) < Pn \rightarrow U = 1$$

Go up if Max is waiting at a floor above the elevator:

$$\neg(Pf(\text{Max}) = 0) \wedge Pn < Pl(\text{Max}) \rightarrow U = 2. \text{ and}$$

Go up if Max is in the elevator and wanting to go up:

$$\neg(Pf(\text{Max}) = 0) \wedge Pl(\text{Max}) = Pn \wedge Pn < Pd(\text{Max}) \rightarrow U = 2.$$

In addition to these axioms, two other axioms are required to uniquely determine the value of the Skolem constant **Max**. They are

$$Pf(n) \leq Pf(\text{Max})$$

and

$$Pf(n) = Pf(\text{Max}) \rightarrow \neg(n < \text{Max}).$$

The next section discusses the override control axioms and explains how they are added to these basic control axioms.

C. Override Control Axioms

The full power of ELCOLOG, as for COCOLOG, lies in the ease with which it allows control objectives to be modified. In this case, the two override control objectives each use a predicate symbol to indicate whether the override is in effect or not. These predicate symbols are then logically OR'ed into all the basic conditional control axioms. For example, the control axiom in the case where the elevator is empty is: stay put if all demands are inactive; this becomes

$$\text{Fire} \vee \text{Emergency} \vee (Pf(\text{Max}) = 0) \rightarrow U = 0.$$

So in each case the value of the override predicate must be determined, either through the current state axioms in the case of a fire, or through additional axioms in Th_0 , as in the hospital override case. The axiom in this second case, for the hospital override, is

$$\neg(Pf(n) = 0) \wedge Pd(n) = 4 \rightarrow \text{Emergency}.$$

The complete set of axioms, including the hospital override axioms, is given in Appendix I.

D. Current State Axioms

The current state axioms are added to Th_0 to form Th_k . These axioms are very simple, as they consist only of a set of equality predicates which equates each state projection function to the observed output value (recall this system has full state output, i.e., complete state observation). For example, one axiom in this set for the state shown in Fig. 1 is

$$Pl(1) = 2$$

which simply asserts that the location of the person associated with the demand #1 is the second floor. The current state axioms corresponding to Fig. 1 are given in Appendix I.

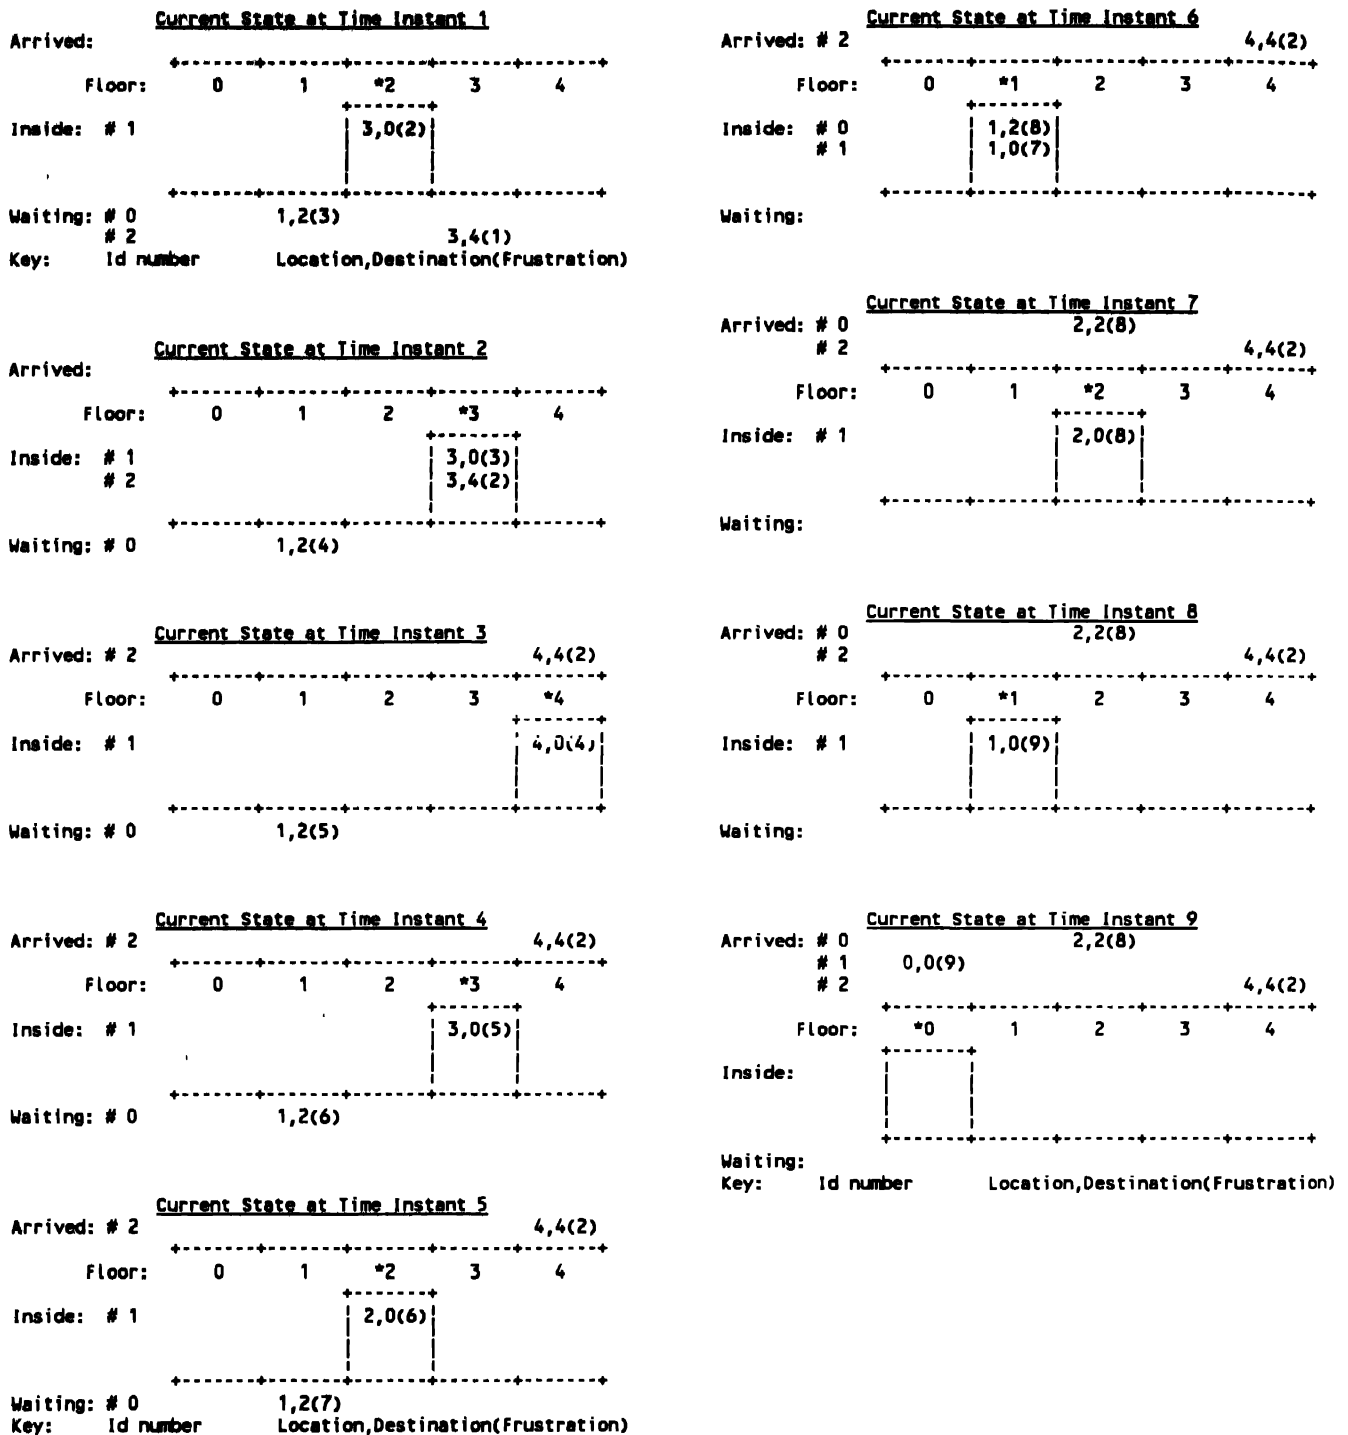

Fig. 1. Elevator control example—hospital override.

VI. IMPLEMENTATION

A. The Automatic Theorem Prover

To determine the control input given an initial state an Automatic Theorem Prover (ATP) is used. This section briefly describes the "Blitzensturm" resolution-refutation theorem prover, developed by Mackling [3], which was used for the simulations. In the propositional logic case (i.e., no variables) resolution is an inference rule which is a generalization of Modus Ponens. This inference rule applies to formulas in canonical clausal form: the formula consists of terms (or the negation of terms) which are OR'ed together. Resolution

works by first searching for two formulas which share a term that appears negated in one formula but not in the other. The new formula is derived by deleting the shared term from both formulas and combining them with the OR operator. For example: the fire override control axiom: $\text{Fire} \rightarrow U = 0$ can be re-written in canonical clausal form as: $\neg \text{Fire} \vee U = 0$. If the current state axiom set includes the formula Fire , then by applying the resolution rule, the new formula $U = 0$ can be derived. In the first-order logic case, the resolution rule involves the process of unification (see [9]).

A proof by refutation starts with a consistent set of axioms, to which is added the negation of the formula to be proven. If

contradiction can be derived using the rules of inference, then at least one of the original formulas must be false, since inference rules cannot derive false formulas from true ones. Since the original set of axioms is consistent, it is the negation of the formula to be proven which must be false, and therefore the formula must be true. For example, the formula to be proven might be $U = 0$, which asserts that the control input is STAY. To prove this, the negation of this formula $\neg(U = 0)$ is added to Th_k . In the case where one of the current state axioms is **Fire**, $U = 0$ can be derived by resolution, as shown above; then $U = 0$ with $\neg(U = 0)$ yields by resolution the empty formula, i.e., a contradiction. The steps leading to the empty formula constitutes a proof of the formula $U = 0$.

A resolution-refutation ATP, defined in terms of these concepts, is an algorithm which recursively applies the resolution inference rule to a set of axioms together with the negation of a formula in order to find the empty formula. In the case where the original formula is, in fact, false, the theorem prover will fail to terminate, since a contradiction cannot be derived from a set of true formulas. Therefore, in practice, it is necessary to run the ATP on all possible control actions simultaneously, and terminate them all as soon as one finds a refutation proof.

We say formula A subsumes formula B if $A \rightarrow B$. For example, $C_1 \vee D$ subsumes $C_1 \vee C_2 \vee D$. It is a fact that, if A subsumes B , then any formula which can be derived by recursively applying the resolution inference rule to A , B , and S can also be derived from only A and S , where S is a given set of additional formulas. The "Blitzensturm" ATP extensively applies the subsumption rule which, in its simplest form, deletes subsumed formulas from the list of formulas at any stage in the resolution process (see [9]). For example, the current state axiom $\neg\text{Fire}$ subsumes the fire override control axiom: $\text{Fire} \rightarrow U = 0$. In this case, the fire override control axiom can be deleted by the ATP, since it is not necessary to prove any control actions. Subsumption is especially useful in keeping the size of the set of formulas manageable while searching for a proof. In particular, note that the combined effect of the resolution rule and the subsumption rule in the above examples is to delete the irrelevant axioms from Th_k depending on whether **Fire** or $\neg\text{Fire}$ appears among the current state axioms. This applies to override controls in general, and so the addition of override controls does not necessarily imply longer proof times.

The ATP has no built-in provision for handling objects of different types. Specifically, the restrictions imposed on indexes are not obeyed by the ATP. However, as explained in [8], the set of axioms can be converted into a single typed language by using domain predicates, which, in ELCOLOG, is the inequality predicate. For example, the first axiom to determine **Max**, in which n is universally quantified, becomes

$$n < 3 \rightarrow \neg(\text{Pf}(\text{Max}) < \text{Pf}(n)).$$

These domain predicates are included in the input file for the ATP.

The Trajectory

The initial state is as shown in Table I. Note that there is one person whose destination is the fourth floor. Appendix II shows the movement of the elevator with the hospital override in effect. In this graphical representation of the state, the elevator travels horizontally, and the triplets of integers display each person's location, destination, and frustration. This trajectory was computed using the Blitzensturm ATP of Mackling [3].

VII. DISCUSSION AND CONCLUSION

A. Computational Complexity

At the time this paper was written, the time required for a single proof was of the order of 100 seconds on a SUN Sparc workstation. This is clearly not suitable for the real time control of an actual elevator. However, significant improvements in proof times are continually being made for T. Mackling's Blitzensturm automatic theorem prover (see [3]), and in view of predicted advances in computer processing speeds it is not unreasonable to expect real time performance for systems of significant complexity in the future.

With regard to more complex systems, it is a fact that the computational complexity of refutation proofs is exponential in the number of axioms [10]. This is the central motivation for the theory of Markovian fragments of COCOLOG [4] (which avoids increasing the size of the axiom set over time). An additional measure to combat increasing complexity is that of a hierarchical control strategy. In this approach, the states of complex systems are aggregated into the state sets of simpler systems at a higher hierarchical level. The computation of control actions will be carried out in a manner that respects this hierarchy.

B. Conclusion

In this paper the elevator control problem is employed to illustrate and apply the underlying concepts of COCOLOG. The essential features of this approach are i) the ability to formulate descriptions of dynamical systems and their control objectives by the use of logical axioms and (ii) a flexibility which permits the easy modification of such axioms, in particular the control axioms. In the elevator example this modification was achieved by the addition of override axioms. In our view, the ease with which we could write in and computationally implement the "emergency" and "fire" overrides to the basic "max first" ELCOLOG control objectives provides evidence for the flexibility of COCOLOG systems, and we suggest the term "objective adaptability" for this property. It should also be emphasized that the use of axioms to formulate control objectives enables the resulting control system to be engineered so as to be provably correct. In general, this property is viewed as being difficult to obtain for finite state machines; for example, in current practise considerable time is spent developing and testing elevator controls.

Finally, we shall mention that experiments are in progress with different COCOLOG formulations of the elevator problem which include simulations of exogenous destination demand flows and permit cyclical ATP iterations which attempt to prove different conditional control theorems.

APPENDIX I

COMPLETE AXIOM SET FOR THE ATP

Equality Axioms

Reflexivity: $a = a$, symmetry: $a = b \rightarrow b = a$, and transitivity: $a = b \wedge b = c \rightarrow a = c$

In addition to these axioms, the appropriate substitution axiom is required for every function and predicate symbol.

Strict Inequality Axioms

Nonreflexivity: $\neg(a < a)$ and transitivity: $a < b \wedge b < c \rightarrow a < c$
Substitution axiom for inequality: $a = b \wedge b < c \rightarrow a < c$

Domain Characterization Axioms

The entire domain consists of positive integers: $a \geq 0$

The entire domain is ordered: $a = b \vee a < b \vee a > b$

Axioms defining the relation between zero and the four positive integers: $0 < 1, 1 < 2, 2 < 3, 3 < 4$

Theorems to aid the Automatic Theorem Prover (oracle information):

$$0 < 2, 0 < 3, 0 < 4, 1 \geq 0, 1 < 3, 1 < 4, 2 \geq 0, 2 \geq 1,$$

$$2 < 4, 3 \geq 0, 3 \geq 1, 3 \geq 2, 4 \geq 0, 4 \geq 1, 4 \geq 2, 4 \geq 3$$

State Projection Functions

P_n is the number of the current floor.

$Pl(n)$ is the location of the person associated with demand $\#n$.

$Pd(n)$ is the destination of the person associated with demand $\#n$.

$Pf(n)$ is the frustration of the person associated with demand $\#n$.

Substitution axioms for equality of the state projection functions

$$m = n \wedge Pl(m) = a \rightarrow Pl(n) = a,$$

$$m = n \wedge Pd(m) = a \rightarrow Pd(n) = a,$$

$$m = n \wedge Pf(m) = a \rightarrow Pf(n) = a$$

Substitution theorems for inequality of the state projection functions

$$m = n \wedge Pl(m) < a \rightarrow Pl(n) < a,$$

$$m = n \wedge Pd(m) < a \rightarrow Pd(n) < a,$$

$$m = n \wedge Pf(m) < a \rightarrow Pf(n) < a$$

Axioms for Control

Fire Override: If there is a fire, stay at the current floor:

$$\text{Fire} \rightarrow U = 0$$

Fire is OR'ed into all of the following control axioms, for clarity, however, it will not appear in the following.

Hospital Override: If someone's destination is the fourth floor (the hospital) then that person has priority

$$n < 3 \wedge \neg(Pf(n) = 0) \wedge Pd(n) = 4 \rightarrow \text{Emergency}.$$

If there is an Emergency, then the following axioms determine Vic

Vic is (an index to) a person:

$$\text{Emergency} \rightarrow (Vic = 0 \vee Vic = 1 \vee Vic = 2)$$

Vic's destination is the fourth floor: $\text{Emergency} \rightarrow Pd(Vic) = 4$

Vic's frustration is not zero: $\text{Emergency} \rightarrow \neg(Pf(Vic) = 0)$

If there is more than one person whose destination is the fourth floor, then the one with the lowest index is treated first

$$n < 3 \wedge \neg(Pf(n) = 0) \wedge Pd(n) = 4 \rightarrow \neg(n < Vic).$$

Control in case of emergency: deliver victim to the fourth floor

$$Pl(Vic) < P_n \rightarrow U = 1, \neg(Pl(Vic) < P_n) \rightarrow U = 2$$

(since Vic will exit on arrival, this last axiom will not cause an attempt to go up from the fourth floor)

Basic Control: The basic control is: attend to the person with maximum frustration level. This is the control action to be taken in the absence of a Fire or an Emergency. To specify this, each of the axioms A_i in the basic control is to be interpreted as: $\neg\text{Fire} \wedge \neg\text{Emergency} \rightarrow A_i$. For clarity and because of space limitations, only the nonoverridden axioms A_i are specified in the following.

Max is (an index to) a person: $\text{Max} = 0 \vee \text{Max} = 1 \vee \text{Max} = 2$
Axioms which uniquely determine Max:

a) No one is more frustrated than Max: $\neg(Pf(n) > Pf(\text{Max}))$

b) Of those who are equally frustrated, none has a lower demand number than Max

$$Pf(n) = Pf(\text{Max}) \rightarrow \neg(n < \text{Max}).$$

Stay put if all demands are inactive: $Pf(\text{Max}) = 0 \rightarrow U = 0$.

Go down if Max is waiting at a floor below the elevator, or if Max is in the elevator and wants to go down

$$Pf(\text{Max}) \neq 0 \wedge Pl(\text{Max}) < P_n \rightarrow U = 1$$

$$Pf(\text{Max}) \neq 0 \wedge Pl(\text{Max}) = P_n \wedge Pd(\text{Max}) < P_n \rightarrow U = 1.$$

Go up if Max is waiting at a floor above the elevator, or if Max is in the elevator and wants to go up.

$$Pf(\text{Max}) \neq 0 \wedge Pl(\text{Max}) > P_n \rightarrow U = 2$$

$$Pf(\text{Max}) \neq 0 \wedge Pl(\text{Max}) = P_n \wedge Pd(\text{Max}) > P_n \rightarrow U = 2.$$

Axioms Describing the Current State

Current state at time instant $k = 1$ is as in Fig. 1

$$\neg\text{Fire}, P_n = 2, Pl(0) = 1, Pd(0) = 2, Pf(0) = 3, Pl(1) = 2,$$

$$Pd(1) = 0, Pf(1) = 2, Pl(2) = 3, Pd(2) = 4, Pf(2) = 1.$$

With the Hospital Override in effect, the next control input should be up ($U = 2$). This is proved by a refutation proof (a contradiction is derived from the negation of the formula to be proved $\neg(U = 2)$).

ACKNOWLEDGMENT

The authors would like to thank T. Mackling and Y. Wei for many insightful and illuminating discussions and to acknowledge the original challenge by W. M. Wonham to formulate the elevator problem in COCOLOG.

Robust Stability Criteria for Dynamical Systems Including Delayed Perturbations

Hansheng Wu and Koichi Mizukami

Abstract—In this note, we consider the problem of robust stability of uncertain time-delay dynamical systems. A new robust stability criteria for linear dynamical systems subject to delayed time-varying and nonlinear perturbations is derived. The results obtained in this note are less conservative than the ones reported so far in the literature. Some analytical methods are employed to investigate the bound on the perturbations so that the systems are stable. A numerical example is given to demonstrate the utilization of our results.

I. INTRODUCTION

It is well known that time delay is often encountered in various engineering systems, such as chemical processes, hydraulic, and rolling mill systems, and its existence is frequently a source of instability. Therefore, the stability problems of time-delay dynamical systems have received considerable attention over the decades (see, e.g., [1]–[8]). Because time-delay dynamical systems often include some perturbations, it is necessary to investigate the problems of robust stability of uncertain time-delay dynamical systems. In [9], for example, the problem of quantitative measures of robustness for linear dynamical systems including delayed nonlinear perturbations is investigated, and by using Razumikhin-type theorems, some bounds on the perturbations are obtained so that the systems remain stable. In [10], a delay-dependent stability condition for the linear uncertain time-delay dynamical systems is presented.

In this note, we consider the problem of robust stability criteria for linear dynamical systems subject to delayed time-varying and nonlinear perturbations. A new bound on the perturbations is presented so that the systems remain stable. Some analytical methods are employed to investigate this bound. Our results show that the robust stability criteria presented in this note is less conservative than the one given in [9]. In addition, since the robust stability condition developed in this note is independent of the delay, the results of this note may be applicable to dynamical systems with uncertain time-delay.

The rest of this note is organized as follows. In Section II, the problem to be tackled is precisely stated. In Section III, the main results of this note are proposed. As an application, an illustrative example is given in Section IV. The simulation of this example demonstrates the utilization of our results.

II. PROBLEM FORMULATION

We consider the linear dynamical systems including delayed perturbations described by the differential-difference equation of the form

$$\frac{dx}{dt} = Ax(t) + \Delta f(x(t-h(t)), t) \quad (1)$$

where $t \in R$ is the 'time,' $x(t) \in R^n$ is the current value of the state, $A \in R^{n \times n}$ is an asymptotically stable matrix, $\Delta f(\cdot, \cdot) : R^n \times R \rightarrow R^n$ is a time-varying nonlinear continuous function. The time-delay $h(t)$ is any nonnegative, bounded, and continuous function. That is, $h(t) \leq \bar{h}$, where \bar{h} is any constant.

Manuscript received February 10, 1993; revised April 29, 1993 and October 1993.

E-Log Number 9407215.

Here, it is worth noting that we do not require for the magnitude of the time-varying delay $h(t)$ to be less than one, i.e., $h(t) < 1$. It is well known that such an assumption is often needed in papers dealing with stability problem of systems with time delay (see, e.g., [8]). Therefore, as will be seen in the next section, the results of this note may be applicable to the case where the time delay function is uncertain.

The initial condition for system (1) is given by

$$x(t) = \psi(t), \quad t \in [t_0 - \bar{h}, t_0] \quad (2)$$

where $\psi(\cdot)$ is a continuous function on $[t_0 - \bar{h}, t_0]$.

We assume that $\Delta f(\cdot, \cdot)$ represents the uncertainty and perturbations acting on system (1), and that there exists a nonnegative constant β such that for all $(x, t) \in R^n \times R$

$$\|\Delta f(x(t-h(t)), t)\| \leq \beta \|x(t-h(t))\| \quad (3)$$

where $\|\cdot\|$ denotes the Euclidean norm.

Now, the problem to be tackled in this note is to find some conditions on the perturbations so that system (1) is stable.

III. MAIN RESULTS

In this section, we derive the stability condition for system (1), which gives the bound on the perturbations. Before stating our main results we give the following definitions.

Definition 1. For any similarity transformation matrix M , we define

$$\mu = \|M\| \|M^{-1}\|. \quad (4)$$

Definition 2. For the asymptotically stable matrix A given in system (1), we define a constant α which satisfies

$$0 < \alpha < \min_i \{|\operatorname{Re} \lambda_i(A)|\}, \quad i = 1, \dots, n \quad (5)$$

where $\lambda_i(\cdot)$ denotes the i th eigenvalue of the square matrix (\cdot) , $\operatorname{Re} \lambda_i(\cdot)$ its real part.

Definition 3. For the symmetric positive definite matrix $P \in R^{n \times n}$, we let

$$\sigma = \frac{\lambda_{\max}(P)}{\lambda_{\min}(P)} \quad (6)$$

where $\lambda_{\max}(\cdot)$ and $\lambda_{\min}(\cdot)$ denote the maximum eigenvalue and the minimum eigenvalue of matrix (\cdot) , respectively, and P satisfies the following Lyapunov-type equation

$$(\dot{A} + \alpha I)^T P + P(\dot{A} + \alpha I) = -Q \quad (7)$$

where I denotes the identity matrix, $Q \in R^{n \times n}$ is any symmetric positive definite matrix, and

$$\dot{A} = M^{-1} A M. \quad (8)$$

Remark 1: Since the matrix A is asymptotically stable, by Definition 1 the matrix $(\dot{A} + \alpha I)$ is also asymptotically stable. Therefore, in the light of the Lyapunov stability theory, Lyapunov-type (7) exists for any symmetric positive definite matrix Q a solution P which is also a symmetric positive definite matrix.

Then, for system (1), we have the following stability condition which results in a bound on the perturbations.

Theorem 1: If the following inequality is satisfied

$$\beta < \rho := \frac{\alpha}{\mu\sigma} \quad (9)$$

then system (1) is stable. More precisely, we have

$$\|z(t)\| \leq \frac{\sigma^{1/2}}{1-\bar{d}} \|D\| \exp\{-\bar{\gamma}(t-t_0)\} \quad (10)$$

where

$$\bar{d} := d(\bar{\gamma}) = e^{\bar{\gamma}\bar{h}} \frac{\mu\sigma\beta}{\alpha-\bar{\gamma}} < 1, \quad \bar{\gamma} \in [0, \alpha] \quad (11a)$$

$$\|D\| := \sup_{\tau \in [t_0-\bar{h}, t_0]} \|M^{-1}\psi(\tau)\| \quad (11b)$$

$$\|z(t)\| := \|M^{-1}\varphi(t)\| \quad (11c)$$

where M is any similarity transformation matrix.

Proof: We transform system (1) with the aid of a similarity transformation matrix M , and get

$$\frac{dz(t)}{dt} = Az(t) + M^{-1}\Delta f(Mz(t-h(t)), t) \quad (12)$$

with an initial condition

$$z(t) = M^{-1}\psi(t), \quad t \in [t_0-\bar{h}, t_0] \quad (13)$$

where $\psi = M^{-1}\varphi$.

Let $z(t)$ be the solution of system (12) with the initial condition (13) and define a positive definite function $V(z)$ as follows

$$V(z) = z^T(t)Pz(t). \quad (14)$$

In the light of Rayleigh principle [11], from (14) we have

$$\lambda_{\min}(P)\|z(t)\|^2 \leq V(z) \leq \lambda_{\max}(P)\|z(t)\|^2. \quad (15)$$

From (7), (12), and (14) we obtain

$$\begin{aligned} \frac{dV(z)}{dt} &= -2\alpha V(z) - z^T(t)Qz(t) \\ &\quad + 2z^T(t)PM^{-1}\Delta f(Mz(t-h(t)), t). \end{aligned} \quad (16)$$

Since both Q and P are positive definite, we also have

$$\frac{dV(z)}{dt} \leq -2\alpha V(z) + 2\mu\beta\lambda_{\max}(P)\|z(t)\|\|z(t-h(t))\|. \quad (17)$$

Therefore, from (17) we obtain the following inequality on $V(z)$

$$\begin{aligned} V(z) &\leq \lambda_{\max}(P)\|D\|^2 \exp\{-2\alpha(t-t_0)\} \\ &\quad + \int_{t_0}^t 2\mu\beta\lambda_{\max}(P) \exp\{-2\alpha(t-\tau)\} \\ &\quad \cdot \|z(\tau)\|\|z(\tau-h(\tau))\| d\tau. \end{aligned} \quad (18)$$

Here, we define an auxiliary function $S(t)$ as follows

$$S(t) = \begin{cases} \sqrt{\lambda_{\max}(P)}\|D\|, & t \in [t_0-\bar{h}, t_0] \\ \sqrt{\hat{S}(t)}, & t \geq t_0 \end{cases} \quad (19)$$

where

$$\begin{aligned} \hat{S}(t) &= \lambda_{\max}(P)\|D\|^2 \exp\{-2\alpha(t-t_0)\} \\ &\quad + \int_{t_0}^t 2\mu\beta\lambda_{\max}(P) \exp\{-2\alpha(t-\tau)\} \\ &\quad \cdot \|z(\tau)\|\|z(\tau-h(\tau))\| d\tau. \end{aligned}$$

Then, comparing (18) with (19) yields

$$S(t) \geq \sqrt{V(z)} \geq \sqrt{\lambda_{\min}(P)}\|z(t)\|. \quad (20)$$

That is

$$\frac{\|z(t)\|}{S(t)} \leq \frac{1}{\sqrt{\lambda_{\min}(P)}}. \quad (21)$$

Furthermore, from (19) we obtain

$$\begin{aligned} \frac{dS(t)}{dt} &= -\alpha S(t) + \mu\beta\lambda_{\max}(P) \frac{\|z(t)\|}{S(t)} \|z(t-h(t))\| \\ &\leq -\alpha S(t) + \frac{\mu\beta\lambda_{\max}(P)}{\sqrt{\lambda_{\min}(P)}} \|z(t-h(t))\|. \end{aligned} \quad (22)$$

Therefore, from (22) we also have

$$\begin{aligned} S(t) &\leq \sqrt{\lambda_{\max}(P)}\|D\| \exp\{-\alpha(t-t_0)\} \\ &\quad + \frac{\mu\beta\lambda_{\max}(P)}{\sqrt{\lambda_{\min}(P)}} \int_{t_0}^t \exp\{-\alpha(t-\tau)\} \\ &\quad \cdot \|z(\tau-h(\tau))\| d\tau. \end{aligned} \quad (23)$$

Comparing (20) with (23) yields

$$\begin{aligned} \|z(t)\| &\leq \sigma^{1/2}\|D\| \exp\{-\alpha(t-t_0)\} \\ &\quad + \mu\sigma\beta \int_{t_0}^t \exp\{-\alpha(t-\tau)\} \\ &\quad \cdot \|z(\tau-h(\tau))\| d\tau. \end{aligned} \quad (24)$$

Here, we first define the following continuous function

$$d(\gamma) := e^{\gamma\bar{h}} \frac{\mu\sigma\beta}{\alpha-\gamma}, \quad \gamma \in [0, \alpha].$$

It is obvious from the condition (9) that

$$d(0) = \frac{\mu\sigma\beta}{\alpha} < 1.$$

Then, according to the property of continuous function, there exists a constant $\bar{\gamma} > 0$ ($\bar{\gamma} < \alpha$) such that $d(\bar{\gamma}) < 1$. Here, for such a constant $\bar{\gamma} > 0$, we define

$$\bar{d} := d(\bar{\gamma}) < 1. \quad (25)$$

Continuing with (24), multiplying both sides of (24) by $\exp\{\bar{\gamma}(t-t_0)\}$ yields

$$\begin{aligned} \|z(t)\| \exp\{\bar{\gamma}(t-t_0)\} &\leq \sigma^{1/2}\|D\| \exp\{-\alpha(t-t_0) + \bar{\gamma}(t-t_0)\} \\ &\quad + \mu\sigma\beta \int_{t_0}^t \exp\{-\alpha(t-\tau) + \bar{\gamma}(t-t_0)\} \\ &\quad \cdot \|z(\tau-h(\tau))\| d\tau. \end{aligned} \quad (26)$$

With trivial manipulations, from (26) we obtain

$$\begin{aligned} \|z(t)\| \exp\{\bar{\gamma}(t-t_0)\} &\leq \sigma^{1/2}\|D\| + \mu\sigma\beta \int_{t_0}^t \exp\{\bar{\gamma}h(\tau)\} \\ &\quad \cdot \exp\{-(\alpha-\bar{\gamma})(t-\tau)\} \|z(\tau-h(\tau))\| \\ &\quad \cdot \exp\{\bar{\gamma}(\tau-h(\tau)-t_0)\} d\tau. \end{aligned} \quad (27)$$

Letting

$$Y_m(t) := \sup_{\rho \in [t_0-\bar{h}, t]} \|z(\rho)\| \exp\{\bar{\gamma}(\rho-t_0)\}$$

from (27) we have

$$\|z(t)\| \exp\{\bar{\gamma}(t-t_0)\} \leq \sigma^{1/2}\|D\| + e^{\bar{\gamma}\bar{h}} \frac{\mu\sigma\beta}{\alpha-\bar{\gamma}} Y_m(t). \quad (28)$$

In the light of the definition of $Y_m(t)$, from (25) and (28) we further obtain

$$\begin{aligned} Y_m(t) &\leq \sigma^{1/2}\|D\| + e^{\bar{\gamma}\bar{h}} \frac{\mu\sigma\beta}{\alpha-\bar{\gamma}} Y_m(t) \\ &= \sigma^{1/2}\|D\| + \bar{d} Y_m(t) \end{aligned}$$

i.e.,

$$Y_m(t) \leq \frac{\sigma^{1/2}}{1-\bar{d}} \|D\|. \quad (29)$$

TABLE I
THE COMPARISON OF THE RESULTS OBTAINED IN [9] AND THIS NOTE

	The Results of [9]	Our Results
Not Transformed	$\rho = 0.1458$	$\rho = 0.1835$
Transformed	$\rho = 0.1780$	$\rho = 0.2383$

Fig 1 Time delay history

From (29) we can obtain that for $t \geq t_0$

$$\|x(t)\| \leq \|x(t_0)\| \exp\{-\gamma(t-t_0)\} \leq \frac{\sigma^{1/\alpha}}{1-\bar{\alpha}} \|D\| \exp\{-\gamma(t-t_0)\} \quad (30)$$

It is obvious from (30) that system (12) is exponentially stable. This implies [noting $\bar{x} = M^{-1}x$] that system (1) is also exponentially stable. \square

Remark 2 The robust stability condition (9) gives a bound on the perturbations. It is worth noting that (9) is independent of delay. Therefore the results obtained here is applicable to the case where the delay function $h(t)$ is uncertain.

Remark 3 The robust stability condition (9) does not include $\lambda(C)/\lambda_{\min}(P)$ which is included in the bound given in [9]. Then our results may be less conservative than the ones given in [9]. This will further be illustrated in the following numerical example.

IV. NUMERICAL EXAMPLE

We recall from [9] the following matrix

$$A = \begin{bmatrix} -3 & -2 \\ 1 & 0 \end{bmatrix} \quad (31)$$

In [9] selecting the similarity transformation matrix M and Q as identity matrix I yields for the perturbations the bound $\rho = 0.158$. Further improvement is obtained by applying the following transformation suggested in [12] for the perturbations

$$M = \begin{bmatrix} 0.99964 & -0.26217 \\ 0.02660 & 0.95937 \end{bmatrix} \quad (32)$$

yields a robust bound $\rho = 0.178$.

Our results this bound can further be improved. Here, if we select $\alpha = 0.5$, $M = I$, and

$$Q = \begin{bmatrix} 15.000 & 3.000 \\ 3.000 & 2.647 \end{bmatrix} \quad (33)$$

Fig 2 Simulation of example for $\gamma = 0.22$

then we can have $\rho = 0.1835$. Furthermore, we also employ the transformation (32) and let

$$Q = \begin{bmatrix} 8.000 & 1.000 \\ 1.000 & 0.126 \end{bmatrix} \quad (34)$$

then we can obtain a bound $\rho = 0.23893$ which improves the bound reported in [9] for the perturbations (by 34%).

The comparison of our results with the ones obtained in [9] is shown in Table I. It is obvious from Table I that the results obtained in [9] are more conservative than our ones. To further confirm this, the simulation of this example for $\gamma = 0.22$ ($< \rho = 0.2383$) is depicted in Fig 2. Here we have employed for the simulation the following

$$\Delta f(\bar{x}) = \begin{bmatrix} 0.20 \sin[r_2(t-h(t))] \\ 0.22 \sin[r_1(t-h(t))] \end{bmatrix}$$

$$r_1(t) = [3 \cos(t) \quad 2 \cos(t)]^T$$

and the time varying delay $h(t)$ is given in Fig 1. Note that $h(t)$ is not defined at $t = 0.25n$, $n = 1, 2, \dots$

It is shown from Fig 2 that the system is indeed exponentially stable.

An Efficient Method for Unconstrained Optimization Problems of Nonlinear Large Mesh-Interconnected Systems

Shin-Yeu Lin and Ch'i-Hsin Lin

Abstract—We present a new efficient method for solving unconstrained optimization problems for nonlinear large mesh-interconnected systems. This method combines an approximate scaled gradient method with a block Gauss-Seidel with line search method which is used to obtain an approximate solution of the unconstrained quadratic programming subproblem. We prove that our method is globally convergent and demonstrate by several numerical examples its superior efficiency compared to a sparse matrix technique based method. In an example of a system of more than 200 variables, we observe that our method is 3.45 times faster than the sparse matrix technique based Newton-like method and about 50 times faster than the Newton-like method without the sparse matrix technique.

I. INTRODUCTION

In this paper we consider the following unconstrained optimization problem for a nonlinear large mesh-interconnected system

$$\min_{x \in \mathbb{R}^n} J(x) \quad (1)$$

where the objective function $J: \mathbb{R}^n \rightarrow \mathbb{R}$ is continuously differentiable, bounded from below and satisfies the Lipschitz condition that there exists a constant $K > 0$ such that $\|\nabla J(x_1) - \nabla J(x_2)\|_2 \leq K\|x_1 - x_2\|_2, \forall x_1, x_2 \in \mathbb{R}^n$. A general descent algorithm, which is called a scaled gradient method in [1], for solving problem (1) uses the following iterations

$$x^{k+1} = x^k + \gamma^k s^k \quad (2)$$

where k denotes the iteration index, γ^k is a step-size, and s^k is the solution of

$$\min_{s \in \mathbb{R}^n} \frac{1}{2} s^T C(x^k) s + \nabla J(x^k)^T s \quad (3)$$

in which $C(x^k)$ is a positive definite matrix.

For a large mesh-interconnected system, if $C(x^k)$ is selected so that (2) is a Newton or Newton-like method, $C(x^k)$ may be a sparse matrix. The solution of (3), which is the solution of the linear system

$$C(x^k) s = -\nabla J(x^k) \quad (4)$$

can be obtained using the sparse matrix technique, which is a very powerful means for solving linear equations in a circuit system [2] or

an electric power system [3]. This technique effectively reduces the amount of computer memory needed and improves the computation time dramatically because it stores only nonzero elements and ignores operations involving zeros in the solution process [2]. Thus, a sparse matrix technique based Newton or Newton-like method is much more efficient than a method with quadratic convergence rate.

In this paper, we will present a new method for solving (1) for a large mesh-interconnected system to compete with a sparse matrix technique based method. Our method combines an approximate scaled gradient method with a block Gauss-Seidel with line search (BGSLS) method. Although each of the above methods is well known, combining them into one method is a new approach. The basic idea behind this method is to preserve the advantages and discard the disadvantages of the block Gauss-Seidel method. We have observed in many numerical experiments [4] that the block Gauss-Seidel method approaches its convergence point very fast in the first few iterations and then slows down around that point. This fact indicates that the block Gauss-Seidel method is better suited for use as a descent direction generator rather than as an optimization algorithm by itself. To improve the quality of the descent direction further, we use an exact line search at the end of each cycle of the block Gauss-Seidel method and thus form a BGSLS method. Executing the BGSLS method for a finite number of iterations with appropriate stopping criteria will generate the descent direction needed for the approximate scaled gradient method. We will show in this paper that our method is a globally convergent descent algorithm. It is difficult to give an analytical convergence rate for our method because of the nature of the method. However, since the major computation required by our method lies in the execution of the BGSLS method, our method will be efficient if the BGSLS method can generate an effective descent direction in several iterations. Intuitively, our method should be efficient and effective, for two reasons: i) only small minimization problems are involved in each iteration of the BGSLS method and ii) the exact line search used at the end of each iteration of the BGSLS method greatly improves the quality of the descent direction.

II. SOLUTION METHOD

A. The Approximate Scaled Gradient Method

The approximate scaled gradient method [1] is

$$x^{k+1} = x^k + \gamma^k s^k \quad (5)$$

where s^k is an approximate solution of (3) and γ^k is a step-size. To ensure global convergence, we use Armijo-type rule to determine the step-size by

$$\gamma^k = \beta^{m_k} \lambda \quad (6)$$

where $0 < \beta < 1$, $\lambda > 0$, and m_k is the smallest nonnegative integer such that makes the following inequality hold for some positive constant K_2

$$J(x^k + \beta^{m_k} \lambda s^k) - J(x^k) \leq -\frac{K_2}{2} \beta^{m_k} \lambda \|s^k\|_2^2. \quad (7)$$

Remark 2.1: a) Condition (7) is to ensure a sufficient decrement of the objective function obtained in each iteration of (5); the satisfaction of this condition serves as a terminating criteria for our Armijo-type step-size rule (6). b) As will be shown in Theorem 2.1, the matrix $\frac{1}{2} C(x^k) - K_2 I$ being nonnegative definite is a sufficient condition for (5) to converge. This sufficient condition provides a value for λ .

Lemma 2.1: Suppose (3) is solved by a descent iterative algorithm starting from $s = 0$ for any arbitrary number of iterations, and let \hat{s}^k denote the final value of s . Then $\nabla J(x^k)^T \hat{s}^k < 0$.

This lemma can easily be verified by the fact that $\frac{1}{2}(\hat{s}^k)^T C(x^k) \hat{s}^k - \nabla J(x^k)^T \hat{s}^k < 0$. Thus, our approximate scaled gradient method (5) will be an efficient descent algorithm for solving (1) if the descent algorithm we employ to obtain \hat{s}^k is efficient.

B Block Gauss-Seidel with Line Search (BGSLS) Method

1) **One Block Gauss-Seidel Cycle:** Let us partition s into p subvectors such that $s = [s_1 s_2 \cdots s_p]^T$. Then one block Gauss-Seidel cycle is to perform

$$\min_{s_i} \frac{1}{2} s^T C(x^k) s + \nabla J(x^k)^T s \quad (8)$$

from $i = 1$ to p . In (8), the subvector s_i is taken as the vector of minimizing variables while the variables in the subvectors $s_1, \dots, s_{i-1}, s_{i+1}, \dots, s_p$ are held fixed at their current values. Note that compared to (3), (8) is a small unconstrained minimization problem for every i .

Remark 2.2. On the partition of the s -vector, there are two extremes corresponding to $p = 1$ and $p = n$. The case of $p = 1$ is not the interest of this paper. For the case of $p = n$, the descent direction generated by (8) has very poor quality. Thus, a good partition should take the following two factors into account: a) computational burden of solving (8) and b) the quality of descent direction generated. In fact, the above two factors have conflicting interests; at this stage, we have not yet achieved an optimal way to partition the s -vector. Nonetheless, for a network-structure like system, it would be beneficial if each partitioned subnetwork is mesh-interconnected, and the sizes of all subnetworks do not differ much.

2) **Optimal Step-Size** Let $s^{(i)}$ denote the value of s after solving (8) for s_i . Then $s^{(0)}$ represents the initial value and $s^{(p)}$ the final value of s for one block Gauss-Seidel cycle. Suppose $s^{(0)}$ is not the optimal solution of (3). Then the following inequality holds

$$\begin{aligned} \frac{1}{2} (s^{(0)})^T C(x^k) s^{(0)} + \nabla J(x^k)^T s^{(0)} \\ > \frac{1}{2} (s^{(p)})^T C(x^k) s^{(p)} + \nabla J(x^k)^T s^{(p)}. \end{aligned} \quad (9)$$

Furthermore, because $C(x^k)$ is positive definite, $\frac{1}{2} s^T C(x^k) s + \nabla J(x^k)^T s$ is a convex function in s . Based on this fact, we may verify that

$$\begin{aligned} \frac{1}{2} (s^{(p)})^T C(x^k) s^{(p)} + \nabla J(x^k)^T s^{(p)} \\ \geq \frac{1}{2} (s^{(0)})^T C(x^k) s^{(0)} + \nabla J(x^k)^T s^{(0)} \\ + [C(x^k) s^{(0)} + \nabla J(x^k)]^T (s^{(p)} - s^{(0)}). \end{aligned} \quad (10)$$

Then, combining (9) and (10), we obtain the following lemma.

Lemma 2.2: Let $s^{(0)}$ and $s^{(p)}$ denote the initial and final values of s -variables, respectively, for one block Gauss-Seidel cycle of the BGSLS method. Suppose $s^{(0)}$ is not an optimal solution of (3). Then

$$[C(x^k) s^{(0)} + \nabla J(x^k)]^T (s^{(p)} - s^{(0)}) < 0. \quad (11)$$

The above inequality implies that $s^{(p)} - s^{(0)}$ is a descent direction of $\frac{1}{2} s^T C(x^k) s + \nabla J(x^k)^T s$ at $s = s^{(0)}$.

Therefore, we can determine the exact optimal step-size $\hat{\alpha}$ to update variable s by

$$s'' = s^{(0)} + \hat{\alpha} (s^{(p)} - s^{(0)}) \quad (12)$$

where s'' denotes the updated s , and the optimal step-size

$$\hat{\alpha} = - \frac{[C(x^k) s^{(0)} + \nabla J(x^k)]^T (s^{(p)} - s^{(0)})}{[s^{(p)} - s^{(0)}]^T C(x^k) [s^{(p)} - s^{(0)}]} \quad (13)$$

is obtained by solving the following one-dimensional minimization problem

$$\begin{aligned} \min_{\alpha \geq 0} \{ & \frac{1}{2} [s^{(0)} + \alpha (s^{(p)} - s^{(0)})]^T C(x^k) [s^{(0)} + \alpha (s^{(p)} - s^{(0)})] \\ & + \nabla J(x^k)^T [s^{(0)} + \alpha (s^{(p)} - s^{(0)})] \}. \end{aligned}$$

3) **One Iteration of the BGSLS Method.** The following three operations form one iteration of the BGSLS method: i) execute one block Gauss-Seidel cycle; ii) determine α ; and iii) update s'' . s'' will be the initial value $s^{(0)}$ for the next iteration of the BGSLS method.

4) **Convergence of the BGSLS Method:** This iterative BGSLS method will converge to the solution of (3), as described in the following lemma. The proof of the lemma is given in the Appendix.

Lemma 2.3: Assuming that there exists a constant $K_2 > 0$ such that $\frac{1}{2} C(x^k) - K_2 I$ is nonnegative definite for all x^k , then a) the BGSLS method is a descent method, and b) any limit point of the sequence generated by the BGSLS method is a solution of (3).

5) **Stopping Criteria of the BGSLS Method:** As pointed out in Section I, the BGSLS method approaches a solution point of (3) very quickly in the first few iterations; however, it then slows down around that point. In fact, it was this characteristic of the BGSLS method that gave us the idea of combining it with the approximate scaled gradient method. Therefore, to obtain the \hat{s}^k needed in (5), we do not need to execute the BGSLS method until it converges. In fact, we can stop the BGSLS method after a finite number of iterations. Consequently, one of the stopping criteria of this method is if the improvement of the objective function satisfies

$$\frac{Q(t) - Q(t+1)}{Q(t)} \times 100\% < \xi\% \quad (15)$$

where $Q(t) = \frac{1}{2} s(t)^T C(x^k) s(t) + \nabla J(x^k)^T s(t)$, t denotes the iteration index of the BGSLS method, and $\xi\%$ is a preselected percentage. To ensure that (5) converges, another stopping criteria

$$\|s(t+1)\|_2 < K_1 \|\nabla J(x^k)\|_2 \quad (16)$$

for some $K_1 > 0$, for all $t > t'$, where t' is a finite positive integer, should also be satisfied. Then, the $s(t+1)$ which satisfies stopping criteria (15) and (16) will be set as \hat{s}^k . An explanation of the need for (16) will be given in the proof of Theorem 2.1. The existence of K_1 and t' is ensured by the following corollary, the proof of which is also given in the Appendix.

Corollary 2.1: Let $\{s(t)\}$ denote a sequence generated by the BGSLS method. Under the assumption of Lemma 2.3, there exists a t' such that $\|s(t)\|_2 > K_1 \|\nabla J(x^k)\|_2$ for some $K_1 > 0$ and for all $t > t'$.

C The Algorithm for the Solution Method and its Convergence

Combining Lemma 2.1 and Lemma 2.3 then proves that our method is a descent method.

Lemma 2.4: The combination of the approximate scaled gradient method (5) and the BGSLS method, supplemented by the stopping criteria (15) and (16), is a descent method for solving (1).

1) **The Algorithm:** We are now ready to state our algorithm as follows: *Given data:* i) $s = [s_1, s_2, \dots, s_p]^T$, ii) the values of $\lambda (> 0)$ and $\beta (0 < \beta < 1)$ in Armijo-type rule, iii) the value of $\xi\% (\geq 0\%)$ in (15), and iv) a positive constant K_2 which meets the assumption in Lemma 2.3.

Step 0: Set the values $x^{(0)}$ and set $k = 0$.

Step 1: Set $t = 1$ and set $s(t) = 0$.

Step 2: Set $i = 1$ and $s^{(0)}(t) = s(t)$.

Step 3: Solve (8) to obtain $s^{(i)}$. If $i = p$, go to Step 5; otherwise, set $i = i + 1$ and repeat this step.

Step 4: Compute $s^{(p)}(t) - s^{(0)}(t)$ and determine $\hat{\alpha}(t)$ by (13).

Step 5: Update $s(t+1) = s^{(0)}(t) + \hat{\alpha}(t)[s^{(p)}(t) - s^{(0)}(t)]$.

Step 6: If (15) and (16) are satisfied, set $\hat{s}^k = s(t+1)$ and go to Step 7; otherwise, set $t = t+1$ and return to Step 2.

Step 7: Set $m = 0$.

Step 8: If $J(x^k + \gamma^m \lambda s^k) - J(x^k) \leq -(K_2/2) \gamma^m \lambda \|\hat{s}^k\|_2^2$, set $\gamma^k = \gamma^m \lambda$; otherwise, set $m = m+1$, and repeat this step.

Step 9: Update $x^{k+1} = x^k + \gamma^k \hat{s}^k$, set $k = k+1$, and return to Step 1.

2) Convergence of the Algorithm: The following theorem ensures the convergence of our algorithm. A proof of the theorem is given in the Appendix.

Theorem 2.1: Let $\{x^k\}$ denote the sequence generated by our algorithm. Under the assumption of Lemma 2.3, $\lim_{k \rightarrow \infty} \nabla J(x^k) = 0$.

Remark 2.3: The values of λ , β , and $\xi\%$ do not affect the convergence but will influence the efficiency of our method. Thus, these values can be determined empirically for individual systems.

3) Stopping Criteria of the Algorithm: From Theorem 2.1, we see that as $k \rightarrow \infty$, $\hat{s}^k \rightarrow 0$; however, for practical considerations, our algorithm will stop when $\|\hat{s}^k\|_\infty < \epsilon$ for a reasonable accuracy.

III. EXAMPLES

Most electric power systems are nonlinear large mesh-interconnected systems. The weighted least squares problem in power system state estimation is a typical unconstrained optimization problem and thereby is an adequate example for demonstrating the computational efficiency of our method.

A. The Weighted Least Squares Problem in Power System State Estimation

The power system state estimation problem [6] can be briefly described as follows: For an l -bus¹ power system, the voltage magnitudes and phase angles of all buses constitute the states of the system. Because the bus phase angle cannot be measured, the states of the system have to be estimated based on available measurements, which are functions of the states, such as power transmission line flow, bus voltage magnitude, bus power injection, and transformer tap. All such measurements can be expressed in a general form as $z = h(x) + \eta$, where x is a $2l$ -dimensional vector of state variables, z is an m -dimensional vector of measurements, h denotes m nonlinear measurement functions which are twice continuously differentiable, and η represents an m -dimensional Gaussian random vector of measurement errors with an $m \times m$ diagonal covariance matrix R . A common formulation [5] of this state estimation problem is to solve the following weighted least squares problem²

$$\min_x J(x) (= \frac{1}{2} [z - h(x)]^T R^{-1} [z - h(x)]). \quad (17)$$

Since $h(x)$ is twice continuously differentiable, $J(x)$ in (17) is twice continuously differentiable and thereby satisfies Lipschitz condition. Taking $n = 2l$, the $J(x)$ meets the assumptions given in Section I.

Note: For an authentic power system state estimation [6], bad data processing has to be associated with the solution of (17); if bad measurements are present, they should be eliminated, and the states re-estimated. However, for the purposes of this paper, we will focus on solving (17) only.

¹ The buses of the power systems considered here are similar to nodes in an electrical network.

² The phase angle of the slack bus is considered to be a known value.

B. Conventional Approach

In general, the Newton method may fail to solve (17) because the Hessian matrix of (17) may not be positive definite. Thus, the conventional approach in the power system literature [6] uses a Newton-like method, which is (2) with $C(x^k) = 2H(x^k)^T R^{-1} H(x^k)$ in (3) where $H(x^k) = \nabla h(x^k)$. However, $H(x^k)^T R^{-1} H(x^k)$ may be singular or ill-conditioned, since it is only positive semidefinite. To cope with this difficulty, we can modify the above $C(x^k)$ to ensure the positive definiteness by setting $C(x^k) = 2H(x^k)^T R^{-1} H(x^k) + \delta I$, where δ is a small positive real constant and I is the identity matrix. We see that under this modification, the only assumption needed in Theorem 2.1, $\frac{1}{2} C(x^k) - K_2 I$ is nonnegative definite, is satisfied by taking $K_2 = (\delta/2)$. Furthermore, the numerical stability of our algorithm is guaranteed if δ is not too small. Consequently, (4) becomes

$$[2H(x^k)^T R^{-1} H(x^k) + \delta I]s = -\nabla J(x^k). \quad (18)$$

The matrix $2H(x^k)^T R^{-1} H(x^k) + \delta I$ and the matrix $H(x^k)^T R^{-1} H(x^k)$ are sparse, and (18) can be solved using the sparse matrix technique.

Remark 3.1: a) Because $H(x^k)^T R^{-1} H(x^k)$ may be ill conditioned, methods that use an orthogonal transformation technique to solve $2H(x^k)^T R^{-1} H(x^k)s = -\nabla J(x^k)$ has been developed [7]. However, these methods are computationally very inefficient. b) In [6], the step-size γ^k is set to be 1 for all k . In fact, with a constant step-size such as this there is no guarantee that (2) will converge. c) There are other methods in the power system literature that can obtain an approximate solution for state estimation using a decoupling approach [8]. However, these methods are beyond the scope of this paper, since we are concerned only with methods that solve (1) exactly.

C. Application of the Proposed Method

Let us partition the power system network into $p (> 1)$ subnetworks such that each subnetwork is a connected graph in the topological sense. Let B_i denote the set of buses of the i th subnetwork; then s_{B_i} denotes the subvector of s corresponding to states of the i th subnetwork. Replacing s_i , $C(x^k)$, and $\nabla J(x^k)$ in the proposed algorithm by s_{B_i} , $2H(x^k)^T R^{-1} H(x^k) + \delta I$, and $H(x^k)^T R^{-1} (z - h(x^k))$, respectively, we can apply the proposed algorithm directly to (17). Analogous to (8), we see that $s_{B_1}, \dots, s_{B_{i-1}}, s_{B_{i+1}}, \dots, s_{B_p}$ are held fixed in the i th minimization problem

$$\min_{s_{B_i}} \frac{1}{2} s^T C(x^k) s + \nabla J(x^k)^T s \quad (19)$$

whose solution can be obtained by solving a small set of linear equations involving only the i th subnetwork and the boundary buses outside the i th subnetwork [9].

D. Test Results

We applied our method, the sparse matrix technique based Newton-like method, and the Newton-like method without sparse matrix technique to the weighted least squares problem in state estimation of the IEEE 30-bus power system and the IEEE 118-bus power system. For the cases under consideration, the IEEE 30-bus system was partitioned into three subnetworks, as shown in Fig. 1, in which each subnetwork is indicated by closed dashed contours. The IEEE 118-bus system is partitioned into eight subnetworks. Because of the limitation on the length of this paper, we can not include here a figure of the IEEE 118-bus system, however, this figure can be found in [10]. Nonetheless, we list the bus number of the buses of each subnetwork in the following. Subnetwork 1 contains buses 1 to 12.

TABLE I
COMPARISON OF OUR METHOD WITH NEWTON-LIKE METHOD WITH AND WITHOUT SPARSE MATRIX TECHNIQUE

System	Final objective value			Average CPU time (second:)			Speedup ratio	
	NLWTS ^(Δ) method	NLWS ^(□) method	Our method	NLWTS ^(Δ) method (I)	NLWS ^(□) method (II)	Our method (III)	$\frac{1}{T}$	$\frac{1}{T/I}$
IEEE-30 bus	15.88	15.88	15.88	0.99	0.46	0.27	2.15	3.67
IEEE-118 bus	43.05	43.05	43.05	76.53	5.49	1.59	13.94	48.13

Fig. 1. The IEEE 30-bus system and three partitioned subnetworks.

and bus 117. Subnetwork 2 contains buses 15 to 19, buses 27 to 32, and buses 113 and 114. Subnetwork 3 contains buses 20 to 26, buses 70 to 76, and bus 118. Subnetwork 4 contains buses 33 to 47. Subnetwork 5 contains buses 50 to 61, and buses 63 and 64. Subnetwork 6 contains buses 48, 49, and 62, buses 65 to 69, buses 77 to 81, and buses 97, 98, and 116. Subnetwork 7 contains buses 82 to 96. Subnetwork 8 contains buses 99 to 112. Note that each subnetwork contains about 10 to 20 buses in mesh-interconnected structure though the bus numbers are not consecutive.

In both cases, we took the real-power flow and the reactive-power flow of all transmission lines of each individual system as the measurement data and assumed that some of these are bad data. We set the parameters in our algorithm as follows: $\delta = 0.01$, $\beta = 0.9$ for both systems, $\xi = 50\%$ for the IEEE 30-bus system, and $\xi = 10\%$ for the IEEE 118-bus system, $\lambda = 1.05, 1.10, 1.15$ for the IEEE 30-bus system, and $\lambda = 1.25, 1.30, 1.35$ for the IEEE 118-bus system. Note that each value of λ corresponds to one computer run. We used various values of λ to test Armijo-type rule and average the CPU time. The accuracy ϵ in the stopping criterion of our algorithm, which is described in Subsection II-C-3), was set to be 10^{-2} for both cases. We used a Sun 4/60 workstation to test our algorithm. The simulation results for the case of the IEEE 30-bus system and the use of the IEEE 118-bus system are shown in Table I. The average CPU time of our algorithm is the average CPU time of the outer runs with various values of λ reported on the Sun 4/60 workstation. We also solved the same cases for both systems using the sparse-matrix technique based Newton-like method, with the same setup of Armijo-type rule and same initial guess as our method on the same Sun 4/60 workstation. We used $\|s^k\|_\infty < \epsilon = 10^{-2}$ as the stopping criteria for the sparse matrix technique based Newton-

like method, the test results for which are also shown in Table I. We also applied the Newton-like method without using the sparse matrix technique to the same cases on the same workstation with the same setup of Armijo-type rule, same initial guess, and same stopping criteria as the sparse matrix technique based Newton-like method. The resulting average CPU times are also reported in Table I for the cases of both systems. We see that our algorithm achieved the same final objective value as the Newton-like methods. As expected, the sparse matrix technique based Newton-like method was much faster than the Newton-like method without the sparse matrix technique in both cases, especially in the case of the IEEE 118-bus system, which has more sparsity. Compared to the sparse matrix technique based Newton-like method, our method also performs better with the larger system. From the speedup ratio shown in Table I, we see that in the case of the IEEE 118-bus system, our method is 3.45 times faster than the sparse matrix technique based Newton-like method and 48.13 times faster than the Newton-like method without the sparse matrix technique. This demonstrates the dramatic increase in efficiency provided by our method. In order to better appreciate the merits of our algorithm, in Fig. 2 we describe the details of the progression of our algorithm and the Newton-like method with the sparse matrix technique in solving the case of the IEEE 118-bus system when $\lambda = 1.35$. The result of our algorithm is shown by the curve marked with circles \circ and associated with the Arabic numeral iteration index. Each circle indicates the CPU time accumulated (horizontal axis) at that iteration versus the corresponding value of the objective function (vertical axis) in the progression. The curve marked with asterisks $*$ and associated with the Roman numeral iteration index corresponds to the Newton-like method with the sparse matrix technique. Our algorithm takes 12 iterations to meet the stopping criteria $\|s^k\|_\infty < 10^{-2}$, while the sparse matrix technique based Newton-like method takes only 11 iterations to meet the stopping criteria $\|s^k\|_\infty < 10^{-2}$. However, we see that the amount of CPU time taken up by each iteration of our algorithm is far less than that for each iteration of the Newton-like method with the sparse matrix technique. This shows the effectiveness and efficiency of using the BGSLs method to generate the descent direction. Furthermore, when our algorithm has nearly reached the optimal objective value, the Newton-like method with the sparse matrix technique has just finished its first iteration and the corresponding objective value is still quite far away from the optimal value. The efficiency of our algorithm is obvious.

IV. CONCLUSION

We have developed a globally convergent algorithm for unconstrained optimization problems of nonlinear large mesh-interconnected systems. Although, due to the nature of our method, an analytical convergence rate is not available, the dramatic increase in efficiency provided by our method can be observed both from the method itself and from the simulation results. It is worth noting that the BGSLs method can be processed by parallel processors if the order of the partitioned subnetworks is suitably arranged [11]. Thus, the speed of our method may be further increased by using parallel processors.

APPENDIX

Proof of Lemma 2.3: a) Let $T = \{s \in \mathbb{R}^{2n} | C(x^k)s + \nabla J(x^k) = 0\}$ denote the solution set of (3). Then if $s \notin T$, the descent property of the BGSLs method follows directly from Lemma 2.2 and (12)–(14). According to the Global Convergence Theorem [12, pp. 187–188], b) can be proven if we show that i) the BGSLs method is a descent method, ii) the sequence generated by the BGSLs method lies in a compact set, and iii) the mapping of any iteration of the BGSLs method is closed. Clearly, i), which is a), has been shown. In the following, we will prove ii) and iii).

Because $C(x^k)$ is positive definite, the unique minimum solution of (3) is

$$s^* = -C(x^k)^{-1} \nabla J(x^k). \quad (A1)$$

Let the set $S \equiv \{s \in \mathbb{R}^{2n} | -\frac{1}{2} \nabla J(x^k)^T C(x^k)^{-1} \nabla J(x^k) \leq \frac{1}{2} s^T C(x^k) s + \nabla J(x^k)^T s \leq 0\}$. Then $S \neq \emptyset$, since $0 \in S$. We claim that S is compact. Clearly, S is closed. Thus, it is enough to show that S is bounded. Suppose not, $\exists s \in S$ \exists

$$\|s\|_2 > \max \left(\frac{\|\nabla J(x^k)\|_2 + 1}{K_2}, \left| \frac{1}{2} \nabla J(x^k)^T C(x^k)^{-1} \nabla J(x^k) \right| + 1 \right). \quad (A2)$$

For this s and by the assumption that $\frac{1}{2} C(x^k) - K_2 I > 0$, we have

$$\begin{aligned} & \left| \frac{1}{2} s^T C(x^k) s + \nabla J(x^k)^T s \right| \\ & \geq \left| \frac{1}{2} s^T C(x^k) s \right| - |\nabla J(x^k)^T s| \\ & \geq K_2 \|s\|_2^2 - \|\nabla J(x^k)\|_2 \|s\|_2 \\ & = (K_2 \|s\|_2 - \|\nabla J(x^k)\|_2) \|s\|_2. \end{aligned} \quad (A3)$$

From (A2)

$$\begin{aligned} & (K_2 \|s\|_2 - \|\nabla J(x^k)\|_2) \|s\|_2 > \|s\|_2 \\ & > \left| \frac{1}{2} \nabla J(x^k)^T C(x^k)^{-1} \nabla J(x^k) \right|. \end{aligned} \quad (A4)$$

Thus, from (A3) and (A4), we obtain that $\left| \frac{1}{2} s^T C(x^k) s + \nabla J(x^k)^T s \right| > \left| \frac{1}{2} \nabla J(x^k)^T C(x^k)^{-1} \nabla J(x^k) \right|$. This inequality contradicts $s \in S$. Hence S must be bounded. From (a), the BGSLs method is a descent method. Thus, every point in the sequence $\{s(t)\}$ generated by the BGSLs method starting from $s = 0$ should satisfy

$$\frac{1}{2} s(t)^T C(x^k) s(t) + \nabla J(x^k)^T s(t) \leq 0, \quad \forall t \quad (A5)$$

moreover, by the descent property

$$\begin{aligned} & \frac{1}{2} s^T C(x^k) s + \nabla J(x^k)^T s \\ & \leq \frac{1}{2} s(t)^T C(x^k) s(t) + \nabla J(x^k)^T s(t), \quad \forall t. \end{aligned} \quad (A6)$$

From (A1) the left-hand side of (A6) equals $-\frac{1}{2} \nabla J(x^k)^T C(x^k)^{-1} \nabla J(x^k)$, thus from (A5) and (A6), the sequence $\{s(t)\}$, $\forall t$, must lie inside the compact set S . This proves ii). Next, we will prove iii). Based on the fact that the composition of closed mappings is a closed mapping, and the exact line search method is also a closed mapping [12, p. 210], it is enough to show iii) if we can show that the mapping of Step 3 of our algorithm is closed. This is true because (8) is a bounded, unconstrained quadratic minimization problem with positive definite $C(x^k)$. This completes the proof. \square

Proof of Corollary 2.1: Since by Lemma 2.3, the sequence $\{s(t)\}$ converges to a point s^* satisfying $C(x^k)s^* + \nabla J(x^k) = 0$, then $\|C(x^k)\|_2 \|s^*\|_2 \geq \|\nabla J(x^k)\|_2$. Let $K_0 = (1/\sup_k \|C(x^k)\|_2)$. We have $\|s^*\|_2 \geq K_0 \|\nabla J(x^k)\|_2$. Let $K_1 = (K_0/2) > 0$ and let $\tau = K_1 \|\nabla J(x^k)\|_2$. Then $\tau > 0$ since we only need to consider the case $\|\nabla J(x^k)\|_2 \neq 0$. Because $\{s(t)\}$ converges to s^* , there exists a t' such that $\|s^* - s(t)\|_2 < \tau$ for all $t > t'$. Consequently, $\|s(t)\|_2 > \|s^*\|_2 - \tau \geq K_0 \|\nabla J(x^k)\|_2 - K_1 \|\nabla J(x^k)\|_2 = K_1 \|\nabla J(x^k)\|_2$ for all $t > t'$. \square

Proof of Theorem 2.1: From Corollary 2.1, we see that $\forall k$, with $\nabla J(x^k) \neq 0$, there must exist a t' such that the stopping criteria (16)

$$\|s(t)\|_2 > K_1 \|\nabla J(x^k)\|_2, \quad \text{for some } K_1 > 0, \quad \forall t > t' \quad (A7)$$

is satisfied. Furthermore, by assumption, we have $\frac{1}{2} s(t)^T C(x^k) s(t) - s(t)^T K_2 s(t) \geq 0, \forall t$; and from (A5), we have $-\frac{1}{2} s(t)^T C(x^k) s(t) - \nabla J(x^k)^T s(t) \geq 0, \forall t$; these two inequalities lead to

$$-K_2 \|s(t)\|_2^2 \geq \nabla J(x^k)^T s(t), \quad \forall t. \quad (A8)$$

Then, the following proof mostly follows the proof of the convergence theorem for descent algorithms given in [1, pp. 203–204]. A Descent Lemma given in [1, pp. 203–204] states that if $J(\cdot)$ is continuously differentiable and there exists a positive constant K such that $\|\nabla J(x) - \nabla J(y)\| \leq K \|x - y\|, \forall x, y \in \mathbb{R}^n$, then $J(x+y) \leq J(x) + \nabla J(x)^T y + (K/2) \|y\|_2^2, \forall x, y \in \mathbb{R}^n$. By the assumptions on $J(\cdot)$ given in Section I, we may use the Descent Lemma and (A8) to obtain

$$\begin{aligned} J(x^k + \gamma^k s^k) & \leq J(x^k) + \gamma^k \nabla J(x^k)^T s^k + \frac{K}{2} \gamma^{k^2} \|s^k\|_2^2 \\ & \leq J(x^k) - \gamma^k \left(K_2 - \frac{K \gamma^k}{2} \right) \|s^k\|_2^2. \end{aligned} \quad (A9)$$

If $0 < \gamma^k < (K_2/K)$, we can derive that

$$-\gamma^k \left(K_2 - \frac{K \gamma^k}{2} \right) \leq -\frac{K_2}{2} \gamma^k. \quad (A10)$$

By (A9) and (A10), we have

$$J(x^k + \gamma^k s^k) \leq J(x^k) - \frac{K_2}{2} \gamma^k \|s^k\|_2^2. \quad (A11)$$

If $\lambda \geq (K_2/K)$, $0 < \beta < 1$, since $\{\beta^m \lambda\}$, $m = 0, 1, \dots$ is a monotonic decreasing sequence approaching 0, there must exist an m such that $\beta^m \lambda < (K_2/K)$. Let m_k be the smallest nonnegative integer satisfying the above inequality, then the following holds

$$\beta \frac{K_2}{K} \leq \beta^{m_k} \lambda < \frac{K_2}{K}. \quad (A12)$$

If $0 < \lambda < (K_2/K)$, $0 < \beta < 1$, then

$$\beta \lambda < \lambda < \frac{K_2}{K}. \quad (A13)$$

In this case, we can view $m_k = 0$ which is the smallest nonnegative integer for $\beta^{m_k} \lambda < (K_2/K)$. Now, for any $\lambda > 0$, $0 < \beta < 1$, and let m_k be either the m_k determined by (A12) or $m_k = 0$ by (A13); from (A11), there must exist an $m'_k \leq m_k$ (or $m'_k = 0$ if $m_k = 0$) such that

$$J(x^k + \beta^{m'_k} \lambda \hat{s}^k) \leq J(x^k) - \frac{K_2}{2} \beta^{m'_k} \lambda \|\hat{s}^k\|_2^2. \quad (\text{A14})$$

Note that $0 < \gamma^k < (K_2/K)$ is sufficient for (A14) to hold explains why $m'_k \leq m_k$. This shows that Step 8 of our algorithm will terminate for certain m'_k . Since $\beta^{m'_k} \geq \beta^{m_k}$, from (A12) and (A13), $\beta^{m'_k} \lambda \geq \min\{\beta \lambda, \beta(K_2/K)\}$. Let $\tau \equiv \frac{1}{2} K_2 \cdot \min\{\beta \lambda, \beta(K_2/K)\}$, then τ is finite and positive, and

$$J(x^k + \beta^{m'_k} \lambda \hat{s}^k) \leq J(x^k) - \tau \|\hat{s}^k\|_2^2. \quad (\text{A15})$$

Then, each iteration of our algorithm ensures a decrement of the objective function by at least the amount $\tau \|\hat{s}^k\|_2^2$. Since $J(x)$ is bounded from below, we assume $c \in \mathbb{R}$ is a lower bound of $J(x)$, then from (A15), we have

$$0 \leq J(x^{k+1}) - c \leq J(x^k) - c - \tau \|\hat{s}^k\|_2^2, \quad \forall k. \quad (\text{A16})$$

Then, by (A16), $\sum_{k=0}^{\infty} \|\hat{s}^k\|_2^2 \leq (J(x^0) - c/\tau) < \infty$, and (A7) shows that $\lim_{k \rightarrow \infty} \nabla J(x^k) = 0$. \square

On the Possible Divergence of the Projection Algorithm

Erjen Lefeber and Jan Willem Polderman

Abstract—It is shown by means of an example that the projection algorithm does not always converge.

I. INTRODUCTION

It is well known that parameter identification of linear systems depends very much on the excitation of the signals. Generally speaking, all identification algorithms require the signals to be sufficiently exciting. In applications such as adaptive control, however, excitation is often not possible. The question then arises how useful the standard identification schemes are. In this note we consider the case where the data can be modeled exactly by a linear time invariant discrete-time model. It is a fact, that for such systems recursive least squares always produce a convergent sequence of parameter estimates, although it is of course not guaranteed that the limit will be the true parameter [1].

For the projection algorithm a similar result or its negation is to the best of our knowledge not available in the literature. Properties that can be derived without any assumptions on the signals can be found in [1]. Nothing is said about convergence there (see also [2, Problem 12.14]). In [3], the algorithm is used for adaptive pole assignment. Since the adaptive algorithm could be analyzed without proving convergence of the parameter estimates, the possible convergence is not studied there either.

In this note we show by means of an example that the projection algorithm does not necessarily converge. This is in contrast with recursive least squares.

The construction of the counter example is as follows. Firstly we construct a sequence of real vectors that satisfies at least some of the properties of the projection algorithm and which does not converge. Secondly we show that the sequence could as well have been obtained by applying the projection algorithm to an appropriate input/output system. Hence, rather than fitting the estimates to the data, we fit the data to the estimates.

II. THE PROJECTION ALGORITHM

For the sake of completeness, we briefly describe the projection algorithm. Let the system be described by

$$y(k+1) = \bar{\theta}^T \phi(k) \quad \bar{\theta} \in \mathbb{R}^n. \quad (1)$$

The projection algorithm is defined as follows: Suppose that the estimate of $\bar{\theta}$ at time k is θ_k , define $G_{k+1} := \{\theta \in \mathbb{R}^n \mid y(k+1) = \theta^T \phi(k)\}$. Define θ_{k+1} as the orthogonal projection of θ_k on G_{k+1} . The recursion is given by

$$\theta_{k+1} = \theta_k + \frac{\phi(k)}{\|\phi(k)\|^2} (y(k+1) - \theta_k^T \phi(k)). \quad (2)$$

Notice that G_{k+1} contains the true parameter $\bar{\theta}$. Regardless of the input sequence, the following two properties hold.

- Property 2.1:** 1) For all k : $\|\bar{\theta} - \theta_{k+1}\| \leq \|\bar{\theta} - \theta_k\|$.
2) $\lim_{k \rightarrow \infty} (\theta_{k+1} - \theta_k) = 0$.

It is obvious that from Property 2.1 we cannot conclude that θ_k is a fundamental sequence, and in fact we will see that it need not be.

Fig. 1. The set S .

III. A COUNTEREXAMPLE

The idea of the counterexample is that we will first construct a sequence $(a_k, b_k) \in \mathbb{R}^2$ with the properties that:

- 1) (a_{k+1}, b_{k+1}) is obtained from (a_k, b_k) by orthogonally projecting the latter onto a line passing through a fixed point.
- 2) The sequence does not converge.

Notice that this sequence is constructed in a similar way as the sequence of estimates in the projection algorithm. Subsequently we will show that the particular sequence is equal to the sequence of estimates produced by applying the projection algorithm to a particular first-order system. That will establish the claim that the algorithm does not necessarily produce a convergent sequence of estimates. The key idea is that we fit the data to the estimates rather than the estimates to the data.

A. Construction of the Sequence

The sequence $\{a_k, b_k\}$ will be defined inductively

$$(a_0, b_0) := (1/2, 4). \quad (3)$$

Suppose now that (a_k, b_k) has been constructed. Let L_k be the line passing through $(1/2, 1)$ and (a_k, b_k) . Define (a_{k+1}, b_{k+1}) as the orthogonal projection on a line L_{k+1} yet to be defined. L_{k+1} will be a line passing through $(1/2, 1)$ with the property that the distance between (a_k, b_k) and its orthogonal projection on L_{k+1} is exactly $1/(k+1)$. There are two possibilities for L_{k+1} , one which requires a clockwise rotation of L_k to obtain L_{k+1} and one for which this rotation would be counter clockwise. This freedom of choice will now be used as follows. Define the region $S := \{(a, b) \mid -1 < -2a < b - 2 \wedge b > 1\}$. See Fig. 1. Determine the two possibilities for (a_{k+1}, b_{k+1}) . When both points are in S , rotate L_k in the same direction as L_{k-1} was rotated to obtain L_k , to get L_{k+1} , otherwise rotate L_k in the opposite direction. L_1 of course requires a counter clockwise rotation of L_0 . Notice that now every $(a_k, b_k) \in S$. Of course, the recursion could in principle be written in formulas; we feel, however, that this would not add much to our understanding.

Lemma 3.1: i) The sequence $\{(a_k, b_k)\}$ is well-defined. ii) The sequence $\{(a_k, b_k)\}$ does not converge.

Proof:

- i) Define $r_k := \sqrt{(1/2 - a_k)^2 + (1 - b_k)^2}$ and $\delta_{k+1} := \sqrt{(a_{k+1} - a_k)^2 + (b_{k+1} - b_k)^2}$. From the construction it follows that

$$r_{k+1}^2 + \delta_{k+1}^2 = r_k^2. \quad (4)$$

Since $\delta_{k+1} = 1/(k+1)$ it follows that

$$r_{k+1}^2 = r_k^2 - 1/(k+1)^2. \quad (5)$$

If we disregard for a moment the restriction imposed by S , we conclude that (a_{k+1}, b_{k+1}) can be constructed from (a_k, b_k) provided $r_k^2 - 1/(k+1)^2 > 0$. Now, from (5) it follows that

$$r_{k+1}^2 = r_0^2 - \sum_{j=0}^k 1/(j+1)^2 \quad (6)$$

hence we should have $r_0^2 > \pi^2/6$, since in our case $r_0^2 = 9$ this condition is satisfied.

As a byproduct we obtain that $\lim_{k \rightarrow \infty} r_k^2 = 9 - \pi^2/6$. It should be clear that from this we can also conclude that the requirement that $(a_k, b_k) \in S$ does not impose a restriction on the existence of the sequence.

- ii) From the fact that $r_k \rightarrow \sqrt{9 - \pi^2/6}$ and since $\delta_{k+1} = 1/(k+1)$, it follows that $\angle(L_k, L_{k+1})$ is $O(1/k+1)$. Therefore the sequence of lines $\{L_k\}$ does not converge and hence nor does $\{(a_k, b_k)\}$. \square

Lemma 3.2. Consider the i/o system

$$y(k+1) = (1/2)y(k) + u(k), \quad y(0) = 1.$$

There exists an input sequence $\{u(k)\}$, such that the projection algorithm, initialized in (a_0, b_0) generates $\{(a_k, b_k)\}$ as the sequence of estimates.

Proof: This is now easy. All we have to do is make sure that at time $k+1$, $G_{k+1} = L_{k+1}$, or equivalently, $(a_{k+1}, b_{k+1}) \in G_{k+1}$ and $y(k) \neq 0$. Otherwise stated $u(k)$ has to be such that

$$1/2 y(k) + u(k) = a_{k+1} y(k) + b_{k+1} u(k). \quad (7)$$

Hence we should take

$$u(k) = \frac{a_{k+1} - 1/2}{1 - b_{k+1}} y(k). \quad (8)$$

Since $(a_{k+1}, b_{k+1}) \in S$, this can indeed be done.

To complete the proof we have to check that for all k the output $y(k)$ will be nonzero. From (8) it follows that

$$y(k+1) = \left(1/2 + \frac{a_{k+1} - 1/2}{1 - b_{k+1}}\right) y(k). \quad (9)$$

Since $y(0) = 1$, and since $(a_{k+1}, b_{k+1}) \in S$, it follows from (9) that $y(k) \neq 0$.

Notice that since $(a_k, b_k) \in S$, we actually have that the sequences u and y are bounded. \square

We have now proved the following theorem.

Theorem 3.3: There exists a system of the form (1), a bounded input sequence u and an initialization of the projection algorithm, such that the resulting sequence of estimates does not converge.

IV. CONCLUSION

By means of an example, we have shown that the sequence of estimates generated by the projection algorithm does not necessarily converge. Of course, the sequence of inputs needed for the example is fairly artificial. In applications such as adaptive control, however, it is most desirable to derive as many properties of the identification part as possible without having to rely on the specific nature of the input. For the input will depend in a highly nonlinear fashion on the estimates. Our construction shows that convergence is not automatically among the properties that can be derived without additional assumptions on the input sequence.

A Comment on the Method of the Closest Unstable Equilibrium Point in Nonlinear Stability Analysis

E. Noldus and M. Loccupier

Abstract—A counterexample is presented to a theorem which has been proposed as a theoretical basis for the method of the closest unstable equilibrium point to estimate asymptotic stability regions in nonlinear systems. An additional condition is formulated under which the theorem is valid. Its implications on the applicability of the method are discussed.

I. INTRODUCTION

The method of the closest unstable equilibrium point (c.u.e.p.) is a well-known direct method of the Lyapunov type for estimating regions of asymptotic stability (RAS) in nonlinear systems analysis. The method has been described, among others, by Chiang *et al.* [1], [2] and various applications, for example to the power system transient stability problem have been reported [3]–[5]. Its basic principle is the following: Consider an autonomous nonlinear dynamical system

$$\dot{x} = f(x) \quad (1)$$

where $x \in R^n$ represents the state and $f(\cdot)$ satisfies the sufficient conditions for the existence and the uniqueness of the solutions for given initial conditions. Suppose that a scalar function $V(x) \in C^n$, $n \geq 1$, can be found such that along the solutions of (1)

$$\begin{aligned} \dot{V}(x) &\leq 0, \forall x \in R^n \\ &= 0 \Leftrightarrow \dot{x} = 0. \end{aligned} \quad (2)$$

By (2), $V(x)$ is a Lyapunov function of (1) in R^n . Let \bar{x}_* be a locally asymptotically stable (l.a.s.) equilibrium state and let $\Omega(\bar{x}_*) \subset R^n$ be its exact RAS. Suppose that on the stability boundary $\partial\Omega(\bar{x}_*)$, $V(x)$ reaches an absolute minimum at $x = \hat{x}_*$ and let

$$\min_{x \in \partial\Omega(\bar{x}_*)} V(x) = V(\hat{x}_*) = V_{\min}. \quad (3)$$

Then it is well known that \hat{x}_* is an unstable equilibrium point of the system (1) [1]. Furthermore for any k in the interval

$$V(\hat{x}_*) < k \leq V_{\min}$$

the set

$$S \triangleq \{x: V(x) < k\}$$

the union of a number of connected, disjoint subsets

$$S = S_1 \cup S_2 \cup \dots \cup S_i;$$

$$S_i \cap S_j = \emptyset \quad \text{for } i \neq j$$

Fig. 1. Phase portrait of the system (5), (6) and level sets ∂S_1 for varying level values k , for the numerical values $a = 2$, $b = 1$, $\mu = 0.8$.

one of which, say S_1 contains \hat{x}_* . This subset S_1 is a RAS for \hat{x}_*

$$S_1 \subseteq \Omega(\hat{x}_*).$$

The largest stability region S_1 is obtained for $k = V_{\min}$. In [1] Chiang and Thorp have reported a theorem pertaining to the existence of the minimum V_{\min} , and a scheme for computing the corresponding stability region S_1 based on it.

Theorem [1]: If system (1) has a Lyapunov function $V(x)$ in R^n which satisfies (2) and if $\Omega(\hat{x}_*)$ is not dense in R^n , then V_{\min} as defined by (3) exists and \hat{x}_* is an unstable equilibrium state.

The proof relies on the property that if for $k = q$ the set \bar{S}_1 is a closed and bounded neighborhood of \hat{x}_* which contains no other equilibria, and if for some $p > q$ there are no equilibrium states in the set $\bar{S}_1|_{k=p} - \bar{S}_1|_{k=q}$ then

$$\bar{S}_1|_{k=p} \text{ is also closed and bounded.} \quad (4)$$

In Section II a counterexample to this result and to the property (4) is presented. It is pointed out, however, that the theorem is valid under the additional assumption that all trajectories on the stability boundary $\partial\Omega(\hat{x}_*)$ are bounded for $t \geq 0$. Section III discusses the implications of this proposition for the c.u.e.p. method.

II. EXAMPLE

Consider an example of the form

$$\dot{x} = f(x) \triangleq -\frac{\partial V(x)}{\partial x} \quad (5)$$

where $x \in R^2$ and

$$V(x) \triangleq e^{-x_1} - (2x_2^2 - x_2^4)v_1(x_1) \quad (6)$$

with

$$v_1(x_1) = [e^{-x_1} + ae^{-\mu x_1^2} + b]$$

and $a > 0$, $b > 0$ and $\mu > 0$. Then

$$\dot{V}(x) = \left[\frac{\partial V(x)}{\partial x} \right]^T \dot{x} = -\dot{x}^T \dot{x} \quad (7)$$

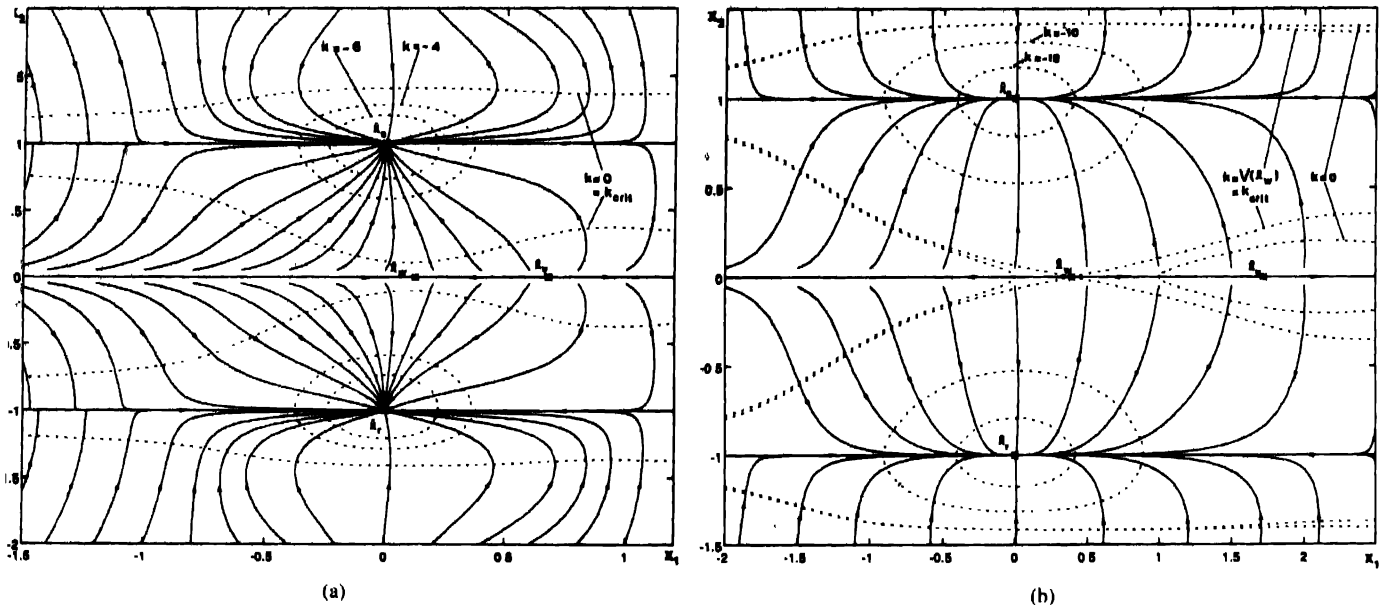

Fig. 2. Phase portrait and level sets ∂S_1 for the system (5), (8) and a): for the numerical values $a = 8$, $b = 1$, $c = 0.75$, $\mu = 5$ (V_{\min} does not exist.); b): $a = 20$, $b = 1$, $c = 1$, $\mu = 1$ ($V_{\min} = V(\hat{x}_m)$).

such that $V(x)$ is a Lyapunov function in R^2 which satisfies the conditions (2). Differentiating $V(x)$ w.r.t. x_1 and x_2 yields the state equations

$$\begin{aligned}\dot{x}_1 &= e^{-x_1} - (2x_2^2 - x_2^4) \\ &\quad \cdot [e^{-x_1} + 2\mu a x_1 e^{-\mu x_1^2}] \\ \dot{x}_2 &= 4x_2(1 - x_2^2) \\ &\quad \cdot [e^{-x_1} + a e^{-\mu x_1^2} + b].\end{aligned}$$

The phase portrait is symmetric w.r.t. the x_1 -axis. There are two equilibrium states, $\hat{x}_s = (0, 1)$ and $\hat{x}_r = (0, -1)$. Computing the Jacobian $J(x) = \partial f(x)/\partial x$ and substituting the coordinates of the equilibria produces $J(\hat{x}_s) = J(\hat{x}_r) = \text{diag} [-2\mu a, -8(1 + a + b)]$, such that \hat{x}_s and \hat{x}_r are stable nodes. Furthermore

$$\begin{aligned}x_2 = 0 &\Rightarrow \dot{x}_2 = 0; \\ \dot{x}_1 &= e^{-x_1} \\ x_2 = \pm 1 &\Rightarrow \dot{x}_2 = 0; \\ \dot{x}_1 &= -2\mu a x_1 e^{-\mu x_1^2}\end{aligned}$$

such that there is a single trajectory coinciding with the x_1 -axis, while the straight lines $x_2 = 1$ and $x_2 = -1$ each consist of two trajectories converging to, respectively, \hat{x}_s and \hat{x}_r for $t \rightarrow +\infty$. Finally all solutions are bounded for $t \geq 0$, except the solution whose trajectory coincides with the x_1 -axis (see Appendix A). Because of (7) all solutions which are bounded for $t \geq 0$ converge to an equilibrium state as $t \rightarrow +\infty$. Fig. 1 displays the system's phase portrait. Replacing (6) by

$$V(x) \triangleq e^{-x_1} - c e^{-\mu x_1^2} - (2x_2^2 - x_2^4)v_2(x_1) \quad (8)$$

where $a > 0$, $b > 0$, $c > 0$, $\mu > 0$ and

$$v_2(x_1) = [e^{-x_1} + (a - c)e^{-\mu x_1^2} + b]$$

produces a slightly modified example with state equations

$$\begin{cases} \dot{x}_1 = e^{-x_1} - 2\mu c x_1 e^{-\mu x_1^2} + (2x_2^2 - x_2^4) \frac{dv_2(x_1)}{dx_1} \\ \dot{x}_2 = 4x_2(1 - x_2^2)v_2(x_1) \end{cases} \quad (9)$$

where $dv_2(x_1)/dx_1 = -[e^{-x_1} + 2\mu(a - c)x_1 e^{-\mu x_1^2}]$.

If $a \geq c$ and c is sufficiently large, then the structure of the phase portrait is identical to the previous one, except that there are two additional equilibrium states $\hat{x}_m(p, 0)$ and $\hat{x}_n(q, 0)$ on the positive x_1 -axis. It is easily verified that \hat{x}_m (closest to the origin) is a saddle point and \hat{x}_n is an unstable node. Now there are three trajectories on the x_1 -axis (see Fig. 2(a) and (b)). In both examples $\Omega(\hat{x}_s) = \{x; x_2 > 0\}$ and $\Omega(\hat{x}_r) = \{x; x_2 < 0\}$ while $\partial\Omega(\hat{x}_s) = \partial\Omega(\hat{x}_r) = \{x; x_2 = 0\}$.

For the first example Fig. 1 shows the set S_1 for increasing values of $k > V(\hat{x}_s) = -(a + b)$. Note that $\lim_{x_1 \rightarrow -\infty} V(x) \triangleq V_1(x_2) = -b(2x_2^2 - x_2^4)$, which reaches an absolute minimum $V_{\min}(x_2) = -b$ at $x_2 = \pm 1$, and a relative maximum $V_{\max}(x_2) = 0$ at $x_2 = 0$.

Recall that the stability boundary $\partial\Omega(\hat{x}_s) = \partial\Omega(\hat{x}_r)$ coincides with the axis $x_2 = 0$. Hence S_1 remains bounded for $-(a + b) < k < -b$, but it becomes unbounded for $-b \leq k \leq 0$. It remains a region of attraction for \hat{x}_s as long as $k \leq 0$. The unboundedness of S_1 for $-b \leq k \leq 0$ contradicts (4). Although the system has a Lyapunov function in R^2 which satisfies (2) and $\Omega(\hat{x}_s)$ is not dense in R^2 , $V(x)$ does not have a minimum on $\partial\Omega(\hat{x}_s)$, which is counterexample to Chiang's [1] theorem quoted above.

III. DISCUSSION

In the procedure sketched in the introduction the set S_1 grows monotonically and continuously for increasing $k > V(\hat{x}_s)$, since $V(x) \in C^1$ where $r \geq 1$. S_1 remains a region of attraction of \hat{x}_s as long as ∂S_1 does not intersect the stability boundary $\partial\Omega(\hat{x}_s)$. Let

$$V_0 \triangleq \inf_{x \in \partial\Omega(\hat{x}_s)} V(x). \quad (10)$$

Then the largest obtainable stability region of the form S_1 corresponds to the critical value $k_{crit} = V_0$. In the first example $V_0 = 0$. If $V(x)$ possesses an absolute minimum V_{\min} for $x \in \partial\Omega(\hat{x}_s)$, then $V_0 = V_{\min}$. The existence of a minimum is guaranteed if

$$\text{All trajectories on } \partial\Omega(\hat{x}_s) \text{ are bounded for } t \geq 0 \quad (11)$$

and hence by (2) converge to an equilibrium state as $t \rightarrow +\infty$ (see Appendix B). So (11) constitutes an additional (sufficient) condition which guarantees the applicability of the c.u.e.p. method. Property (11) certainly holds if it can be shown that $\Omega(\hat{x}_s)$ is bounded, or if it can be shown that all trajectories are bounded

Fig. 3. Phase portrait and level sets ∂S_1 for the system (5), (8) and for the numerical values $a = 2$, $b = 1$, $\mu = 0.8$.

for $t \geq 0$. The latter property can often be proved using a suitable Lyapunov function. For example if $V(x)$ satisfies (2) and is radially unbounded, then all solutions are bounded for $t \geq 0$. In [6], [7] the structure of the stability boundary has been studied under a set of assumptions including the convergence of all solutions on $\partial\Omega(\hat{x}_*)$ to an equilibrium state.

The second example shows that even when there are equilibrium states on $\partial\Omega(x_*)$, V_{\min} does not necessarily exist. If

$$V(x_n) = e^{-\mu} - e^{-\mu\rho^2} > \lim_{t \rightarrow +\infty} V(x) = 0$$

then V_{\min} does not exist, while $V_0 = 0$. This case is illustrated in Fig. 2(a). If $V(\hat{x}_n) < 0$ then V_{\min} exists and the c.u.e.p. method can be applied with $k_{crit} = V(\hat{x}_n)$ (see Fig. 2(b)).

If V_{\min} does not exist then in general $k_{crit} = V_0$ cannot be determined since in (10), $\partial\Omega(x_*)$ is unknown. In such cases the only conclusion possible is that for increasing k the set S_1 remains a RAS as long as it is bounded and does not contain other equilibria than x_* . To illustrate the latter point consider a final example of the form (5) where

$$V(x) \triangleq e^{-x_1} - \varphi(x_2)[e^{-x_1} + ae^{-\mu x_1^2} + b] \quad (12)$$

and

$$\begin{aligned} \varphi(x_2) &\triangleq 2x_2^2 - x_2^4 \quad \text{for } x_2 \geq 0 \\ &\triangleq 0 \quad \text{for } x_2 < 0. \end{aligned}$$

Note that $V(x) \in C^1$. This system's phase portrait is identical to the phase portrait of Fig. 1 in the half plane $x_2 \geq 0$, while for $x_2 < 0$ all trajectories are straight lines parallel to the x_1 -axis ($x_2 = \text{constant}$; $x_1 \rightarrow +\infty$ for $t \rightarrow +\infty$). The system has a single equilibrium state $\hat{x}_*(0, 1)$ with stability region $\Omega(\hat{x}_*) = \{x: x_2 > 0\}$.

For increasing k the set S_1 remains a RAS of \hat{x}_* as long as it is bounded. For $k > 0$, S_1 is unbounded and contains trajectories that converge to infinity for $t \rightarrow +\infty$, hence it is not a RAS any more (see Fig. 3). The critical value $k_{crit} = 0$ cannot be determined if the stability boundary $\partial\Omega(\hat{x}_*)$ is unknown.

Finally it should be stressed that (11) is only a sufficient but not a necessary condition for the existence of an absolute minimum of $V(x)$ for $x \in \partial\Omega(\hat{x}_*)$. Any other sufficient condition for the existence of the minimum yields a valid alternative version of the fundamental theorem of the c.u.e.p. method. In [2, Theorem 9], and

in [8, Theorem 4.1], Chiang has provided such an alternative which is suitable for studying the power system transient stability problem. An energy function $V(x)$ is introduced, which for the application to the power system model plays the role of a Lyapunov function, upon which three conditions are imposed:

- 1) Along any trajectory $x(t)$, $\dot{V}(x(t)) \leq 0$.
- 2) Along any nontrivial trajectory the set $\{t \in R; \dot{V}(x(t)) = 0\}$ has measure zero in R .
- 3) Along any trajectory, if $V(x(t))$ is bounded then $x(t)$ is bounded.

The conditions of Theorem 4.1 in [8] guarantee the existence of an absolute minimum of the energy function on the stability boundary. In fact Chiang has shown that under these conditions the c.u.e. point, where the absolute minimum is reached, is generically unique.

APPENDIX

A. Proof of the Boundedness of Solutions

Since the Lyapunov function (6) is a special case of (8) consider the system defined by (5), (8). Let

$$W(x) \triangleq (1 - x_2^2)^2.$$

Then using (9)

$$\begin{aligned} \dot{W}(x) &= -16x_2^2(1 - x_2^2)^2 v_2(x_1) \\ &\leq -16x_2^2(1 - x_2^2)^2 b \leq 0 \end{aligned} \quad (13)$$

since $a \geq c$, (13) implies that

$$\min[x_2^2(0), 1] \leq x_2^2(t) \leq \max[x_2^2(0), 1] \quad (14)$$

$\forall t \geq 0$ such that

$$\dot{W}(x) \leq -\lambda_1 W(x)$$

hence

$$W(x) \leq [1 - x_2^2(0)]^2 e^{-\lambda_1 t}; \quad \forall t \geq 0 \quad (15)$$

where $\lambda_1 \triangleq 16b \min[x_2^2(0), 1] > 0$ if $x_2(0) \neq 0$. Furthermore by (9)

$$\dot{x}_1 = (1 - x_2^2)^2 [e^{-x_1} + 2\mu(a - c)x_1 e^{-\mu x_1^2}] - 2\mu a x_1 e^{-\mu x_1^2} \quad (16)$$

hence

$$\dot{x}_1 > 0 \quad \text{for } x_1 \leq -m \text{ and } m \text{ sufficiently large.} \quad (17)$$

Finally by (16), $x_1 = 0$ and $x_2^2 \neq 1$ imply that $\dot{x}_1 > 0$, such that $x_1(0) > 0$ implies that $x_1(t) > 0$ for all $t \geq 0$. Now by (16)

$$\dot{x}_1 \leq (1 - x_2^2)^2 (1 + n) e^{-x_1} \quad \text{for } n > 0 \text{ and sufficiently large}$$

or, defining $\rho \triangleq (1 + n)[1 - x_2^2(0)]^2$, $y \triangleq e^{-x_1}$ and using (15)

$$\dot{y} \leq \rho e^{-\lambda_1 t}.$$

Integrating the latter expression yields

$$y(t) \leq y_0 - \frac{\rho}{\lambda_1} e^{-\lambda_1 t} < y_0; \quad \forall t \geq 0$$

and for some finite y_0 . It follows that

$$x_1(t) \leq \ln y_0 < \infty; \quad \forall t \geq 0 \quad (18)$$

if $x_1(0) > 0$ and $x_2(0) \neq 0$. (14), (17) and (18) prove the boundedness for $t \geq 0$ of all solutions for which $x_2(0) \neq 0$.

B. Existence of V_{\min}

Let $\hat{X} \triangleq \{\hat{x}_1, \dots, \hat{x}_m\}$ be the set of equilibrium points on $\partial\Omega(\hat{x}_*)$ and let $V_{\min} \triangleq \min V(\hat{x}_i)$ for $i = 1 \dots m$. If $x_0 \in \partial\Omega(\hat{x}_*)$ then the trajectory starting at x_0 at $t = 0$ converges to an equilibrium point $\hat{x}_i \in \partial\Omega(\hat{x}_*)$. Since along this trajectory $V(x)$ is nonincreasing it follows that $V(x_0) \geq V(\hat{x}_i) \geq V_{\min}$ for all $x_0 \in \partial\Omega(\hat{x}_*)$. This proves the existence of the minimum of $V(x)$ on $\partial\Omega(\hat{x}_*)$.

Boundaries of Conditional Quadratic Forms—A Comment on "Stabilization via Static Output Feedback"

D. Cheng and C. F. Martin

Abstract—Motivated by the above paper,¹ this note considers the boundaries of a quadratic form with all possible constraints over a given subspace. Essential upper (or lower) bounds are presented provided they exist. It mends a mild incompleteness in the proof of the main result.

1. INTRODUCTION

It is well known (see, e.g., [2]) that for a real symmetric matrix M

$$\min \sigma(M) \leq \frac{x^T M x}{x^T x} \leq \max \sigma(M), x \neq 0 \quad (1)$$

where $\sigma(M)$ is the set of eigenvalues of M .

In the above paper, necessary and sufficient conditions for the existence of a stabilizing static output feedback gain matrix were presented. In the proof of the main result, Theorem 3.1, the following fact was used (for the sake of consistency we use our notations).

Given a real symmetric matrix: $M_{n \times n}$, and a matrix $K_{m \times n}$ with $\text{rank}(K) = r < n$. Assume

$$x^T(M)x < 0; \forall x \in \text{Ker}(K). \quad (2)$$

Then

$$\alpha = \sup_{x \notin \text{Ker}(K)} \frac{x^T M x}{x^T K^T K x} < \infty, x \notin \text{Ker}(K). \quad (3)$$

Manuscript received January 26, 1994; revised June 28, 1994.

C. F. Martin is with the Department of Mathematics, Texas Tech University, Lubbock, TX 79409 USA.

IEEE Log Number 9407224.

A mild incompleteness in the proof¹ is: They did not claim and prove that the α (defined in (3.4), which is the same as in (3)), is upper bounded, i.e., $\alpha < +\infty$. It is essential for constructing R ($R^{-1} \geq \alpha I$). It was pointed by a nominated reviewer that this boundedness is also assumed in [2] without proof. From the following discussion one sees that this fact is not trivial. We call it the problem of boundaries of conditional quadratic forms. It can be considered as a generalization of (1), because when $\dim(K) = 0$, our results in this note will coincide with (1).

In the next section we prove (3) by giving the essential upper bound, which may be of independent interest. Then in Section III we discuss all other constraints.

II. MAIN RESULT

Let the matrices $M_{n \times n}$, $K_{m \times n}$, with $\text{rank}(K) = r < n$, be as above. Then there exists a linear transformation Φ such that

$$K\Phi = (S \quad 0)$$

where S is the first r columns, and thus S has full rank. It follows that $S^T S$ is a positive definite matrix, so we can define a positive definite E as

$$E = (S^T S)^{1/2} > 0. \quad (4)$$

It is easy to prove that (2) is equivalent to the fact that after the linear transformation Φ , M has the following form

$$\Phi^T M \Phi = \begin{pmatrix} A & B \\ B^T & -Q \end{pmatrix}. \quad (5)$$

Then we define a characteristic matrix C as

$$C = E^{-1}(A + BQ^{-1}B^T)E^{-1}. \quad (6)$$

Using the above notations, we can prove the following theorem.

Theorem 1: Under condition (2), we have the essential upper bound as

$$\sup_{x \notin \text{Ker}(K)} \frac{x^T M x}{x^T K^T K x}, x \notin \text{Ker}(K) = \max \sigma(C). \quad (7)$$

Proof: It is clear that $x \in \text{Ker}(K)$, if and only if

$$y = \Phi^{-1}x = \begin{pmatrix} 0 \\ y_2 \end{pmatrix}.$$

Since Q is positive definite, $Q^{1/2} > 0$ is well defined. Using (5), a straightforward computation shows that

$$\begin{aligned} \sup_{x \notin \text{Ker}(K)} \frac{x^T M x}{x^T K^T K x}, x \notin \text{Ker}(K) &= \sup_y \frac{y^T \begin{pmatrix} A & B \\ B^T & -Q \end{pmatrix} y}{y^T \begin{pmatrix} S^T S & 0 \\ 0 & 0 \end{pmatrix} y} \\ &= \sup_y \frac{y_1^T (A + BQ^{-1}B^T)y_1 - \|Q^{1/2}y_2 - Q^{-1/2}B^T y_1\|^2}{y_1^T S^T S y_1} \\ &= \sup_{y_1 \neq 0} \frac{y_1^T (A + BQ^{-1}B^T)y_1}{y_1^T S^T S y_1} \end{aligned} \quad (8)$$

¹ A. Trofino-Neto and V. Kucera, *IEEE Trans. Automat. Contr.*, vol. 38, no. 5, pp. 764-765, May 1993.

where

$$y = \Phi^{-1}x = \begin{pmatrix} y_1 \\ y_2 \end{pmatrix}, \quad y_1 \neq 0.$$

The last equality is obtained by setting $y_2 = Q^{-1}B^T y_1$.

Recalling the definitions of E and C in (4) and (6), we get

$$\begin{aligned} & \sup_{y_1 \neq 0} \frac{y_1^T (A + BQ^{-1}B^T)y_1}{y_1^T S^T S y_1} \\ &= \sup_{Z \neq 0} \frac{Z^T C Z}{Z^T Z}, \text{ where } Z = E y_1. \end{aligned}$$

From (1), it can be seen that

$$\begin{aligned} & \sup_x \frac{x^T M x}{x^T K^T K x}, x \notin \text{Ker}(K) \\ &= \max \sigma(C) < +\infty. \end{aligned} \quad (9)$$

Since the transformation Φ is not unique, the last thing we have to do is to show that the essential upper bound obtained in (9) is independent of the choice of Φ . Theoretically, essential upper bound is unique. But, we use a particular Φ to get it, and the parameters A, B, C, E , etc. in the expression depend on Φ . So we must show that the upper bound is independent of Φ . Let $\tilde{\Phi} = (\tilde{\phi}_1 | \tilde{\phi}_2)$, where $\text{Span}(\phi_2) = K^\perp$, be another suitable linear transformation, and $\tilde{\Phi} = \Phi T = (\phi_1 | \phi_2)T$. Since $\text{Span}(\phi_2) = \text{Span}(\tilde{\phi}_2) = K^\perp$, it follows that

$$T = \begin{pmatrix} T_1 & 0 \\ T_2 & T_3 \end{pmatrix}.$$

Now, a straightforward computation shows that the corresponding expressions under the new transformation are

$$\begin{aligned} & \begin{pmatrix} S^T S & 0 \\ 0 & 0 \end{pmatrix} = (K\tilde{\Phi})^T (K\tilde{\Phi}) \\ &= T^T (K\Phi)^T (K\Phi) T = \begin{pmatrix} T_1^T S^T S T_1 & 0 \\ 0 & 0 \end{pmatrix} \end{aligned}$$

and

$$\begin{aligned} & \begin{pmatrix} A & B \\ \tilde{B}^T & -\tilde{Q} \end{pmatrix} = \begin{pmatrix} T_1^T & T_2^T \\ 0 & T_3^T \end{pmatrix} \begin{pmatrix} A & B \\ B^T & -Q \end{pmatrix} \begin{pmatrix} T_1 & 0 \\ T_2 & T_3 \end{pmatrix} \\ &= \begin{pmatrix} T_1^T A T_1 + T_2^T B^T T_1 + T_1^T B T_2 - T_2^T Q T_2 & T_1^T B T_3 - T_2^T Q T_3 \\ T_1^T B^T T_1 - T_1^T Q T_2 & -T_1^T Q T_3 \end{pmatrix}. \end{aligned} \quad (10)$$

Using them, we finally have $\tilde{S}^T \tilde{S} = T_1^T S^T S T_1$, $\tilde{A} + \tilde{B} \tilde{Q}^{-1} \tilde{B}^T = T_1^T (A + BQ^{-1}B^T)$.

Therefore, the parameters obtained by the new transformation provide

$$\begin{aligned} & \sup_{y_1 \neq 0} \frac{y_1^T (A + \tilde{B} \tilde{Q}^{-1} \tilde{B}^T) y_1}{y_1^T \tilde{S}^T \tilde{S} y_1} \\ &= \sup_{Z \neq 0} \frac{Z^T C Z}{Z^T Z}, \text{ where } Z = E T_1 y_1. \end{aligned}$$

Q.E.D

III. GENERALIZATION

As we mentioned before, conditional quadratic form (3) is a generalization of the famous result (1). So the boundary problem of expression (3) has both theoretical and practical interests. To make (3) meaningful $x \notin \text{Ker}(K)$. Moreover, without constrain on $\text{Ker}(K)$ expression (3) has no boundary. (2) is a particular constrain. This section consider all other possible constraints on subspace $\text{Ker}(K)$. They may be applied to mini-max problems of quadratic forms.

Case 2: Condition (2) is replaced by

$$x^T (M)x > 0; \forall x \in \text{Ker}(K). \quad (11)$$

In this case, replace $-Q$ by Q in (5) and redefine C in (6) accordingly. Then a parallel discussion shows the following corollary.

Corollary 1: Under condition (11), we have

$$\sup_x \frac{x^T M x}{x^T K^T K x}, x \notin \text{Ker}(K) = \min \sigma(C). \quad (12)$$

Case 3: Assume now we have

$$x^T (M)x = 0; \forall x \in \text{Ker}(K). \quad (13)$$

In this case replace Q by zero in (5). Equation (8) becomes

$$\begin{aligned} & \sup_x \frac{x^T M x}{x^T K^T K x}, x \notin \text{Ker}(K) \\ &= \sup_y \frac{y_1^T (A) y_1 + 2 y_2^T B^T y_1}{y_1^T S^T S y_1}. \end{aligned} \quad (14)$$

From (14) one sees the following corollary.

Corollary 2: Under condition (13), if $B \neq 0$

$$\frac{x^T M x}{x^T K^T K x}, x \notin \text{Ker}(K)$$

has neither upper bound nor lower bound. If $B = 0$

$$\begin{aligned} \min \sigma(E^{-1} M E^{-1}) &\leq \frac{x^T M x}{x^T K^T K x} \leq \max \sigma(E^{-1} M E^{-1}), \\ x &\notin \text{Ker}(K). \end{aligned}$$

Proof: Observe (14). If $B = 0$, the conclusion follows from the standard result (1). If $B \neq 0$, choose

$$y_2 = \mu B^T y_1, \mu \in R.$$

Letting μ go to either $-\infty$ or $+\infty$, one sees that neither upper bound nor lower bound exist. Q.E.D.

Note that in Case 3 we have from (10) that $B = T_1^T B T_3$, and T_1 and T are nonsingular. It is clear that the conclusion in the above corollary is independent of the linear transformation.

Case 4. Assume

$$x^T (M)x \leq 0; \forall x \in \text{Ker}(K). \quad (15)$$

In this case the matrix Q in (5) is positive semi-definite. Then we have the following corollary.

Corollary 3: Under condition (15), if there exists a matrix H with suitable dimension such that $B = H Q$, then

$$\begin{aligned} \sup_x \left(\frac{x^T M x}{x^T K^T K x} \right) &= \max \sigma(E^{-1} (A + H Q H^T) E^{-1}), \\ x &\notin \text{Ker}(K). \end{aligned}$$

Otherwise

$$\frac{x^T M x}{x^T K^T K x}, x \notin \text{Ker}(K)$$

has neither upper bound nor lower bound.

Proof: Let $B = H Q$. Then we can choose

$$T = \begin{pmatrix} I & 0 \\ H^T & I \end{pmatrix}.$$

From (10), new M is block diagonal, and then (8) becomes

$$\begin{aligned} & \sup_x \frac{x^T M x}{x^T K^T K x}, x \notin \text{Ker}(K) \\ &= \sup_y \frac{y_1^T (A + H Q H^T) y_1 - y_2^T Q y_2}{y_1^T S^T S y_1} \\ &\leq \sup_{y_1} \frac{y_1^T (A + H Q H^T) y_1}{y_1^T S^T S y_1}. \end{aligned}$$

The conclusion follows.

If $B \neq HQ$, the rows of B are not all in $\text{Span row } Q$. Without loss of generality we assume

$$Q = \begin{pmatrix} Q_1 & 0 \\ 0 & 0 \end{pmatrix}, \text{ where } Q_1 > 0$$

and partition y_2 as

$$y_2 = \begin{pmatrix} y_{21} \\ y_{22} \end{pmatrix}.$$

Now (8) has the form

$$\frac{x^T M x}{x^T K^T K x}, \quad x \notin \text{Ker}(K) \\ \frac{y_1^T (A)y_1 + 2(y_{21}^T, y_{22}^T) B^T y_1 - t_{21}^T Q_1 y_{21}}{y_1^T S^T S y_1}.$$

The condition: "rows of B are not all in $\text{Span row } Q$ " implies that $3y_{22}$ is not always zero. It is obvious that this term can make the value of the fraction be both positive and negative unbounded.

One can also see from (10) that the condition $B = HQ$ is independent of the linear transformation.

Q.E.D.

Case 5: Assume

$$x^T (M)x \geq 0; \forall x \in \text{Ker}(K). \quad (19)$$

In this case replace $-Q$ by a positive semi-definite Q in (5). Similar to the proof of Case 4, we can show the following.

Corollary 4: Under condition (19), if there exists a suitable dimensional matrix H such that $B = HQ$, then

$$\inf_{x \notin \text{Ker}(K)} \left(\frac{x^T M x}{x^T K^T K x} \right) = \min \sigma(E^{-1}(A + HQH^T)E^{-1}),$$

Otherwise

$$\frac{x^T M x}{x^T K^T K x}, x \notin \text{Ker}(K)$$

has neither upper bound nor lower bound.

IV. CONCLUSION

In this note we discussed the problem of finding the boundaries of conditional quadratic forms with all possible constraints over a subspace. In all cases, the necessary and sufficient conditions for the existence of upper and/or lower bounds are presented. The essential bounds are obtained whenever they exist.

On Robust Stability of 2-D Discrete Systems

W.-S. Lu

Abstract—This note presents a study on robust stability of two-dimensional (2-D) discrete systems in the Fornasini-Marchesini (F-M) state space setting. A measure of stability robustness of a stable F-M model is defined. Relation of this measure to its counterpart in the Roesser state space and related computational issues are addressed. Three lower bounds of the stability-robustness measure defined are derived using an one-dimensional parameterization approach and a 2-D Lyapunov approach. A numerical example is included to illustrate the main results obtained.

1. INTRODUCTION

In this note, we present a study on robust stability of two-dimensional (2-D) discrete systems under unstructured perturbations. Throughout the concerned system is modeled in the Fornasini-Marchesini (F-M) local state space [1] as

$$x(i+1, j+1) = A_1 x(i, j+1) + A_2 x(i+1, j) \quad (1)$$

where $x(i, j) \in R^{n \times 1}$, $A_1, A_2 \in R^{n \times n}$. Recall that system (1) is asymptotically stable if and only if

$$\rho(z_1, z_2) \equiv \det(I_n - z_1 A_1 - z_2 A_2) \neq 0 \text{ for } (z_1, z_2) \in \bar{U} \quad (2)$$

where $\bar{U} = \{(z_1, z_2) : |z_1| \leq 1, |z_2| \leq 1\}$ [1]. To date, results on robust stability of 2-D discrete systems in a local state-space framework are only available for the Roesser model [2]–[6], and one might attribute this to the lack of a Lyapunov stability theory for the F-M model. The objectives of this note are twofold. First, we propose in Section II a quantitative measure, ν , for the unstructured, stable perturbations of a given stable 2-D F-M system, and derive in Section III a lower bound for ν . Issues on numerical evaluation of the bound obtained and the relation of the proposed stability robustness measure with its counterpart in the Roesser state space will also be addressed. Second, we propose in Section IV a Lyapunov approach to analyzing the robust stability of (1), leading to two lower bounds of ν . The proposed approach makes use of the 2-D Lyapunov equation [7] which is a generalization of the 2-D Lyapunov equation investigated recently by Hinamoto [8]. A numerical example is included in Section V to illustrate the main results of the paper.

In the rest of the paper we write $H > 0$ or $H \geq 0$ to mean that the symmetric matrix H is positive definite or positive semi-definite. For a real matrix $P \geq 0$, one can always write

$$P = U^{-1} \Sigma U$$

where U is orthogonal and $\Sigma = \text{diag}\{\sigma_1, \dots, \sigma_n\}$ with $\sigma_k \geq 0$, for $1 \leq k \leq n$. If we denote $\Sigma^{1/2} = \text{diag}\{\sigma_1^{1/2}, \dots, \sigma_n^{1/2}\}$, then

$$P = P^{1/2} P^{1/2}$$

where

$$P^{1/2} = \Sigma^{1/2} U \text{ and } P^{T/2} = (P^{1/2})^T.$$

Such a $P^{1/2}$ is called the nonsymmetric square root of P . The largest and smallest singular value of matrix H is denoted by $\tilde{\sigma}(H)$ and

$\sigma(H)$, respectively, $\|H\|$ denotes the induced 2-norm of H , which is equal to $\bar{\sigma}(H)$. Throughout we shall use A to denote the $n \times 2n$ real matrix $[A_1 \ A_2]$ where A_1 and A_2 are from (1) and call it the system matrix of (1). A is said to be stable if (1) is stable i.e., A satisfies (2).

II. A MEASURE OF ROBUST STABILITY OF SYSTEM (1)

For asymptotically stable system (1), let $A = [A_1 \ A_2]$ and denote by S_u the set of all complex perturbations $\Delta A = [\Delta A_1 \ \Delta A_2] \in \mathbb{C}^{n \times 2n}$ with $A + \Delta A$ unstable, i.e.,

$$S_u = \{\Delta A : [\Delta A_1 \ \Delta A_2] \in \mathbb{C}^{n \times 2n}, A + \Delta A \text{ unstable}\}. \quad (3)$$

Two sets of matrices can be induced from set S_u as follows

$$S_{u1} = \{\Delta A_1 : \Delta A_1 \in \mathbb{C}^{n \times n}, [\Delta A_1 \ 0] \in S_u\} \quad (4)$$

$$S_{u2} = \{\Delta A_2 : \Delta A_2 \in \mathbb{C}^{n \times n}, [0 \ \Delta A_2] \in S_u\}. \quad (5)$$

In words, S_{u1} and S_{u2} are the collection of the first and the second $n \times n$ blocks, respectively, each of which itself causes system instability.

A measure for robust stability of system (1) is defined as

$$\nu = \inf_{\Delta A \in S_u} \|\Delta A\|. \quad (6)$$

Obviously, a perturbed system with system matrix $A + \Delta A$ is stable if $\|\Delta A\| < \nu$.

With the sets S_{u1} and S_{u2} defined in (4) and (5), two auxiliary quantities can be introduced as

$$\mu_1 = \inf_{\Delta A_1 \in S_{u1}} \|\Delta A_1\| \text{ and } \mu_2 = \inf_{\Delta A_2 \in S_{u2}} \|\Delta A_2\|. \quad (7)$$

Since $S_{u1} \subset S_u$ and $S_{u2} \subset S_u$, we have $\nu \leq \mu_1$, $\nu \leq \mu_2$, and hence

$$\nu \leq \min(\mu_1, \mu_2). \quad (8)$$

Shortly we shall see that a relation similar to (8) also holds when the system is modeled in Roesser state space.

Like the 1-D case, ν defined in (6) will be referred to as the stability radius for unstructured complex perturbations for state-space model (1). Since perturbations for a physical 2-D plant are always of real value, a more realistic robust stability measure can be defined as

$$\nu_r = \inf_{\Delta A \in T_u} \|\Delta A\|$$

where T_u is the set of all real perturbations $\Delta A = [\Delta A_1 \ \Delta A_2] \in \mathbb{R}^{n \times 2n}$ with $A + \Delta A$ unstable, i.e.,

$$T_u = \{\Delta A : [\Delta A_1 \ \Delta A_2] \in \mathbb{R}^{n \times 2n}, A + \Delta A \text{ unstable}\}.$$

Note that T_u is a proper subset of S_u and consequently the stability radius for unstructured real perturbations, ν_r , is always no less than ν . This means that ν_r is indeed a less conservative measure for stability robustness. For the 1-D case, the real stability radius has been investigated [17]–[22] and a complete solution has been obtained very recently by Qiu *et al.* [22]. The generalization of the approach of [22] to the 2-D case is however far from straightforward and seems adequate to leave it as a separate topic for research.

Concerning the relation of the proposed stability measure to that of Roesser model, we recall [1] that if a 2-D discrete system has been modeled in the Roesser state space as

$$\begin{bmatrix} x^h(i+1, j) \\ x^v(i, j+1) \end{bmatrix} = \begin{bmatrix} \hat{A}_1 & \hat{A}_2 \\ \hat{A}_3 & \hat{A}_4 \end{bmatrix} \begin{bmatrix} x^h(i, j) \\ x^v(i, j) \end{bmatrix} \equiv \hat{A} \begin{bmatrix} x^h(i, j) \\ x^v(i, j) \end{bmatrix} \quad (9a)$$

it can be remodeled in the Fornasini-Marchesini state-space as (1) with

$$x(i, j) = \begin{bmatrix} x^h(i, j) \\ x^v(i, j) \end{bmatrix}, \quad A_1 = \begin{bmatrix} 0 & 0 \\ \hat{A}_3 & \hat{A}_4 \end{bmatrix}, \text{ and } A_2 = \begin{bmatrix} \hat{A}_1 & \hat{A}_2 \\ 0 & 0 \end{bmatrix}. \quad (9b)$$

Assuming (9a) is stable, the commonly used stability robustness measure of the system (in the Roesser state space) is

$$\xi = \inf_{\Delta \hat{A} \in R_u} \|\Delta \hat{A}\|$$

where

$$R_u = \{\Delta \hat{A} : \hat{A} + \Delta \hat{A} \text{ unstable}\}$$

with

$$\Delta \hat{A} = \begin{bmatrix} \Delta \hat{A}_1 & \Delta \hat{A}_2 \\ \Delta \hat{A}_3 & \Delta \hat{A}_4 \end{bmatrix}.$$

According to the structures of A_1 and A_2 in (9b), perturbation matrix $\Delta \hat{A}$ in the Roesser model is the sum of perturbations for A_1 and A_2 in the F-M model, i.e.,

$$\Delta \hat{A} = \begin{bmatrix} 0 & 0 \\ \Delta \hat{A}_3 & \Delta \hat{A}_4 \end{bmatrix} + \begin{bmatrix} \Delta \hat{A}_1 & \Delta \hat{A}_2 \\ 0 & 0 \end{bmatrix} \equiv \Delta A_1 + \Delta A_2. \quad (10)$$

Hence

$$\xi = \inf_{\Delta \hat{A} \in R_u} \|\Delta \hat{A}\| = \inf_{\Delta A \in S_u} \|\Delta A_1 + \Delta A_2\|$$

where S_u is the set of unstable perturbations $\Delta A = [\Delta A_1 \ \Delta A_2]$ with $\Delta A_1, \Delta A_2$ defined by (10). From $S_{u1} \subset S_u$ and $S_{u2} \subset S_u$, it follows that

$$\begin{aligned} \xi &= \inf_{\Delta A \in S_u} \|\Delta A_1 + \Delta A_2\| \leq \inf_{\Delta A \in S_{u1}} \|\Delta A_1 + \Delta A_2\| \\ &= \inf_{\Delta A_1 \in S_{u1}} \|\Delta A_1\| = \mu_1 \end{aligned}$$

and

$$\begin{aligned} \xi &= \inf_{\Delta A \in S_u} \|\Delta A_1 + \Delta A_2\| \leq \inf_{\Delta A \in S_{u2}} \|\Delta A_1 + \Delta A_2\| \\ &= \inf_{\Delta A_2 \in S_{u2}} \|\Delta A_2\| = \mu_2. \end{aligned}$$

Hence

$$\xi \leq \min(\mu_1, \mu_2). \quad (11)$$

On comparing (11) with (8), we see that ν for the F-M model is in a certain sense similar to ξ in the Roesser model. In the rest of the paper, our attention will be focused on investigating bound ν .

III. A LOWER BOUND OF ν AND ITS EVALUATION

A. A Lower Bound of ν

Let $\Omega = \{(\omega_1, \omega_2) : -\pi \leq \omega_1 \leq \pi, -\pi \leq \omega_2 \leq \pi\}$, and define

$$\gamma = \inf_{(\omega_1, \omega_2) \in \Omega} \underline{\sigma}[I_n - e^{j\omega_1} A_1 - e^{j\omega_2} A_2] \quad (12)$$

where I_n is the identity matrix of dimension n . As

$$\underline{\sigma}[I_n - e^{j\omega_1} A_1 - e^{j\omega_2} A_2] = \underline{\sigma}[e^{-j\omega_1} I_n - A_1 + e^{j(\omega_2 - \omega_1)} A_2]$$

where $\mu = \omega_2 - \omega_1$ and $\omega = -\omega_1$, we have

$$\begin{aligned} \gamma &= \inf_{-\pi \leq \mu \leq \pi} \inf_{-\pi \leq \omega \leq \pi} \underline{\sigma}[e^{j\omega} I_n - A(\mu)] \\ &= \inf_{0 \leq \mu \leq \pi} \inf_{-\pi \leq \omega \leq \pi} \underline{\sigma}[e^{j\omega} I_n - A(\mu)] \end{aligned} \quad (13)$$

where

$$A(\mu) = A_1 + e^{j\mu} A_2 \quad (14)$$

and the last equality in (13) is due to the fact that

$$f(\mu) = \inf_{-\pi \leq \omega \leq \pi} \underline{\sigma}[e^{j\omega} I_n - A(\mu)] \quad (15)$$

is an even function for $\mu \in [-\pi, \pi]$. With the definition of $f(\mu)$ in (15), (13) becomes

$$\gamma = \inf_{0 \leq \mu \leq \pi} f(\mu). \quad (16)$$

To explore the quantitative relation of γ to the robust stability measure ν , we note that (1) is asymptotically stable if and only if all eigenvalues of $A(\mu)$ for each $\mu \in [0, \pi]$ are strictly inside the unit circle [9]. Hence $A + \Delta A$ represents a stable system matrix if and only if $\Delta A \begin{bmatrix} I \\ e^{j\mu} I \end{bmatrix}$ is a stable perturbation of $A(\mu)$ for each $\mu \in [0, \pi]$. Since the exact 2-norm bound of complex, stable perturbations of $A(\mu)$ is equal to $f(\mu) = \min_{-\pi \leq \omega \leq \pi} \sigma[e^{j\omega} I - A(\mu)]$ [10]–[12], it follows that ΔA is a stable perturbation of A if

$$\left\| \Delta A \begin{bmatrix} I \\ e^{j\mu} I \end{bmatrix} \right\| < f(\mu) \text{ for all } \mu \in [0, \pi]. \quad (17)$$

As $\left\| \Delta A \begin{bmatrix} I \\ e^{j\mu} I \end{bmatrix} \right\| \leq \sqrt{2} \|\Delta A\|$ and $f(\mu) \geq \gamma$, (17) holds if

$$\|\Delta A\| < \frac{\gamma}{\sqrt{2}} \equiv \gamma_0. \quad (18)$$

This proves the following proposition.

Proposition 1: Define γ by (12). $\gamma_0 = \gamma/\sqrt{2}$ is a lower bound of the robust-stability measure ν defined by (6).

Two immediate consequences from above analysis are as follows.

Proposition 2: $\Delta A = [\Delta A_1 \quad \Delta A_2]$ is a stable perturbation for system (1) if

$$\|\Delta A_1\| + \|\Delta A_2\| < \gamma. \quad (19)$$

Proof: For any μ

$$\left\| \Delta A \begin{bmatrix} I \\ e^{j\mu} I \end{bmatrix} \right\| \leq \|\Delta A_1\| + \|\Delta A_2\|. \quad (20)$$

So if (19) holds, then $f(\mu) \geq \gamma$ leads (20) to (17). \square

Proposition 3: ΔA is a stable perturbation for system (1) if

$$\tilde{\gamma} < \gamma \quad (21)$$

where

$$\tilde{\gamma} = \sup_{0 \leq \mu \leq \pi} \|\Delta A_1 + e^{j\mu} \Delta A_2\|. \quad (22)$$

Proof: If (21) holds, then for any μ

$$\left\| \Delta A \begin{bmatrix} I \\ e^{j\mu} I \end{bmatrix} \right\| \leq \tilde{\gamma} < \gamma \leq f(\mu)$$

which leads to (17). \square

B. Computational Issues

We see from (13) that computing γ is a minimization problem with the objective function given by $F(\omega, \mu) = \sigma[e^{j\omega} I - A(\mu)]$. Because of the periodicity of $F(\omega, \mu)$ with respect to ω and μ , this minimization can be considered as an unconstrained problem, hence efficient optimization methods such as quasi-Newton algorithms can be used to find γ . As $F(\omega, \mu)$ represents the smallest singular value of a two-parameter matrix, there is in general no closed-form formula to compute the gradient of $F(\omega, \mu)$. For any $\delta > 0$, however, elementary properties of singular values [13, Chapter 6] imply that

$$|F(\omega + \delta, \mu) - F(\omega, \mu)| \leq |e^{j(\omega + \delta)} - e^{j\omega}| \leq \delta$$

and

$$|F(\omega, \mu + \delta) - F(\omega, \mu)| \leq \|A(\mu + \delta) - A(\mu)\| \leq \delta \|A_1\|$$

indicating that for any $\delta > 0$, ratio $[F(\omega + \delta, \mu) - F(\omega, \mu)]/\delta$ and $[F(\omega, \mu + \delta) - F(\omega, \mu)]/\delta$ are bounded by unity and $\|A_1\|$, respectively. Hence the gradient of $F(\omega, \mu)$ if it exists is bounded and reliable approximation of it can be obtained using simple numerical differentiations (i.e., the above difference ratio) with sufficiently small δ .

An alternative approach to the numerical evaluation of γ is to make use of (16) in conjunction with the fact that for a fixed μ , $f(\mu)$ defined by (15) is the exact bound for stable, complex perturbations of the system with $A(\mu)$ as its system matrix. Consequently, $f(\mu)$ for a fixed μ can be computed using the efficient bisection method proposed by Byers [14]. Again, due to the periodicity of $f(\mu)$, (15) is indeed a scalar minimization problem, which can be solved using, for example, the modified three-point-pattern algorithm [15, Section 7.3].

We shall touch upon these computational issues again in Section V through an illustrative example.

IV. LOWER BOUNDS DERIVED USING THE GENERALIZED 2-D LYAPUNOV EQUATION

A. The Generalized 2-D Lyapunov Equation

In [7] the following proposition was given.

Proposition 4 [7]: Equation (1) is asymptotically stable if there are positive definite P , W_1 , and W_2 such that

$$Q = \begin{bmatrix} P^{1/2} W_1 P^{1/2} & 0 \\ 0 & P^{1/2} W_2 P^{1/2} \end{bmatrix} - A^T P A > 0 \quad (23)$$

and that

$$I_n - W_1 - W_2 \geq 0. \quad (24)$$

This proposition is a generalization of the 2-D Lyapunov theorem proposed recently by Hinamoto [8]. It was shown in [7] that as compared to Hinamoto's result, the generalized Lyapunov equation (23) can be used to confirm stability of a broader class of 2-D discrete systems in the F-M state space setting. As [7] has not been available to the reader, for the sake of convenience a proof of Proposition 4 is given in Appendix A.

B. Two Lower Bounds of ν

Consider a stable system (1) that satisfies (23) and (24) with some positive definite P , W_1 and W_2 , and let the perturbed system be given by

$$x(i+1, j+1) = (A_1 + \Delta A_1)x(i, j+1) + (A_2 + \Delta A_2)x(i+1, j). \quad (25)$$

The matrices P , W_1 , and W_2 are employed to construct the Lyapunov function

$$\phi(i, j) = \phi_1(i, j) + \phi_2(i, j) \quad (26)$$

where

$$\phi_1(i, j) = x^T(i, j+1) P^{1/2} W_1 P^{1/2} x(i, j+1) \quad (27)$$

$$\phi_2(i, j) = x^T(i+1, j) P^{1/2} W_2 P^{1/2} x(i+1, j). \quad (28)$$

Define

$$\phi_{11}(i, j) = \phi_1(i+1, j) + \phi_2(i, j+1). \quad (29)$$

By (24)

$$\begin{aligned} \phi_{11}(i, j) &= x^T(i+1, j+1) P^{1/2} (W_1 + W_2) P^{1/2} x(i+1, j+1) \\ &\leq x^T(i+1, j+1) P x(i+1, j+1). \end{aligned} \quad (30)$$

Now using (23) and (25)–(30) we compute

$$\begin{aligned} \Delta \phi(i, j) &= \phi_{11}(i, j) - \phi(i, j) \\ &\leq \hat{x}^T(i, j) [(A^T + \Delta A) P (A + \Delta A) - \hat{P}] \hat{x}(i, j) \\ &\leq -[\sigma(Q) - 2\hat{\sigma}^{1/2}(\hat{P} - Q)\hat{\sigma}^{1/2}(P)] \|\Delta A\| \\ &\quad - \hat{\sigma}(P) \|\Delta A\|^2 \|\hat{x}(i, j)\|^2 \end{aligned}$$

where

$$\tilde{x}(i, j) = \begin{bmatrix} x(i, j+1) \\ x(i+1, j) \end{bmatrix} \quad \text{and} \quad \tilde{P} = \begin{bmatrix} P^{T/2} W_1 P^{1/2} & 0 \\ 0 & P^{1/2} W_2 P^{1/2} \end{bmatrix}. \quad (31)$$

Hence if

$$\|\Delta A\| < \frac{[\bar{\sigma}(\tilde{P} - Q) + \underline{\sigma}(Q)]^{1/2} - \bar{\sigma}^{1/2}(\tilde{P} - Q)}{\bar{\sigma}^{1/2}(P)} \quad (32)$$

then $\Delta\phi(i, j) < 0$ for all i, j , and a typical argument (see, e.g., [16]) applies to show the stability of the perturbed system (25).

An alternative Lyapunov function may be defined as

$$v(i, j) = [\phi_1(i, j) + \phi_2(i, j)]^{1/2}. \quad (33)$$

Similarly we define

$$v_{11}(i, j) = [\phi_1(i+1, j) + \phi_2(i, j+1)]^{1/2} \quad (34)$$

and use (24) to write

$$v_{11}(i, j) \leq [x^T(i+1, j+1) P x(i+1, j+1)]^{1/2}. \quad (35)$$

Now (23), (25), (33), and (35) imply that

$$\begin{aligned} \Delta v(i, j) &= v_{11}(i, j) - v(i, j) \\ &\leq [\tilde{x}^T(i, j)(A + \Delta A)^T P (A + \Delta A)\tilde{x}(i, j)]^{1/2} \\ &\quad - [\tilde{x}^T(i, j)\tilde{P}\tilde{x}(i, j)]^{1/2} \\ &\leq -\left[\frac{\underline{\sigma}(Q)}{\sigma^{1/2}(\tilde{P} - Q) + \sigma^{1/2}(P)} - \bar{\sigma}^{1/2}(P) \|\Delta A\| \right] \\ &\quad \|x(i, j)\|. \end{aligned}$$

Thus if

$$\|\Delta A\| < \frac{\underline{\sigma}(Q)}{\sigma^{1/2}(P)[\sigma^{1/2}(P - Q) + \bar{\sigma}^{1/2}(\tilde{P})]} \quad (36)$$

then $\Delta v(i, j) < 0$ for all i, j , and therefore, the perturbed system (25) will remain stable.

Although our numerical experience indicates that the lower bounds of ν given in (32) and (36) usually stay quite close each other, the bound given in (32) is always better than that in (36) as is shown in the next proposition.

Proposition 5.

$$\beta_{L,2} \leq \beta_{L,1} \quad (37)$$

where

$$\beta_{L,1} = \frac{[\bar{\sigma}(P - Q) + \underline{\sigma}(Q)]^{1/2} - \bar{\sigma}^{1/2}(P - Q)}{\bar{\sigma}^{1/2}(P)} \quad (38)$$

$$\beta_{L,2} = \frac{\underline{\sigma}(Q)}{\bar{\sigma}^{1/2}(P)[\bar{\sigma}^{1/2}(\tilde{P} - Q) + \sigma^{1/2}(\tilde{P})]} \quad (39)$$

with \tilde{P} given by (31).

The proof of the above proposition can be found in Appendix B.

C. Remarks on Numerical Solutions of the Generalized 2-D Lyapunov Equation

To compute lower bound $\beta_{L,1}$ or $\beta_{L,2}$, one must find positive definite P , W_1 , and W_2 that satisfy (23) and (24). Although constraints (24), $P > 0$, $W_1 > 0$ and $W_2 > 0$ can be put together as a set of linear matrix inequalities (LMI's), it is difficult to formulate the problem of solving (23) as a convex programming problem such as those investigated in [23] and [24], since solving (23) cannot be formulated as a problem of minimizing λ with $\lambda B(x) - A(x) > 0$ where x is the vector collecting all the parameters in P , W_1 , and W_2 , and $B(x)$ and $A(x)$ are matrices depending on x affinely. The approach taken here is to reformulate the problem as conventional

constrained minimization problem as follows. Note that (23) and (24) are equivalent to

$$\tilde{Q} \equiv I_{2n} - \begin{bmatrix} V_1^T & 0 \\ 0 & V_2^T \end{bmatrix} \tilde{A}^T \tilde{A} \begin{bmatrix} V_1 & 0 \\ 0 & V_2 \end{bmatrix} > 0 \quad (40)$$

and

$$I - V_1^{-T} V_1^{-1} - V_2^{-T} V_2^{-1} \geq 0 \quad (41)$$

respectively, where $T = P^{-1/2}$, $\tilde{A} = [\tilde{A}_1 \ \tilde{A}_2]$, $\tilde{A}_i = T^{-1} A_i T$, $W_i = V_i^{-T} V_i^{-1}$ ($i = 1, 2$), which are in turn equivalent to

$$\underset{\substack{V_1, V_2 \\ \text{non-singular}}} \text{minimize} \quad \left\| \tilde{A} \begin{bmatrix} V_1 & 0 \\ 0 & V_2 \end{bmatrix} \right\| < 1. \quad (42)$$

Solving the constrained minimization problem (42) is in general numerically intensive in the sense that it usually requires a fairly large amount of computations to obtain a local minimum, due primarily to the iterative nature of the algorithm. When the norm of system matrix A or the norm of a weighted version of A is small in a sense specified below, however, solutions to the generalized 2-D Lyapunov equation (23) and (24) can be found easily. For example, if

$$\|A\| < \frac{1}{\sqrt{2}} \quad (43)$$

then $W_1 = W_2 = \frac{1}{2} I_n$ and $P = I_n$ satisfy (24) and lead Q in (23) to

$$Q = \frac{1}{2} I_{2n} - A^T A$$

which is positive definite. The above choice of W_1 , W_2 , and P leads to $\tilde{P} = \frac{1}{2} I_{2n}$, $\bar{\sigma}(P - Q) = \|A\|^2$, $\underline{\sigma}(Q) = \frac{1}{2} - \|A\|^2$, and $\bar{\sigma}(P) = 1$. The two lower bounds in this case are found equal, being

$$\beta_{L,1} = \beta_{L,2} = \frac{1}{\sqrt{2}} - \|A\|. \quad (44)$$

Another simple case is when weights $\alpha > 0$ and $\beta > 0$ can be found such that

$$\frac{1}{\alpha^2} + \frac{1}{\beta^2} = 1 \quad (45)$$

and

$$\|[\alpha A_1 \ \beta A_2]\| < 1. \quad (46)$$

Obviously, $W_1 = \frac{1}{\alpha^2} I_n$, $W_2 = \frac{1}{\beta^2} I_n$, and $P = I_n$ satisfy (24) and lead Q in (23) to

$$Q = \begin{bmatrix} \frac{1}{\alpha^2} I & 0 \\ 0 & \frac{1}{\beta^2} I \end{bmatrix} - A^T A \quad (47)$$

which is positive definite if (46) holds. The two lower bounds in this case are given by

$$\beta_{L,1} = [\|A\|^2 + \underline{\sigma}(Q)]^{1/2} - \|A\| \quad (48)$$

and

$$\beta_{L,2} = \frac{\underline{\sigma}(Q)}{\|A\| + \max(\alpha^{-1}, \beta^{-1})}. \quad (49)$$

V. AN EXAMPLE

Consider a fourth-order F-M model with

$$A_1 = \begin{bmatrix} 0.0058 & 0.2853 & -0.2432 & 0.1246 \\ -0.0084 & 0.2377 & 0.1606 & -0.1404 \\ -0.0084 & -0.0217 & 0.1785 & 0.1662 \\ -0.0245 & 0.0884 & -0.0321 & 0.2428 \end{bmatrix}$$

$$A_2 = \begin{bmatrix} 0.0495 & 0.0687 & 0.2030 & -0.3013 \\ 0.1630 & 0.4817 & -0.0993 & 0.1814 \\ -0.2842 & 0.1790 & 0.5551 & 0.0799 \\ 0.2112 & -0.1887 & -0.0895 & 0.5604 \end{bmatrix}.$$

As $\|A\| = 0.7791$ exceeds $1/\sqrt{2} \approx 0.7071$, we attempt to find positive scalars α and β that satisfy (45) and (46). Using (45) we write $\beta = \alpha/\sqrt{\alpha^2 - 1}$ and define the objective function

$$e(\alpha) = \|[\alpha A_1 \quad \frac{\alpha}{\sqrt{\alpha^2 - 1}} A_2]\| \text{ for } 1 < \alpha < \infty. \quad (50)$$

Applying the modified three-point-pattern minimization algorithm [15, Chapter 7] to the bracket (i.e., an interval of α) [1.1, 3], it took 12 iterations with 17.796 Kflops (10^3 floating point operations) to find the minimum of $e(\alpha)$, $e(\alpha^*) = 0.9001 < 1$ at $\alpha^* = 2$. This leads to a solution to (23)–(24) with $W_1 = 0.25I_4$, $W_2 = 0.75I_4$, and $P = I_4$. It follows from Proposition 4 that the 2-D system is stable. From (47)–(49), lower bounds β_{L_1} and β_{L_2} were found to be $\beta_{L_1} = 0.0310$ and $\beta_{L_2} = 0.0300$. The total number of flops used in computing β_{L_1} or β_{L_2} is about 21 Kflops. To evaluate the lower bound β_0 in (18), a quasi-Newton optimization method was used to evaluate ν , where the gradient of $F(\omega, \mu)$ was performed numerically with $h = 10^{-6}$. It took nine iterations (with 241.6 Kflops) to obtain $\gamma = 0.1775$ at $[\omega^*, \mu^*] = [0.0252 \ 0.3856]$, which leads to $\beta_0 = 0.1255$. It is noted that bound β_0 is considerably less conservative as compared to β_{L_1} and β_{L_2} although computing β_0 is far more expensive in this case.

VI. CONCLUDING REMARKS

A robust stability measure has been proposed and three lower bounds of ν for F-M 2-D discrete systems have been derived by two distinct approaches. It appears from the numerical example discussed in Section V that the bounds β_{L_1} and β_{L_2} derived using the Lyapunov approach are quite conservative. This could be improved by carrying out the optimization problem (42) rather than using (50). As a matter of fact, the norm in (42) becomes $e(\alpha)$ in (50) if $T = I_1$, $V_1 = \alpha I_1$ and $V_2 = \frac{\alpha}{\sqrt{\alpha^2 - 1}} I_4$ with $\alpha > 1$ are chosen. With more parameters in (42), better lower bounds β_{L_i} ($i = 1, 2$) can be found at the expense of higher computation intensity.

APPENDIX A

Proof of Proposition 4: We prove the proposition by contradiction. Suppose the conditions of the proposition are satisfied but (1) is unstable. Then there is $(z_1, z_2) \in \bar{U}^*$ such that

$$\det(I_n - z_1 A_1 - z_2 A_2) = 0. \quad (51)$$

Hence there exists vector $v \neq 0$ such that

$$v = A \begin{bmatrix} z_1 I_n \\ z_2 I_n \end{bmatrix} v. \quad (52)$$

Using (23) and (52), we compute

$$v^* P v = v^* [\bar{z}_1 I_n \quad \bar{z}_2 I_n] \begin{bmatrix} P^{1/2} W_1 P^{1/2} & 0 \\ 0 & P^{1/2} W_2 P^{1/2} \end{bmatrix} \begin{bmatrix} z_1 I_n \\ z_2 I_n \end{bmatrix} v - v^* Q v,$$

where v^* denotes the complex conjugate transpose of v , \bar{z}_i is the complex conjugate of z_i ($i = 1, 2$), and $v_z^* = v^* [\bar{z}_1 I_n \quad \bar{z}_2 I_n]$. It follows that

$$v^* P^{1/2} (I_n - |z_1|^2 W_1 - |z_2|^2 W_2) P^{1/2} v = -v_z^* Q v. \quad (53)$$

By (51) we note that $(z_1, z_2) \neq (0, 0)$, hence $v_z \neq 0$. So $Q > 0$ means that the right-hand side of (53) is strictly negative. On the other side of equation, $|z_1| \leq 1$ and $|z_2| \leq 1$ and the positive semi-definiteness of $I_n - W_1 - W_2$ [see (24)] imply that $I - |z_1|^2 W_1 - |z_2|^2 W_2 \geq 0$. Therefore the left-hand side of (53) is nonnegative, leading to a contradiction. This completes the proof. \square

APPENDIX B

Proof of Proposition 5: Let $a = \underline{g}(Q)$, $b = \bar{\sigma}(P)$, $c = \bar{\sigma}(\bar{P} - Q)$, and $d = \bar{\sigma}(\bar{P})$. Note that $a > 0$, $b > 0$, $c \geq 0$, $d > 0$, and that

$$\bar{\sigma}(\bar{P} - Q) \leq \bar{\sigma}(\bar{P}) - \underline{g}(Q)$$

which implies that

$$(a + c)^{1/2} + c^{1/2} \leq c^{1/2} + d^{1/2}. \quad (54)$$

Since $b > 0$ and $d > 0$, it follows from (54) that

$$\frac{a}{b^{1/2}(c^{1/2} + d^{1/2})} \leq \frac{(a + c)^{1/2} - c^{1/2}}{b^{1/2}}. \quad \square$$

Multivariable System Identification via Continued-Fraction Approximation

Rolf Johansson

Abstract—This paper presents theory for multivariable system identification using matrix fraction descriptions and the matrix continued fraction description approach which, in turn, yields a lattice-type order-recursive structure. Once the matrix continued-fraction expansion has been determined, it is straightforward to obtain solutions to both the left and right coprime factorizations of transfer function estimates and, in addition, a solution to problems of state estimation (observer design) and pole-assignment control. An important and attractive technical property is that calculation of transfer functions on the form of right and left coprime factorizations, calculation of state variable observers, and regulators all can be made using causal polynomial transfer functions defined by means of matrix sequences of the continued-fraction expansion applied in causal and stable forward-order and backward-order recursions.

1. INTRODUCTION

A long-standing and somewhat embarrassing problem in system identification is how to extend identification methods developed for single-input single-output systems to the case of multi-input multi-output systems. One important reason for this situation is that a large variety of ARMAX-type system parameterizations are suitable system descriptions and that no unique parameterization can be easily defined [13]–[14], [16], [18], [20]. This leaves a user with uncertainty as to the validity and numerical accuracy of calculations—e.g., state estimation and control, based on such transfer function estimates. For instance, consider the following two factorizations

$$\begin{cases} A_R(z^{-1})\xi = u & \text{and} \\ y = B_R(z^{-1})\xi \end{cases} \quad \begin{cases} A_L(z^{-1})Q(z^{-1})\xi = u \\ y = B_L(z^{-1})Q(z^{-1})\xi \end{cases} \quad Q \text{ unimodular} \quad (1)$$

where the partial state ξ provides a link to state-space realizations via the controllable canonical form [14, p. 403]. Clearly, the transfer functions of the two factorizations in (1) cannot be distinguished and there is no obvious choice of factorization to be preferred. As ξ is not known, there is also little hope to estimate (A_R, B_R) by ordinary methods of identification. As a result there are no general purpose methods nor software available whereas many control design procedure actually require coprime matrix fraction descriptions (MFD). As there are no established methods to find MFD's such as (1) from data, it remains a relevant problem in system identification to develop effective identification methods for such model structures [13], [16], [20]. A technical problem in this context is that statistical consistency of estimates of the matrix fractions becomes a meaningless issue as there is no unique parameter set towards which estimates may converge. Another as yet unsettled issue is the relationship between transfer function estimation, state estimation, and control system design.

A suitable starting point is to focus interest on transfer functions that are matrices of rational functions and transfer functions that can be approximated by a rational approximant (or a series of approximants for a sequence of increasing model orders). Approximation

Fig. 1. Expansion of a transfer function $G^{(i-1)}(z)$ into the coefficients $c^{(2i-1)}$, $c^{(2i)}$ and a residual transfer function block $G^{(i)}(z)$ as practiced in continued fraction approximation.

Fig. 2. Interpretation of the continued fraction expansion as a recursive transfer function relationship in a forward (right) or a forward/backward manner (left).

of complex-valued functions can be made by means of polynomials (Taylor series expansions) or rational functions (continued fraction approximation). Like infinite power series, continued fraction approximation can be used to represent certain types of analytic functions. Contrary to representations by power series, continued-fraction (CF) approximation may converge in regions that contain isolated singularities of the function to be represented and the approximants take on values in the extended complex plane $C \cup \{\infty\}$; see [8] and [23]. The method is well known from circuit theory and from the theory underlying the Routh criterion and the method has also been used for model reduction of linear systems [3]–[4], [6], [9]–[12], [15], multivariable systems [1]–[2], [7], and realization theory [2], [17], although recent focus in model reduction has been shifted towards methods based on balanced realization.

Consider an asymptotically stable system with a transfer function $G(z)$ in the forward shift operator or z -transform variable z . Then, the transfer function $\tilde{G}(z)$ may be expanded according to continued fraction which for a scalar $G(z)$ takes on the form

$$\begin{aligned} \tilde{G}(z) &= \frac{B(z^{-1})}{A(z^{-1})} = \frac{1}{c^{(1)} + \frac{1}{\frac{c^{(2)}}{z} + G^{(1)}(z)}} \\ &= \frac{1}{c^{(1)} + \frac{1}{\frac{c^{(2)}}{z} + \frac{1}{c^{(3)} + \frac{1}{\frac{c^{(4)}}{z} + G^{(2)}(z)}}}} \end{aligned} \quad (2)$$

with coefficients $\{c^{(j)}\}_{j=1}^{2m}$ —or more generally polynomials $\{c^{(j)}(z^{-1})\}_{j=1}^{2m}$ —and a residual transfer function block $G^{(m)}(z)$. The extension to multi-input multi-output systems is straightforward and even a block-diagram interpretation is possible; see Figs. 1–2. If $G^{(i)}(z) = 0$ (and thus $Y^{(i)} = 0$) at some stage i , the continued

fraction approximation terminates and results in a rational function approximant. Terminating continued fraction approximation are of particular importance in model reduction where methods can be proposed according to various principles of approximation—for instance, the approximation $G^{(m)}(z) \approx 0$, which truncates the sequence of coefficients after $2m$, $G^{(m)}(z) \approx G^{(m)}(1)$, which preserves the static gain of the system, or the Padé approximation which is known to sometimes providing poor approximants [12]. All such alternatives result in reduced-order models of order m with the approximant

$$H^{(m)}(z) = \frac{B^{(m)}(z^{-1})}{A^{(m)}(z^{-1})} \quad (3)$$

with continued-fraction coefficients obtained from polynomial coefficients by means of calculations reminiscent of those for the Routh criterion of stability. Recursions of the continued-fraction approximation therefore induce a ladder-type circuit theory reminiscent of lattice structures in spectral estimation (Fig. 2) and with the transfer matrix $M^{(i)}(z^{-1})$ relating stage i to stage $i-1$ in the order-recursive equation

$$\begin{pmatrix} Y^{(i)}(z) \\ U^{(i)}(z) \end{pmatrix} = M^{(i)}(z^{-1}) \begin{pmatrix} Y^{(i-1)}(z) \\ U^{(i-1)}(z) \end{pmatrix}$$

where

$$M^{(i)}(z^{-1}) = \begin{pmatrix} 1 + c^{(2i-1)}c^{(2i)}z^{-1} & -c^{(2i)}z^{-1} \\ -c^{(2i-1)} & 1 \end{pmatrix}. \quad (4)$$

A major difference between the present approach and the lattice filters used for whitening operations in signal processing is the property of its lattice transfer function

$$\begin{pmatrix} 1 & K_f z^{-1} \\ K_b & z^{-1} \end{pmatrix}, \quad K_f, K_b = \text{reflection coefficients} \quad (5)$$

which is not a unimodular matrix.

The main purpose of the present paper is to show how to obtain multivariable transfer function models from data on the form of coprime MFD's and to clarify the close relationship between the continued-fraction approximation and solutions to the Diophantine equation which is important in control system analysis for control design and observer design.

II. MULTIVARIABLE MODELING AND CONTROL

Let $\mathbb{R}[x]$ denote the polynomials in the indeterminate x with coefficients in \mathbb{R} , and let the set of $n \times m$ -matrices with entries in $\mathbb{R}[x]$ be denoted $\mathbb{R}^{n \times m}[x]$. Consider the input and output variables $U^{(i)} \in \mathbb{R}^m$, $Y^{(i)} \in \mathbb{R}^p$ for $i = 0, 1, \dots, n$ and matrices $C^{(2i)} \in \mathbb{R}^{p \times m}$, $C^{(2i-1)} \in \mathbb{R}^{m \times p}$ ($i = 1, \dots, n$) which exhibit the dependencies (Fig. 2)

$$\begin{aligned} Y^{(i-1)}(z) &= C^{(2i)}z^{-1}U^{(i)}(z) + Y^{(i)}(z) \\ U^{(i)}(z) &= -C^{(2i-1)}Y^{(i-1)}(z) + U^{(i-1)}(z) \end{aligned} \quad (6)$$

with a mixed backward/forward dependence in the recursion order i and with boundary values

$$\begin{pmatrix} Y^{(0)}(z) \\ U^{(0)}(z) \end{pmatrix} = \begin{pmatrix} Y(z) \\ U(z) \end{pmatrix} \quad (7)$$

and with z^{-1} denoting the backward shift operator or z -transform variable. A pure forward-order recursive equation for the continued fraction in (6) can be obtained as

$$\begin{pmatrix} Y^{(i)}(z) \\ U^{(i)}(z) \end{pmatrix} = \begin{pmatrix} I_{p \times p} + C^{(2i)}C^{(2i-1)}z^{-1} & -C^{(2i)}z^{-1} \\ -C^{(2i-1)} & I_{m \times m} \end{pmatrix} \cdot \begin{pmatrix} Y^{(i-1)}(z) \\ U^{(i-1)}(z) \end{pmatrix}. \quad (8)$$

Let $C^{(2i)}(x) \in \mathbb{R}^{p \times m}[x]$, $C^{(2i-1)}(x) \in \mathbb{R}^{m \times p}[x]$ for $i = 1, 2, \dots, n$. The polynomial matrix

$$M^{(i)}(x) = \begin{pmatrix} I_{p \times p} + C^{(2i)}C^{(2i-1)}x & -C^{(2i)}x \\ -C^{(2i-1)} & I_{m \times m} \end{pmatrix} \in \mathbb{R}^{(m+p) \times (m+p)}[x] \quad (9)$$

is unimodular with a unit determinant (i.e., $\det M^{(i)}(x) = 1$) and the inverse of $M^{(i)}(x)$ is

$$(M^{(i)}(x))^{-1} = \begin{pmatrix} I_{p \times p} & C^{(2i)}x \\ C^{(2i-1)} & I_{m \times m} + C^{(2i-1)}C^{(2i)}x \end{pmatrix}. \quad (10)$$

The matrix of (10) is unimodular since its inverse is also a polynomial matrix and from (10) is concluded that the order recursion of the continued fraction expansion is invertible so that

$$\begin{aligned} \begin{pmatrix} Y^{(i-1)}(z) \\ U^{(i-1)}(z) \end{pmatrix} &= (M^{(i)}(z^{-1}))^{-1} \begin{pmatrix} Y^{(i)}(z) \\ U^{(i)}(z) \end{pmatrix} \\ &= \begin{pmatrix} I_{p \times p} & C^{(2i)}z^{-1} \\ C^{(2i-1)} & I_{m \times m} + C^{(2i-1)}C^{(2i)}z^{-1} \end{pmatrix} \cdot \begin{pmatrix} Y^{(i)}(z) \\ U^{(i)}(z) \end{pmatrix}. \end{aligned} \quad (11)$$

An important technical property is that forward as well as backward order recursions are to be made using causal polynomial transfer functions which both are defined by means of the matrix sequences $\{C^{(2i-1)}\}$ and $\{C^{(2i)}\}$.

Now introduce the following notation for the matrix product

$$\begin{pmatrix} A_L^{(i)}(z^{-1}) & -B_L^{(i)}(z^{-1}) \\ S_L^{(i)}(z^{-1}) & R_L^{(i)}(z^{-1}) \end{pmatrix} = M^{(i)}(z^{-1})M^{(i-1)}(z^{-1}) \cdots M^{(1)}(z^{-1}) \quad (12)$$

and its inverse

$$\begin{pmatrix} R_R^{(i)}(z^{-1}) & B_R^{(i)}(z^{-1}) \\ -S_R^{(i)}(z^{-1}) & A_R^{(i)}(z^{-1}) \end{pmatrix} = (M^{(1)}(z^{-1}))^{-1} \cdots (M^{(i-1)}(z^{-1}))^{-1} (M^{(i)}(z^{-1}))^{-1} \quad (13)$$

with the backward polynomial transfer matrix $(M^{(i)}(z^{-1}))^{-1}$ defined by (10).

Lemma 1: Bezout identity and coprime factorizations

i) Any solution $X_L \in \mathbb{R}^{p \times p}[x]$ and $Y_L \in \mathbb{R}^{m \times p}[x]$ to the Diophantine equation

$$A_L^{(i)}(x)X_L(x) + B_L^{(i)}(x)Y_L(x) = I_{p \times p} \quad (14)$$

can be written

$$\begin{aligned} X_L &= R_R^{(i)} + B_R^{(i)}N \\ Y_L &= S_R^{(i)} - A_R^{(i)}N \end{aligned} \quad (15)$$

for some polynomial matrix $N \in \mathbb{R}^{m \times p}[x]$.

- ii) Any solution $X_R \in \mathbb{R}^{m \times m}[x]$ and $Y_R \in \mathbb{R}^{n \times p}[x]$ to the Diophantine equation

$$X_R(x)A_R^{(i)}(x) + Y_R(x)B_R^{(i)}(x) = I_{m \times m} \quad (16)$$

can be written

$$\begin{aligned} X_R &= R_L^{(i)} - N B_L^{(i)} \\ Y_R &= S_L^{(i)} + N A_L^{(i)} \end{aligned} \quad (17)$$

for some polynomial matrix $N \in \mathbb{R}^{m \times p}[x]$.

- iii) The matrix factorizations $\{(A_L^{(i)}(x), B_L^{(i)}(x))\}_{i=1}^n$ for $i = 1, 2, \dots, n$ are left coprime and the matrix factorizations $\{(A_R^{(i)}(x), B_R^{(i)}(x))\}_{i=1}^n$ for $i = 1, 2, \dots, n$ are right coprime.

A proof for the Bezout identity for general rings and—as a special case—for polynomial matrices is to be found in [22, Chapter 4]. According to the definitions in (12) and (13), it can be concluded that for any i we have the generalized Bezout identity (cf. [14, p. 382])

$$\begin{aligned} I_{(m+p) \times (m+p)} &= \begin{pmatrix} A_L^{(i)} & -B_L^{(i)} \\ S_L^{(i)} & R_L^{(i)} \end{pmatrix} \begin{pmatrix} R_R^{(i)} & B_R^{(i)} \\ -S_R^{(i)} & A_R^{(i)} \end{pmatrix} \\ &= \begin{pmatrix} A_L^{(i)} R_R^{(i)} + B_L^{(i)} S_R^{(i)} & A_L^{(i)} B_R^{(i)} - B_L^{(i)} A_R^{(i)} \\ S_L^{(i)} R_R^{(i)} - R_L^{(i)} S_R^{(i)} & S_L^{(i)} B_R^{(i)} + R_L^{(i)} A_R^{(i)} \end{pmatrix} \end{aligned}$$

with

$$\begin{aligned} \deg A_L^{(i)} &= \deg A_R^{(i)} = i \\ \deg B_L^{(i)} &= \deg B_R^{(i)} = i \\ \deg R_L^{(i)} &= \deg R_R^{(i)} = i - 1 \\ \deg S_L^{(i)} &= \deg S_R^{(i)} = i - 1 \\ A_L^{(i)}(0) &= R_R^{(i)}(0) = I_{p \times p} \\ A_R^{(i)}(0) &= R_L^{(i)}(0) = I_{m \times m} \end{aligned} \quad (18)$$

Note that particular and homogenous solutions to the Diophantine equation (14) can be extracted from (18) and that direct substitution of (15) into (14) gives

$$\begin{aligned} A_L^{(i)} X_L + B_L^{(i)} Y_L &= A_L^{(i)} (R_R^{(i)} + B_R^{(i)} N) + B_L^{(i)} (S_R^{(i)} - A_R^{(i)} V) \\ &= (A_L^{(i)} R_R^{(i)} + B_L^{(i)} S_R^{(i)}) + (A_L^{(i)} B_R^{(i)} + B_L^{(i)} A_R^{(i)}) N \\ &= I_{p \times p} + 0_{p \times m} \cdot N = I_{p \times p}. \end{aligned} \quad (19)$$

Coprime matrix fraction descriptions originating from terminating continued fraction expansions of polynomial order n are suitable for multivariable system modeling. Let the control object be represented as

$$\begin{aligned} \begin{pmatrix} A_L^{(n)}(z^{-1}) & -B_L^{(n)}(z^{-1}) \\ S_L^{(n)}(z^{-1}) & R_L^{(n)}(z^{-1}) \end{pmatrix} \begin{pmatrix} Y(z) \\ U(z) \end{pmatrix} &= \begin{pmatrix} Y^{(n)}(z) \\ U^{(n)}(z) \end{pmatrix} \\ \begin{pmatrix} R_R^{(n)}(z^{-1}) & B_R^{(n)}(z^{-1}) \\ -S_R^{(n)}(z^{-1}) & A_R^{(n)}(z^{-1}) \end{pmatrix} \begin{pmatrix} Y^{(n)}(z) \\ U^{(n)}(z) \end{pmatrix} &= \begin{pmatrix} Y(z) \\ U(z) \end{pmatrix} \end{aligned}$$

where

$$\begin{pmatrix} Y^{(n)}(z) \\ U^{(n)}(z) \end{pmatrix} = \begin{pmatrix} E(z) \\ \xi(z) \end{pmatrix} \quad (20)$$

with ξ as the partial state [14] and $E(z)$ as disturbance inputs and modeling error, $E(z)$ ideally being zero. In fact, (20) provides a means of correspondence between various system representations and, for instance, incorporates pole-assignment control which is easily calculated:

Theorem 1—Pole-Assignment to the Origin: Assume that the control object be described by (20). The control laws

$$\begin{aligned} i) \quad U(z) &= -R_L^{-1}(z^{-1}) S_L(z^{-1}) Y(z) \\ &\Rightarrow (S_L \quad R_L) \begin{pmatrix} Y \\ U \end{pmatrix} = 0_{n \times 1} \\ ii) \quad \begin{cases} R_R(z^{-1}) \xi_R(z) = Y(z) \\ U(z) = -S_R(z^{-1}) \xi_R(z) \end{cases} \\ &\Rightarrow \begin{pmatrix} R_R \\ -S_R \end{pmatrix} \xi_R = \begin{pmatrix} Y \\ U \end{pmatrix} \end{aligned} \quad (21)$$

both achieve pole assignment to the origin and $\xi = 0$.

Proof: For control law i) is found that

$$\begin{aligned} 0_{m \times 1} &= (S_L \quad R_L) \begin{pmatrix} Y \\ U \end{pmatrix} \\ &= (S_L \quad R_L) \cdot \begin{pmatrix} R_R & B_R \\ -S_R & A_R \end{pmatrix} \begin{pmatrix} E \\ \xi \end{pmatrix} \\ &= (S_L R_R - R_L S_R \quad S_L B_R + R_L A_R) \begin{pmatrix} E \\ \xi \end{pmatrix} \\ &= (0 \quad I_{m \times m}) \begin{pmatrix} E \\ \xi \end{pmatrix} = \xi \end{aligned} \quad (22)$$

with pole polynomial $S_L B_R + R_L A_R = I_{m \times m}$ as follows from (18) and the Bezout identity. Similarly, for control law ii) is found that with system dynamics determined from

$$\begin{aligned} \begin{pmatrix} E \\ \xi \end{pmatrix} &= \begin{pmatrix} A_L & -B_L \\ S_L & R_L \end{pmatrix} \begin{pmatrix} Y \\ U \end{pmatrix} \\ &= \begin{pmatrix} A_L & -B_L \\ S_L & R_L \end{pmatrix} \begin{pmatrix} R_R \\ -S_R \end{pmatrix} \xi_R \\ &= \begin{pmatrix} A_L R_R + B_L S_R \\ S_L R_R - R_L S_R \end{pmatrix} \xi_R \\ &= \begin{pmatrix} I_{p \times p} \\ 0_{m \times p} \end{pmatrix} \xi_R \end{aligned} \quad (23)$$

with the pole polynomial $A_L R_R + B_L S_R = I_{p \times p}$. Rearrangement gives

$$\begin{pmatrix} \xi_R \\ \xi \end{pmatrix} = \begin{pmatrix} E \\ 0_{m \times 1} \end{pmatrix} \quad (24)$$

which effectively decouples the state ξ from perturbation E . Moreover, the partial state ξ_R of the control law ii) provides an observer for the disturbance E . \square

It can be concluded that matrices $\{C^{(2i-1)}\}$, $\{C^{(2i)}\}$ with real-valued elements generate left and right coprime factorizations of a strictly proper control object and associated controllers. Using system equivalence results [21, pp. 73-74] there exist procedures to generate the corresponding controllable and observable state-space realizations and controllability indices and observability indices can be obtained [21, p. 51].

III. A MULTIVARIABLE IDENTIFICATION ALGORITHM

It remains to determine the continued fraction expansion matrices $\{C^{(2i-1)}\}_{i=1}^n$, $\{C^{(2i)}\}_{i=1}^n$ for nonunique transfer function estimates originating from standard identification methods—e.g., least-squares

identification For the case of least-squares identification, it is suitable to organize model and data sequences $\{y_k\}$ and $\{u_k\}$ according to

$$\begin{aligned} y_k &= -A_1 y_{k-1} - \dots - A_n y_{k-n} + B_1 u_{k-1} + \dots + B_n u_{k-n}, \\ y_k &\in \mathbb{R}^p \\ \phi_k &= (-y_{k-1}^T \dots -y_{k-n}^T \quad u_{k-1}^T \dots u_{k-n}^T)^T, \\ \phi_k &\in \mathbb{R}^{n(m+p)} \\ \theta &= (A_1 \quad \dots \quad A_n \quad B_1 \quad \dots \quad B_n)^T \\ \theta &\in \mathbb{R}^{n(m+p) \times p} \end{aligned} \quad (25)$$

which for N samples and model order n suggests the linear regression model

$$\mathcal{M} \quad \mathcal{Y}_N = \Phi_N \theta$$

with

$$\mathcal{Y}_N = \begin{pmatrix} y_1^T \\ y_2^T \\ \vdots \\ y_N^T \end{pmatrix}$$

and

$$\Phi_N = \begin{pmatrix} \phi_1^T \\ \phi_2^T \\ \vdots \\ \phi_N^T \end{pmatrix} \quad (26)$$

As a result of the nonuniqueness of parameters the normal equations of the associated least-squares estimation of θ may exhibit rank deficit and it is natural to apply the least squares solution

$$\theta_N = (\Phi_N^T \Phi_N)^+ \Phi_N^T \mathcal{Y}_N \quad (27)$$

where $(\Phi_N^T \Phi_N)^+$ denotes the matrix pseudo inverse of $\Phi_N^T \Phi_N$. The associated least-squares estimate thus obtained has the smallest 2-norm of all possible minimizers of the least-squares criterion and provides its result in the form of a left matrix factorization

$$\begin{aligned} A(z^{-1})Y(z) &= B(z^{-1})U(z) + W(z) \\ A(z^{-1}) &= I_{p \times p} + A_1 z^{-1} + \dots + A_n z^{-n} \\ B(z^{-1}) &= B_1 z^{-1} + B_2 z^{-2} + \dots + B_n z^{-n} \end{aligned}$$

with input U , output Y , and disturbance W .

Algorithm 1 Let $A_i^{(n)}(x) = I_{p \times p} + \sum_{j=1}^n A_j^{(n)} x^j \in \mathbb{R}^{p \times p}[x]$ and $B_L^{(n)}(x) = \sum_{j=1}^n B_j^{(n)} x^j \in \mathbb{R}^{p \times m}[x]$ denote some nonsingular left MFD $(A(x), B(x))$ of polynomial degree n . Compute for $i = n, n-1, \dots, 1$

$$\begin{aligned} i) \quad & C_j^{(2(n-i+1)-1)} \\ &= (B_{i-j}^{(i)})^+ \left(A_i^{(i)} - \sum_{k=0}^{j-1} B_{i-k}^{(i)} C_k^{(2(n-i+1)-1)} \right), \\ & \quad j = 0, 1, \dots, i-1 \end{aligned}$$

$$\begin{aligned} ii) \quad & C_j^{(2(n-i+1))} \\ &= (A_{i-j-1}^{(i-1)})^+ \left(B_i^{(i)} - \sum_{k=0}^{j-1} A_{i-1-k}^{(i-1)} C_k^{(2(n-i+1))} \right), \\ & \quad j = 0, 1, \dots, i-1 \end{aligned}$$

$$\begin{aligned} iii) \quad & C_j^{(2(n-i+1))}(x) \\ &= \sum_{j=0}^i C_j^{(2(n-i+1))} x^j \in \mathbb{R}^{m \times p}[x], \\ & \quad i = n, n-1, \dots, 1 \end{aligned}$$

$$\begin{aligned} iv) \quad & C_j^{(2(n-i+1)-1)}(x) \\ &= \sum_{j=0}^i C_j^{(2(n-i+1)-1)} x^j \in \mathbb{R}^{p \times p}[x] \\ & \quad i = n, n-1, \dots, 1 \end{aligned}$$

$$\begin{aligned} v) \quad & A_i^{(i-1)}(x) \\ &= A_i^{(i)}(x) - B_i^{(i)}(x) C^{(2(n-i+1)-1)}(x), \\ & \quad A_i^{(n)} = A(x) \end{aligned}$$

$$\begin{aligned} vi) \quad & B_i^{(i-1)}(x) \\ &= B_i^{(i)}(x) - A_i^{(i-1)}(x) C^{(2(n-i+1))}(x) x \\ & \quad B_i^{(n)} = B(x) \end{aligned} \quad (28)$$

where $(\cdot)^+$ denotes a generalized matrix inverse \square

Theorem 2—Termination of Continued Fraction Expansion Let $(A(x), B(x))$ be a strictly proper nonsingular left MFD of polynomial order n with $A(0) = I_{p \times p}$. Algorithm 1 determines the terminating continued fraction expansion matrices $\{C^{(i-1)}(x)\}_{i=1}^n$, $\{C^{(2i)}(x)\}_{i=1}^n$ and unimodular matrices $\{M^{(i)}(x)\}_{i=1}^n$ of Lemma 1 in no more than n steps with

$$\begin{aligned} Q(x)(I_{p \times p} - 0_{p \times n}) &= (A_L^{(0)} - B_L^{(0)}) = (A(x) - B(x)) \\ &= (M^{(1)}(x))^{-1} \dots (M^{(n)}(x))^{-1} (M^{(n)}(x))^{-1} \end{aligned} \quad (29)$$

with $Q(x) \in \mathbb{R}^{p \times p}[x]$ being a left divisor of $(A(x), B(x))$.

Proof Steps v)–vi) of the algorithm embody for $i = n, n-1, \dots, 1$ the order recursion

$$\begin{aligned} & (A_i^{(i-1)} - B_L^{(i-1)}) \\ &= (A_i^{(i)} - B_i^{(i)}) \\ & \quad \left(C^{(2(n-i+1)-1)} I + C^{(2(n-i+1)-1)} C^{(2(n-i+1))} C^{(2(n-i+1)-1)} \right) \end{aligned} \quad (30)$$

The construction similar to a Routh scheme of $\{C^{(2i-1)}(x)\}_{i=1}^n$, $\{C^{(2i)}(x)\}_{i=1}^n$ and the full-rank condition of $(A(x), B(x))$ serve to eliminate terms of degree i from $A_i^{(i-1)}$ and $B_i^{(i-1)}$ so that

$$\begin{aligned} 0 &= A_i^{(i)} x^i - \sum_{k=0}^{i-1} B_{i-k}^{(i)} C_k^{(2(n-i+1)-1)} x^i \\ 0 &= B_i^{(i)} x^i - \sum_{k=0}^{i-1} A_{i-1-k}^{(i-1)} C_k^{(2(n-i+1))} x^i \end{aligned} \quad (31)$$

as long as $B_i^{(i)} \neq 0$. The order recursion of $B_i^{(i)}$ for $i = n, n-1, \dots, 1$ with $\deg B_i^{(i)}(x) = i$ and $B_i^{(0)} = 0_{p \times n}$ and can always be made as $A_L^{(i)}(0) = I_{p \times p}$ for all i . The resultant $A_i^{(0)}$ terminates as a nonsingular left divisor of $(A(x), B(x))$ as $\{M^{(i)}(x)\}_{i=1}^n$ of (29) are unimodular \square

After determination of $C^{(2i-1)}$ and $C^{(2i)}$ in (30) for $i = n, n-1, \dots, 1$, it is straightforward to remove the left divisor $Q(x)$ and to recursively calculate the approximants $\{(A_i^{(i)}, B_i^{(i)})\}_{i=1}^n$ of polynomial degree i according to (12)–(13). The resultant approximant

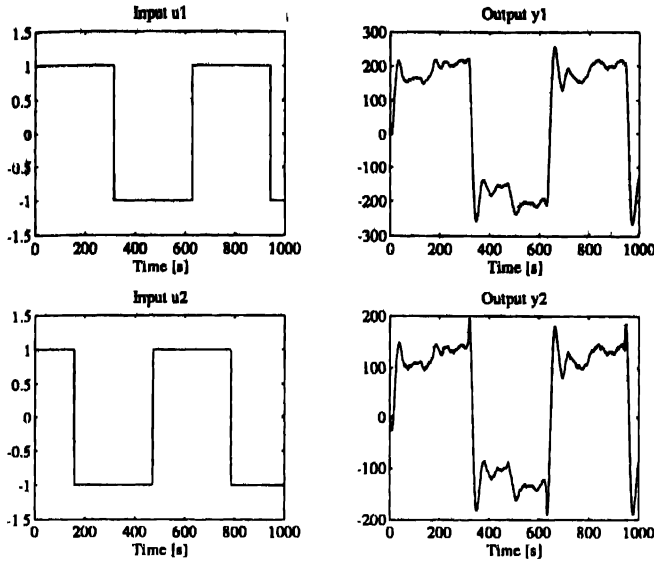

Fig. 3. Input-output data used in Example 2 with apparent cross-coupling properties.

represent coprime factorizations according to Theorem 1 with exact representation of the original transfer function for $i = n$. In particular, the sequences $\{C^{(2i)}\}$, $\{C^{(2i-1)}\}$ are constant matrices whenever the matrix sequences $\{B_i^{(1)}\}_{i=1}^n$ and $\{A_i^{(1)}\}_{i=1}^n$ are full-rank matrices.

Example 1—Common Factors: Consider the following left matrix factorization with the common left divisor $Q(z^{-1}) = I + Dz^{-1}$ (D being assumed invertible)

$$\begin{aligned} A_L^{(2)} &= (I + Dz^{-1})(1 + A_1 z^{-1}) \\ &= I + (D + A_1)z^{-1} + DA_1 z^{-2} \\ B_L^{(2)} &= (I + Dz^{-1})B_1 z^{-1} \\ &= B_1 z^{-1} + DB_1 z^{-2}. \end{aligned} \quad (32)$$

Application of the algorithm gives

$$\begin{aligned} C^{(1)} &= (DB_1)^+ DA_1 \\ A_L^{(1)} &= I + (D + A_1)z^{-1} + DA_1 z^{-2} \\ &\quad - (B_1 z^{-1} + DB_1 z^{-2})C^{(1)} = I + Dz^{-1} \\ C^{(2)} &= D^{-1}DB_1 = B_1 \\ B_L^{(1)} &= B_1 z^{-1} + DB_1 z^{-2} \\ &\quad - (I + Dz^{-1})C^{(2)} z^{-1} = 0. \end{aligned} \quad (33)$$

As $B_L^{(1)} = 0$ this algorithm terminates after one recursion only with the resulting model order $n - 1 = 1$ of the transfer function approximant. The common left divisor $(I + Dz^{-1})$ appears as the approximant $A_L^{(1)}$ as shown in Theorem 3. \square

Example 2—A Simulated Example: Consider the multivariable system

$$y_k = \begin{pmatrix} 1.2 & -0.29 \\ 0.25 & 0.7 \end{pmatrix} y_{k-1} + \begin{pmatrix} -2.0 & 0.07 \\ -10.0 & 1.0 \end{pmatrix} u_{k-1} + w_k, \quad u_k, y_k, w_k \in \mathbb{R}^2 \quad (34)$$

with input $\{u_k\}$, zero-mean white noise $\{w_k\}$ with $\mathcal{E}\{w_i w_j^T\} = I_{2 \times 2} \delta_{ij}$ and output $\{y_k\}$. Simulated data are according to Fig. 3, which exhibit obvious cross-coupling properties. The estimate $\hat{\theta}_N$ for model order $n = 1$ and $N = 1000$ samples of input-output data is

$$\begin{aligned} \hat{\theta}_N &= (\hat{A}_1 \quad \hat{B}_1)^T \\ &= \begin{pmatrix} -1.2012 & 0.2908 & -2.1053 & 0.0916 \\ -0.2490 & -0.7010 & -9.9715 & 1.0123 \end{pmatrix}^T \end{aligned} \quad (35)$$

Fig. 4. Simulated data including partial state, output error, prediction error, and model output with input-output data as used in Example 2.

and the continued-fraction approximation matrices are

$$C^{(1)} = \begin{pmatrix} 0.9797 & -0.2945 \\ 9.4039 & -3.5929 \end{pmatrix}$$

and

$$C^{(2)} = \begin{pmatrix} -2.1053 & 0.0916 \\ -9.9715 & 1.0123 \end{pmatrix}. \quad (36)$$

Polynomial matrices of the right coprime factorization can be computed from the real-valued matrices $C^{(1)}$ and $C^{(2)}$ as

$$\begin{aligned} \begin{pmatrix} B_R(z^{-1}) \\ A_R(z^{-1}) \end{pmatrix} &= \begin{pmatrix} C^{(2)} z^{-1} \\ I + C^{(1)} C^{(2)} z^{-1} \end{pmatrix} \\ &= \begin{pmatrix} -2.1053 z^{-1} & 0.0916 z^{-1} \\ -9.9715 z^{-1} & 1.0123 z^{-1} \\ 1.0 + 0.8736 z^{-1} & -0.2084 z^{-1} \\ 16.0285 z^{-1} & 1.0 - 2.7759 z^{-1} \end{pmatrix}. \end{aligned} \quad (37)$$

Once the continued-fraction matrices $\{C^{(2i-1)}\}_{i=1}^n$ and $\{C^{(2i)}\}_{i=1}^n$ have been determined it is straightforward to obtain the prediction error ε and the partial state ξ according to

$$\begin{aligned} \begin{pmatrix} \varepsilon \\ \xi \end{pmatrix} &= \begin{pmatrix} \hat{A}_L^{(n)} & -\hat{B}_L^{(n)} \\ \hat{S}_L^{(n)} & \hat{R}_L^{(n)} \end{pmatrix} \begin{pmatrix} Y(z) \\ U(z) \end{pmatrix} \\ &= \hat{A}^{(n)} \hat{A}^{(n-1)} \dots \hat{A}^{(1)} \begin{pmatrix} Y(z) \\ U(z) \end{pmatrix}. \end{aligned} \quad (38)$$

The partial state ξ and up to n shifted values of ξ determine the state of the system described according to the controllable canonical state-space realization [14, p. 403], [2]. Thus, the state observer embodied in (38) provides a state estimate that is obtained along with the residual (or prediction error) of transfer function estimation. Simulated data including partial state, output error, prediction error, and model output are shown in Fig. 4.

IV. CONCLUSIONS

We have shown that the continued-fraction expansion provides an alternative parameterization of multivariable systems in the context of system identification. The close relationship between the continued-fraction approximation and solution to the Diophantine equation is

demonstrated. Hence, this parameterization provides a computational link between various matrix factorizations, between transfer function estimation and state estimation, between prediction-error methods and output-error methods, and between model reduction and control. The lattice structure provided by the continued-fraction approximation facilitates calculations and computations can be organized by means of order recursions backwards and forwards. In future work it is intended to investigate identification properties in the presence of colored noise and adaptive control.

All Fixed-Order H_∞ Controllers: Observer-Based Structure and Covariance Bounds

T. Iwasaki and R. E. Skelton

Abstract—This note obtains a parameterization of the set of all stabilizing controllers of order less than or equal to the plant, which yields for the closed-loop transfer matrix a specified H_∞ norm bound. The algebraic results of covariance control are applied to the H_∞ control problem to yield a parameterization in terms of the Lyapunov matrix, which carries many system properties (such as H_2 performance, covariance bounds, system entropy at infinity, etc.). All low-order H_∞ controllers are shown to have observer-based structure for "reduced-order models" of the plant and are characterized by two Riccati equations with a coupling condition.

I. INTRODUCTION

The main objective of this note is to provide a new derivation of the standard H_∞ control theory [1], [2] using the algebraic approach in the covariance control literature [3]–[6]. The idea is to consider the bounded real equation for the closed-loop system as an algebraic problem to be solved for the controller parameters. Similar algebraic approaches in the literature include [4], [7]–[10]. In particular, [7] and [4] (appeared simultaneously) extend the result of [9] to obtain a parameterization of fixed-order output feedback H_∞ controllers. The "standard" case (full control penalty and full measurement noise) was considered in [7] where the existence conditions are characterized by coupled Riccati equations similar to those of [9]. These Riccati equations contain controller parameters, however, and thus the parameterization is implicit. Reference [4] (see [5] for its journal version) solved a singular case (no control penalty and no measurement noise) where existence conditions are given by three matrix equalities without controller parameters, and all fixed-order H_∞ controllers are parameterized explicitly. In [7] and [4], computations of fixed-order controllers are extremely difficult.

Contributions of this note over the existing literature are the following. We consider the "standard case" and remove the controller parameter dependence of the Riccati equations in [7] and obtain explicit formulas for all H_∞ controllers, which allow us to prove the observer-based structure of all H_∞ controllers, including noncentral controllers of order equal to or less than the plant (note that [1] shows the observer-based structure for the central (full-order) controller, but not for any other strictly proper H_∞ controllers). Another contribution is extending the results of [7], [4], to provide a parameterization of all H_∞ controllers in terms of the solution to the bounded real equation, which we call the H_∞ Lyapunov matrix. Recall that the H_∞ Lyapunov matrix is an upper bound for the state covariance [11] and can be used to define several other system properties including system entropy [12] and the (dual) mixed H_2/H_∞ performance measure defined using power semi-norms [13]. (An improved upper bound on H_2 norm is provided in the mixed H_2/H_∞ solutions in [14].) Thus, such a parameterization is useful (especially for the full-order controller case) to incorporate H_2 related performance specifications in addition to the H_∞ norm bound.

Finally, we should mention that our result still has a computational difficulty, as in [7] and [4], for solving the coupled Riccati equations except for the full-order controller case. Thus the computational aspects of the fixed (low) order H_∞ controller design problem needs a more thorough exploration.

We will use the following notation. For a matrix A , A' denotes the transpose, $\rho(A)$ and $\sigma_{\max}(A)$ the spectral radius and the maximum singular value, respectively, and A^+ denotes the Moore-Penrose pseudo-inverse of A . If A is nonnegative definite, $A^{1/2}$ is the (unique) nonnegative definite square root of A . $\|\cdot\|_\infty$ and $\|\cdot\|_2$ denote the H_∞ and H_2 norms, respectively.

II. PRELIMINARIES

Consider the class of dynamic systems described by the state space realizations of the n_p -th-order plant (Σ_p) and the n_c -th-order controller (Σ_c)

$$(\Sigma_p) \begin{cases} \dot{x} = A_1 x + B_1 w + B_2 u \\ z = C_1 x + D_{12} u \\ y = C_2 x + D_{21} w \end{cases}$$

$$(\Sigma_c) \begin{cases} \dot{x}_c = A_c x_c + B_c y \\ u = C_c x_c + D_c y \end{cases}$$

to give the closed-loop system (Σ_{cl})

$$(\Sigma_{cl}) \begin{cases} \dot{x}_{cl} = A_{cl} x_{cl} + B_{cl} w \\ z = C_{cl} x_{cl} + D_{cl} w \end{cases} \quad x_{cl} := \begin{bmatrix} x \\ x_c \end{bmatrix}$$

where $x \in \mathbb{R}^{n_p}$ is the plant state, $w \in \mathbb{R}^{n_w}$ is any external input, including plant disturbances, measurement noise, etc., $u \in \mathbb{R}^{n_u}$ is the control input, $z \in \mathbb{R}^{n_z}$ is the regulated output, $y \in \mathbb{R}^{n_y}$ is the measured output, and $x_c \in \mathbb{R}^{n_c}$ is the controller state. We denote the closed-loop transfer matrix from w to z by T_{zw} . The following assumptions are made for (Σ_p) :

AP1) (A_1, B_1) is stabilizable and (C_2, A_1) is detectable.

AP2) (A_1, B_1) is stabilizable.

AP3) $D_{12}' [C_1' D_{12}] = [0 \ I']$, $I' > 0$
 $D_{21} [B_1' D_{21}'] = [0 \ V']$, $V' > 0$.

AP1) is obviously necessary for the existence of a stabilizing controller. AP2) and AP3) are technical assumptions which are standard in the H_∞ control literature (e.g., [1]). Note that AP2) and AP3) imply that (A_1, B_1) is stabilizable if and only if (A_1, B_1) is stabilizable. This fact can easily be verified by standard manipulations once we notice that

$$[B_1 \ 0] = \begin{bmatrix} B_1 & B_2 D_c \\ 0 & B_c \end{bmatrix} T, \quad T := \begin{bmatrix} I & D_{21}' \\ D_{21} & 0 \end{bmatrix}$$

where T is nonsingular due to the second part of AP3). To state the H_∞ control problem, we need the following definition.

Definition 1: Given a positive scalar γ , the controller (Σ_c) is said to be an H_∞ controller if the following four conditions hold:

C1) (A_c, B_c) is controllable and (A_c, C_c) is observable.

C2) A_c is asymptotically stable.

C3) $\|T_{zw}\|_\infty \leq \gamma$.

C4) $\gamma^2 I - D_{cl}' D_{cl} > 0$.

The first minimality condition reflects the fact that we seek a low-order controller. Note that conditions C2) and C3) imply $\gamma^2 I - D_{cl}' D_{cl} \geq 0$. To utilize Lemma 1 below, we impose condition C4) which excludes the case $\sigma_{\max}(D_{cl}) = \gamma$. Nevertheless, the set of

all stabilizing minimal controllers which yield the strict inequality $\|T_{zw}\|_\infty < \gamma$ is contained in the set of all H_∞ controllers defined above. Without loss of generality, we will set the H_∞ norm bound γ to one to facilitate the rest of our presentation. Now the H_∞ control problem can be stated as follows:

Find the necessary and sufficient conditions for the existence of an H_∞ controller. If one exists, obtain an explicit formula for all such controllers

This problem has been solved [1], [2]. Our objective is to solve this problem by a different approach based on the bounded real lemma given below, which turns out to give an explicit parameterization of all low-order H_∞ controllers in terms of a physically meaningful quantity. To this end, let us state the bounded real lemma modified for controller synthesis. We need the following definitions

$$Q := A_{cl} X_{cl} + X_{cl} A_{cl}' + B_{cl} B_{cl}' + (X_{cl} C_{cl}' + B_{cl} D_{cl}') R^{-1} (X_{cl} C_{cl}' + B_{cl} D_{cl}')' \quad (1)$$

$$R := I - D_{cl}' D_{cl} \quad (2)$$

$$\mathcal{C} := \{ (A_c, B_c, C_c, D_c) : R > 0 \text{ and } \exists X_{cl} \geq 0 \text{ s.t. } Q = 0 \} \quad (3)$$

Lemma 1: Let a plant (Σ_p) and a controller (Σ_c) be given. Suppose AP2) and AP3) hold. Then the following statements are equivalent.

i) The controller (Σ_c) is an H_∞ controller.

ii) The controller (Σ_c) is a minimal realization of some controller $(\tilde{\Sigma}_c) \in \mathcal{C}$.

Proof: Suppose i) holds. Then it is a standard fact (see, for example, [15] for a detailed proof and [16] for relaxation of the controllability assumption in [15]) that $(\Sigma_c) \in \mathcal{C}$. Hence ii) holds. Conversely, suppose ii) holds. Let matrices associated with $(\tilde{\Sigma}_c)$ be denoted with $\tilde{\cdot}$. If (A_c, B_c) is stabilizable, then $(\tilde{A}_c, \tilde{B}_c)$ is stabilizable and, by Lyapunov theory, \tilde{A}_c is asymptotically stable. In this case it is straightforward to show $\|\tilde{T}_{zw}\|_\infty \leq \gamma$. Hence, any minimal realization (Σ_c) of $(\tilde{\Sigma}_c)$ satisfies all four conditions C1)-C4), and we conclude i). Now, when (A_c, B_c) is not stabilizable, it can be shown by a coordinate change that a controllable realization of $(\tilde{\Sigma}_c)$, denoted by $(\tilde{\Sigma}_c)$, is such that $(\Sigma_c) \in \mathcal{C}$ and the corresponding pair $(\tilde{A}_c, \tilde{B}_c)$ is stabilizable. Then the same argument as above applies. This completes the proof.

If we view the (Riccati) equation $Q = 0$ as a Lyapunov equation with a forcing term quadratic in X_{cl} , a nonnegative definite solution X_{cl} can be used to prove closed-loop stability, while also defining the H_∞ performance. Hence we call X_{cl} an " H_∞ Lyapunov matrix." As mentioned in Section I, the "covariance control approach" to the H_∞ control problem taken in this note is the following. Consider the matrix equation $Q = 0$ as an algebraic problem to be solved for the controller parameters. In this case, solvability conditions characterize the set of all H_∞ Lyapunov matrices which can be "assigned" to the closed-loop system by some controller (Σ_c) . Then the general solution to $Q = 0$ provides an explicit formula for all controllers (Σ_c) which yields a specified X_{cl} as an H_∞ Lyapunov matrix. A controller constructed in this way may turn out to be such that (A_{cl}, B_{cl}) is not stabilizable, in which case, the usual bounded real lemma (e.g., [15]) cannot guarantee closed-loop stability. Lemma 1 stated above shows that, even for such a case, the closed-loop system is guaranteed to be internally stable.

Recall that the H_∞ Lyapunov matrix X_{cl} is related to the H_2 performance. As shown in [11], for the error signal $e := C_0 x$, the

H_2 norm of the transfer matrix $T_{e,w}$ from w to e is bounded above by a function of X_{cl} as follows

$$\|T_{e,w}\|_2^2 \leq J := \text{trace} C_0' X_p C_0'$$

where X_p is the 11-block ($n_p \times n_p$) of X_{cl} . The following lemma shows a necessary condition for an H_∞ controller to be "minimal order" in the H_2 related sense

Lemma 2 Given an n_c -th-order controller $(\Sigma_c) \in \mathcal{C}$. Let

$$X_{cl} := \begin{bmatrix} X_p & X_{pc} \\ X_{pc}' & X_c \end{bmatrix} \geq 0 \quad (4)$$

be any solution to $Q = 0$. Suppose $X_{pc}' X_{pc} \succ 0$. Then there exists a controller $(\hat{\Sigma}_c) \in \mathcal{C}$ of order $\hat{n}_c < n_c$ which yields the same H_2 performance bound J .

Proof Using the singular value decomposition of X_{pc} ($X_c^{1/2}$)⁺, define a matrix Ψ as

$$\Psi := \begin{bmatrix} I & 0 \\ 0 & V_1'(X_c^{1/2})^+ \end{bmatrix}, \quad X_{pc}(X_c^{1/2})^+ = U_1 \Sigma_1 V_1'$$

where $V_1 \in \mathbb{R}^{n_c \times n_c}$. Since $\text{rank}(X_{pc}) < n_c$, we have $n_c < n_c$. Noting that $X_{cl} \geq 0$ is equivalent to

$$X_c \geq 0, \quad X_p - X_{pc}' X_c^+ X_{pc} \geq 0, \quad (I - X_c X_c^+) X_c' = 0$$

computation of $Q := \Psi Q \Psi$ verifies that a controller (Σ_c) of order \hat{n}_c given by

$$\hat{A}_c = V_1'(X_c^{1/2})^+ A_c X_c^{1/2} V_1, \quad \hat{B}_c = V_1'(X_c^{1/2})^+ B_c,$$

$$C_c = C_c X_c^{1/2} V_1, \quad D_c = D_c$$

satisfies $Q = 0$ with

$$X_{cl} = \begin{bmatrix} X_p & U_1 \Sigma_1 \\ \Sigma_1 U_1' & I \end{bmatrix} \geq 0 \quad (5)$$

Since the 11-block of X_{cl} is identical to that of X_{cl} , the controller $(\hat{\Sigma}_c)$ yields the same H_2 performance bound.

By mathematical equivalency, if $X_{pc}' X_{pc} \succ 0$, then there exists a controller of lower order which has the same entropy at infinity when $C_1 = C_0$ [12]. By duality, the same statement can apply to the mixed H_2/H_∞ cost of Doyle *et al.* [13].

Lemmas 1 and 2 motivate us to define the following

Definition 2 A controller (Σ_c) is said to be an admissible H_∞ controller if $(\Sigma_c) \in \mathcal{C}$ and there exists a matrix $X_{cl} \geq 0$ which solves $Q = 0$ and satisfies $X_{pc}' X_{pc} \succ 0$.

Since we look for H_∞ controllers of low order, we will restrict our attention to admissible H_∞ controllers in the rest of this paper. It should be noted that the conditions $X_{pc}' X_{pc} \succ 0$ and $X_{cl} \geq 0$ imply that $X_c \succ 0$.

III ALL LOW ORDER H_∞ CONTROLLERS

This section provides a parameterization of all admissible H_∞ controllers in terms of the H_∞ Lyapunov matrix. Mathematical tools developed in covariance control theory are useful here [5]. To state the result, let \mathcal{L} be a subset of real symmetric matrices defined as follows. $X_{cl} \in \mathbb{R}^{(n_p+n_c) \times (n_p+n_c)}$ is an element of \mathcal{L} if

$$X_{cl} := \begin{bmatrix} X_p & X_{pc} \\ X_{pc}' & X_c \end{bmatrix} \geq 0, \quad X_{pc}' X_{pc} \succ 0$$

and there exist $L_{cl} \in \mathbb{R}^{n_p \times n_u}$, $L_1 \in \mathbb{R}^{n_p \times n_v}$ and $L_D \in \mathbb{R}^{n_u \times n_v}$ such that

$$A X_p + X_p A' + X_p C_1' C_1 X_p + B_1 B_1' - B_2 U^{-1} B_2' + L_{cl} L_{cl}' = 0 \quad (6)$$

$$A \bar{X}_p + \bar{X}_p A' + \bar{X}_p (C_1' C_1 - C_2' U^{-1} C_2) \bar{X}_p + B_1 B_1' + L_1 L_1' = 0 \quad (7)$$

$$(I - X_{pc}' X_{pc}^+) [L_{cl} L_{cl}' - \Gamma_{cl} R_{cl}^{-1} \Gamma_{cl}'] (I - X_{pc} X_{pc}^+) = 0, \quad (8)$$

$$\|D_{12} L_D D_{21}\| < 1 \quad (9)$$

where

$$\bar{X}_p = X_p - X_{pc}' X_c^{-1} X_{pc},$$

$$R_{cl} = U^{-1} - L_D V L_D', \quad \Gamma_{cl} = X_p C_2' L_D' + B_2 U^{-1}$$

The following theorem shows that \mathcal{L} is indeed the set of all H_∞ Lyapunov matrices X_{cl} which can be used to prove that a controller (Σ_c) is admissible. It also gives an explicit formula for all controllers which yield a given H_∞ Lyapunov matrix for the closed-loop system. A proof is given in the appendix. We shall need the following definitions

$$P = X_{cl} V^{-1}, \quad P_+ = X_{cl} V_1^{-1},$$

$$A = P_+ A P, \quad B_2 = P_+ B_2, \quad C_2 = C P \quad (10)$$

$$R_{cl} = V^{-1} - L_D' U L_D, \quad V_{cl} = B_2' L_D + X_{cl} C_2' V^{-1}$$

$$\Gamma_{cl} = \bar{X}_p C_2' L_D' + B_2 U^{-1}, \quad \Gamma_{cl} = B_2' L_D + X_{cl} C_2' V^{-1}$$

$$\Theta = I - X_{cl} X_{pc}^+, \quad \Gamma_{cl} = \Theta L_{cl}, \quad H_{cl} = \Theta L_{cl} R_{cl}^{-1/2}$$

$$F_{cl} = \Theta I_{cl}, \quad H_{cl} = \Theta I_{cl} R_{cl}^{-1/2}$$

Theorem 1 The following statements are equivalent

- i) There exists an admissible H_∞ controller
- ii) $\mathcal{L} \neq \emptyset$

In this case, let (Σ_c) be any controller. Then the following statements are equivalent

- iii) (Σ_c) is an admissible H_∞ controller
- iv) There exist $X_{cl} \in \mathcal{L}$ and orthogonal matrices Γ_{cl} and F_{cl} such that

$$A = \hat{A} + B_2 C_c - B_c C_2 + B_2 D C_2' + P_+ [\bar{X}_p C_1' C_1 - L_1 U_1 H_{cl}^{1/2} (B_c + N R_{cl}^{-1} D)' X_{pc}^+] P \quad (11)$$

$$B_c = P_+ (L_1 U_1 R_{cl}^{1/2} + \Gamma_{cl}),$$

$$C_c = (L_{cl} U_{cl} R_{cl}^{1/2} - \Gamma_{cl}')' (X_{cl}^+)', \quad D_c = L_D$$

where L_D satisfies (9) and

$$N := X_{cl} C_{cl}' + X_{pc}' C_2' D_{cl}' + B_{cl}' V D_{cl}'$$

$$U_{cl} = E_{cl}^+ H_{cl} + N_{FU} F_{cl} N_{HU}', \quad U_{cl} = -E_{cl}^+ H_{cl} + N_{LV} F_{cl} N_{HV}' \quad (12)$$

where columns of N_{FU} , N_{HU} , N_{LV} , and N_{HV} are orthonormal bases for the null spaces of E_{cl} , H_{cl} , E_{cl} , and H_{cl} , respectively.

Theorem 1 shows the observer-based structure of all (low order) H_∞ controllers. In particular, if we consider strictly proper controllers ($D_c = 0$), (11) yields

$$\dot{x}_c = \hat{A}x_c + \hat{B}_2 u + B_c(y - \hat{C}_2 x_c) + \hat{w},$$

$$u = C_c x_c, \quad \hat{w} := P_+(\bar{X}_p C_1' C_1 - L_1 U_V V^{-1/2} B_c' X_{pc}^+) P_{X_c}$$

where $(\hat{A}, \hat{B}_2, \hat{C}_2)$ are defined in (10). Thus any low order strictly proper admissible H_∞ controller has the structure of state-estimator plus estimated-state feedback for the "reduced-order model" $(\hat{A}, \hat{B}_2, \hat{C}_2)$ of the original plant, obtained by keeping only the states belonging to the range space of X_{pc} (or $X_p - \bar{X}_p$). As in the full-order case (see [1]), a low-order H_∞ estimator also has an extra term \hat{w} , which can be thought of loosely as an estimate for the worst case L_2 disturbance.

Note that the two Riccati equations (6) and (7) are the familiar ones which describe the existence conditions for an H_∞ controller [2] if i) X_p is invertible so that (6) can be multiplied by X_p^{-1} from both sides, and ii) the free matrices L_c and L_1 are set to zero. Since the controller order is fixed (n_c is specified by the dimension of $X_{c,t}$), we have another condition (8). The familiar spectral radius condition in [1] is implicitly embedded in the set \mathcal{L} : by the definition of X_p and the positiveness of $X_{c,t}$, we require $X_p \geq \bar{X}_p \geq 0$, which is equivalent to $\rho(X_p^{-1} \bar{X}_p) \leq 1$ when $X_p > 0$. Notice that the third condition (8) disappears if we consider the full-order ($n_c = n_p$) controller case since X_{pc} becomes square and invertible. Thus a full-order H_∞ controller can be designed by solving two Riccati equations. The more detailed exploration of the full-order case, including explicit upper bounds on the plant state covariance and the control input covariance in terms of the H_∞ Lyapunov matrix, can be found in the conference version of this note [17]. For the general case ($n_c < n_p$), however, finding $X_{c,t} \geq 0$ that satisfies all three conditions (6)–(8) does not seem to be tractable. Homotopic continuation methods [18] may be useful to solve the coupled Riccati equations.

IV. CONCLUSION

The set of all H_∞ controllers of order equal to or less than the plant is parameterized in terms of the H_∞ Lyapunov matrix, which carries many system properties such as H_2 -related performances and the system entropy. The H_∞ Lyapunov matrices, which can be "assigned" to the closed-loop system by some controller, are characterized by the two Riccati equations and the coupling condition in Theorem 1, which are numerically nontrivial to solve for the general low-order controller case. Hence, the computational issue remains open for further research. The coupling condition disappears for the full-order case, and thus the computational problem becomes much easier as in the literature [1]. Our novel results show that any low-order H_∞ controller has observer-based structure. This has been shown [1] only for the full-order (central) H_∞ controller. The observer part of the low-order H_∞ controller estimates the states of the "reduced-order model" of the original plant obtained by some model reduction methods based on a projection formulation.

APPENDIX

Proof of Theorem 1: Recall that all H_∞ controllers are characterized by $Q = 0$ and $R > 0$ in (1) and (2). Note that R is positive definite if and only if $\|D_{12} D_{21}\| < 1$. So we consider the following mathematical problem: Given $D_c (= L_{11})$ such that the above norm bound constraint is satisfied, find necessary and sufficient conditions for the solvability of $Q = 0$ for (A, B, C) . The proof begins with necessity.

Necessity: Suppose (Σ_c) is an admissible H_∞ controller. Then $Q = 0$ holds for some $X_{c,t} \geq 0$, or equivalently

$$\begin{bmatrix} I & -X_{pc} X_{c,t}^{-1} \\ 0 & I \end{bmatrix} Q \begin{bmatrix} I & 0 \\ -X_{c,t}^{-1} X_{pc}' & I \end{bmatrix} = 0$$

whose partitioned blocks are given by (c.f. [7])

$$A \bar{X}_p + \bar{X}_p A' + \bar{X}_p (C_1' C_1 - C_2' V^{-1} C_2) \bar{X}_p + B_1 B_1' + (X_{pc}' X_{c,t}^{-1} B_c - \bar{\Gamma}_1) R_V^{-1} (X_{pc}' X_{c,t}^{-1} B_c - \bar{\Gamma}_1)' = 0, \quad (13)$$

$$(A + \bar{X}_p C_1' C_1) X_{pc} + \bar{X}_p C_2' B_c' - X_{pc}' X_{c,t}^{-1} A_c X_c + \bar{\Gamma}_1' R_V^{-1} N' - X_{pc}' X_{c,t}^{-1} B_c (C_2 X_{pc} + V B_c' + V' L_D R_V^{-1} N') = 0, \quad (14)$$

$$A_c X_c + X_c A_c' + X_{pc}' (C_1' C_1 - C_2' V^{-1} C_2) X_{pc} + N R_V^{-1} N' + (B_c + X_{pc}' C_2' V^{-1}) V' (B_c + X_{pc}' C_2' V^{-1})' = 0. \quad (15)$$

Also, it is necessary that 11-block of Q is equal to zero, i.e.,

$$A X_p + X_p A' + X_p C_1' C_1 X_p + B_1 B_1' - B_2 U^{-1} B_2' + (X_{pc}' C_c' + \Gamma_{11}) R_{11}^{-1} (X_{pc}' C_c' + \Gamma_{11})' = 0. \quad (16)$$

Since the last term in (16) is nonnegative definite with rank $\leq n_u$, it is necessary that (6) holds for some $L_{11} \in \mathbb{R}^{n_p \times n_u}$ satisfying

$$L_{11} L_{11}' = (X_{pc}' C_c' + \Gamma_{11}) R_{11}^{-1} (X_{pc}' C_c' + \Gamma_{11})'. \quad (17)$$

Similarly for (13), it is necessary that (7) holds for some $L_1 \in \mathbb{R}^{n_p \times n_v}$ satisfying

$$L_1 L_1' = (X_{pc}' X_{c,t}^{-1} B_c - \bar{\Gamma}_1) R_V^{-1} (X_{pc}' X_{c,t}^{-1} B_c - \bar{\Gamma}_1)'. \quad (18)$$

Now, applying the result (Appendix C) of [5], there exists a C_c satisfying (17) if and only if the equality in (8) holds, and all solutions C_c are given by

$$C_c = (L_{11}' U_{11}' R_{11}^{1/2} - \Gamma_{11}')' (X_{pc}^+)' \quad (19)$$

where U_{11} is defined by (12) with F_{11} being an arbitrary orthogonal matrix. Thus we have established the necessity of (6)–(9).

Sufficiency: Now, suppose conditions (6)–(9) hold. We need to show the existence of a controller which satisfies (13)–(15). In the necessity part of the proof, we have shown that C_c given by (19) satisfies (16) under supposed conditions. To prove sufficiency, we will construct B_c and A_c satisfying (13)–(15) together with C_c given by (19).

Using the result of [5] again, there exists a B_c satisfying (18) if and only if

$$(I - X_{pc}' X_{pc}^+) [L_1 L_1' - \bar{\Gamma}_1 R_V^{-1} \bar{\Gamma}_1'] (I - X_{pc}' X_{pc}^+) = 0 \quad (20)$$

holds and all solutions B_c are given by

$$B_c = X_c X_{pc}^+ (L_1 U_{11}' R_V^{1/2} + \bar{\Gamma}_1) \quad (21)$$

where U_{11} is defined by (12) with F_{11} being an arbitrary orthogonal matrix. It can be verified that the conditions (6)–(9) imply that (20) always holds. Thus, B_c given by (21) solves (13).

Next, note that (14) is solvable for A_c if and only if $(I - X_{pc}' X_{pc}^+) \hat{Q}_{12} = 0$ holds where \hat{Q}_{12} is the left hand side of (14). In this case, the unique solution A_c is given by

$$A_c = X_c X_{pc}^+ \hat{Q}_{12} X_c^{-1}. \quad (22)$$

Now we claim that the above solvability condition is always satisfied by the choice of B_c and C_c given by (21) and (19), respectively. To

prove this, it is sufficient to show that

$$\bar{Q}_{12} := (I - X_{pc} X_{pc}^+) \bar{Q}_{12} X_c^{-1} X_{pc}' = 0 \quad (23)$$

since $X_c > 0$ and $X_{pc}' X_{pc} > 0$. Substituting (19) and (21) into (23), and using (12), after some manipulations, we obtain $\bar{Q}_{12} = 0$. Thus A_c , B_c , and C_c given by (22), (21), and (19) solve (13) and (14) provided (6)–(9) holds.

Finally, straightforward algebraic manipulations show that (15) also holds. The basic steps are the following. First solve (14) for $X_{pc} X_c^{-1} A_c X_c$ and then substitute into

$$\bar{Q}_{22} = X_{pc} X_c^{-1} Q_{22} X_c^{-1} X_{pc}'$$

where Q_{22} denotes the left hand side of (15). Using (7)–(9) and (17)–(18), after some manipulations, it can be verified that $\bar{Q}_{22} = 0$, which implies (15). This completes the proof. Q E D

Intrinsic Difficulties in Using the Doubly-Infinite Time Axis for Input-Output Control Theory

Tryphon T. Georgiou and Malcolm C. Smith

Abstract—We point out that the natural definitions of stability and causality in input-output control theory lead to certain inconsistencies when inputs and outputs are allowed to have support on the doubly-infinite time-axis. In particular, linear time-invariant systems with right-half plane poles cannot be considered to be both causal and stabilizable. In contrast, there is no such conflict when the semi-infinite time axis is used.

I. DISCUSSION

Consider two systems P_i ($i = 1, 2$) defined in terms of convolution representations

$$y(t) = \int_{-\infty}^{\infty} h_i(t - \tau) u(\tau) d\tau = h_i * u$$

where $h_1(t) = e^t$ for $t \geq 0$ and zero otherwise, and $h_2(t) = -e^t$ for $t \leq 0$ and zero otherwise. Both systems have Laplace transfer functions $1/(s-1)$, but with differing regions of convergence. The first system is unstable and causal, and the second is stable and noncausal (in fact anticausal) according to the usual definitions. To view these systems abstractly in the input-output setting (or in the behavioral framework of [3]) we need to work out the system trajectories for signals in some function space, say \mathcal{L}_2 . This amounts to finding the graph, i.e., the set of input-output pairs in \mathcal{L}_2 . We mention that an explicit working out of such an approach for the semi-infinite time-axis is given in [2]. The remarks below are concerned with the case of the doubly-infinite time-axis.

We consider first P_2 . From [1 p. 158] $f \in \mathcal{L}_1$ and $g \in \mathcal{L}_1$ implies $f * g \in \mathcal{L}_1$ and

$$\|f * g\|_1 \leq \|f\|_1 \|g\|_1$$

Thus, P_2 can be alternatively represented by the following graph on $\mathcal{L}_2(-\infty, \infty)$

$$\mathcal{G}_{P_2}(-\infty, \infty) = \left(\begin{array}{c} 1 \\ \frac{1}{s-1} \end{array} \right) \mathcal{L}_2(-j\infty, j\infty) \quad (1)$$

after transforming to the frequency domain. (As usual, \mathcal{L}_2 denotes the Fourier transform which maps $\mathcal{L}_2(-\infty, \infty)$ isometrically and isomorphically onto $\mathcal{L}_2(-j\infty, j\infty)$ and $\mathcal{L}_2[0, \infty)$ onto the Hardy space \mathcal{H}_2 of the right-half plane [1, Chapter 19]. Functions in \mathcal{H}_2 can be extended analytically into the right-half plane by replacing $j\omega$ by s .)

Now consider P_1 . We will first restrict the inputs to the space $\mathcal{L}_2[0, \infty)$. Since

$$y(t) = \int_0^t e^{t-\tau} u(\tau) d\tau = e^t \int_0^t e^{-\tau} u(\tau) d\tau$$

a necessary condition for $y(t) \in \mathcal{L}_2[0, \infty)$ is that

$$\int_0^t e^{-\tau} u(\tau) d\tau \rightarrow 0$$

Fig. 1. Standard feedback configuration.

as $t \rightarrow \infty$, which is equivalent to $\langle e^{-t}, u \rangle = 0$. In fact, this is also sufficient since then

$$y(t) = -e^t \int_t^\infty e^{-\tau} u(\tau) d\tau = h_2 * u.$$

Thus the domain of P_1 in $\mathcal{L}_2[0, \infty)$ is equal to the orthogonal complement of $e^{-t}\mathbb{C}$ and, moreover, P_1 coincides with P_2 on this domain. After taking transforms, the orthogonal complement of $1/(s+1)\mathbb{C}$ is $(s-1)/(s+1)\mathcal{H}_2$. Therefore the graph of P_1 restricted to signals with support on $[0, \infty)$ becomes (in the frequency domain)

$$\hat{G}P_1|_{[0, \infty)} = \begin{pmatrix} \frac{s-1}{s+1} \\ 1 \end{pmatrix} \mathcal{H}_2 =: GH_2.$$

Since P_1 is shift invariant, the graph of P_1 on $\mathcal{L}_2(-\infty, \infty)$ contains (again, expressed in the frequency domain) the infinite union

$$\bigcup_{t \geq 0} e^{st} GH_2. \quad (2)$$

The graph of P_1 on $\mathcal{L}_2(-\infty, \infty)$ is actually slightly bigger than (2) (see below) but we will not need it for the next part of the discussion.

We now turn our attention to the requirement of stabilizability in the feedback configuration of Fig. 1. Our definition of stability is the usual one: for all external \mathcal{L}_2 disturbance inputs, there must be solutions of the feedback equations in \mathcal{L}_2 so that the closed-loop operators are norm bounded. If P_1 is stabilized by some compensator C on $\mathcal{L}_2(-\infty, \infty)$, then it turns out that the graph of P_1 must be closed. (This is a standard argument which proceeds as follows. Take a Cauchy sequence in the graph of P_1 and set this equal to $\begin{pmatrix} d_1 \\ d_2 \end{pmatrix}$. Since by assumption the feedback equations have unique solutions they must be given by: $u_1 = d_1$, $y_1 = d_2$, $u_2 = 0$, $y_2 = 0$. Now take the limit of the Cauchy sequence at the external inputs. Since the closed-loop operators are bounded, this pair of signals must also appear at u_1, y_1 .) Thus, the graph of P_1 must contain the closure of (2). But the closure of the infinite union (2) equals the graph of P_2 ! Moreover, since P_2 is an anticausal operator, then there are $\mathcal{L}_2(-\infty, \infty)$ input-output pairs which satisfy the convolution representation for P_2 but not for P_1 . Such a pair is: $u(t) = e^{-t}(t \geq 0)$, 0 ($t < 0$) and $y(t) = -e^{-|t|}/2$, which equals

$$\begin{pmatrix} \hat{u} \\ \hat{y} \end{pmatrix} = \begin{pmatrix} \frac{1}{s+1} \\ \frac{1}{(s-1)(s+1)} \end{pmatrix} \quad (3)$$

in the transform domain. Thus, it seems incorrect to close the graph of P_1 and use the ordinary definition of input-output stability. On the other hand, stabilizability of P_1 would require that any pair of possible disturbance signals d_1, d_2 could act on the feedback system in Fig. 1 and produce a bounded response. If, however, a disturbance

$$\begin{pmatrix} \hat{d}_1 \\ \hat{d}_2 \end{pmatrix} = \begin{pmatrix} \hat{u} \\ \hat{y} \end{pmatrix}$$

with \hat{u}, \hat{y} as in (3), is allowed to act on the input ports in Fig. 1, then there exists no solution which is consistent with the feedback equations and the integral representation of P_1 .

Of the following possible remedies, none seem to be satisfactory:

- 1) To consider P_1 to be nonstabilizable on $\mathcal{L}_2(-\infty, \infty)$, and to restrict attention to open-loop stable systems only.
- 2) To seek an alternative definition of closed-loop stability for the $\mathcal{L}_2(-\infty, \infty)$ case which would agree with the common belief that P_1 is stabilized by proportional negative feedback of gain greater than one.
- 3) To identify the systems P_1, P_2 .

It should be noted that the use of extended spaces does not improve the situation, since the difficulty is to determine the correct behavior for signals in $\mathcal{L}_2(-\infty, \infty)$.

Option (1) is a correct conclusion based on existing definitions. This would mean, however, that the doubly-infinite set-up is of limited interest for control purposes, since systems which in the usual sense are "open-loop unstable" would have to be excluded. Option (2) does not seem to provide any satisfactory alternatives. It is, of course, possible to restrict attention to the subspace of \mathcal{L}_2 consisting of functions which have support on some interval $[T, \infty)$ for some arbitrary finite T . This would treat the graph of P_1 precisely as (2) and would work with driving signals in $\bigcup_{T \geq 0} e^{sT} \mathcal{H}_2$, which is not a closed subspace of $\mathcal{L}_2^2(-j\infty, j\infty)$. This appears to be a rather cosmetic solution, however, which more or less amounts to working on the half line. A more natural avenue would be to consider the actual $\mathcal{L}_2(-\infty, \infty)$ graph of the convolution operator P_1 . Similar reasoning to the above shows that this is the same as the graph of P_2 , but with the restriction that the inputs satisfy

$$\int_{-\infty}^{\infty} e^{-\tau} u(\tau) d\tau = 0.$$

Again, this means that the graph P_1 is not a closed subspace of $\mathcal{L}_2^2(-\infty, \infty)$ and the problem is then to find a suitable subspace for the external driving signals. The option of trying to work on some subspace of $\mathcal{L}_2(-\infty, \infty)$ with signals which "decay sufficiently fast" towards minus infinity again does not seem to offer a satisfying resolution. Option (3), although unsatisfactory, is perhaps not as outrageous as would first appear. If we consider the system represented by the differential equation

$$\dot{y} = y + u$$

we can reproduce the trajectories of P_1 by solving this equation forwards in time and those of P_2 by solving it backwards. This more or less amounts to abandoning any notion of causality (compare with the need to consider the anticausal trajectory (3) as a valid input-output pair for P_1). This is not a natural option, however, if the direction of time is well defined (which is a basic assumption if we consider questions of control.)

II. CONCLUSION

The purpose of this note has been to point out certain features of input-output control theory on the doubly infinite time axis which appear intrinsically unsatisfactory. The difficulties are not of a mathematical nature—a consistent picture is obtained with a variety of definitions. The problem lies in trying to escape from conclusions which limit the engineering relevance of the theory, e.g., among the causal systems, only the stable ones are stabilizable. If the definitions lead to such a conclusion, then it would not seem worthwhile to develop an elaborate theory of stabilization in that context. In contrast we remark that input-output systems theory on the doubly infinite time axis does have many important uses, e.g., in discussions of fundamental limitations in filtering imposed by causality conditions or in system approximation using Hankel operators.

Regional Observability of a Thermal Process

A. El Jai, E. Zerrik, M. C. Simon, and M. Amouroux

Abstract—The realization of a ceramic protector covering a subregion of a substrate and using chemical vapor deposition (cvd) techniques needs the temperature field in the deposition zone to be controlled. A feedback control of this temperature is based on the knowledge of the temperature in the considered subregion. The difficulty occurs because measurements can only be obtained out of the deposition zone. The purpose of this paper is to give an original approach for the reconstruction of the state in the deposition subregion.

I. MOTIVATION

Thermal treatment is a usual technique to elaborate materials. The quality of the produced material depends on the control of the temperature field. The purpose of the treatment may be either the improvement of mechanical properties of surfaces (to be reinforced by metallic or by ceramic substrate) or the prevention against corrosion or oxidation.

In the considered problem we try to realize a ceramic protector using chemical vapor deposition (cvd) techniques [7]. Only a part of the substrate is concerned with the deposition. Thermal and mechanical qualities of the obtained material depend on the homogeneity of the temperature field of the material. The control of the temperature field in the concerned zone is determined by observations outside the concerned zone. Such a problem can be solved with using a regional observability concept [4].

The aim of this paper is to give an extension of parabolic systems observability connected to the above problem. If the system is defined in a space domain Ω , we are concerned with the state observation not in the whole domain Ω but only in a given subregion $\omega \subset \Omega$. This situation occurs in many practical applications where the knowledge of the state is necessary only in a critical subregion. The measurements are given by means of a finite number of sensors which may be pointwise or zone and located inside Ω or in its boundary $\partial\Omega = \Gamma$. Let y be the state of a system (S) with a state space $X = L^2(\Omega)$, and assume that a state y_0 at a given time t_0 is unknown. Suppose now that measurements are given by means of an output $z \in Z$ (depending on the number and the structure of the sensors, the measurement interval, ...). The studied problem concerns the reconstruction of the state y_0 on the subregion ω .

The next section is devoted to the regional reconstruction of the state, then we develop a numerical approach, and in the last section the results are applied to the considered thermal process.

II. REGIONAL OBSERVATION PROBLEM

A. Problem Statement

Let

- Ω be a regular bounded open set of \mathbb{R}^n , ($n = 1, 2$ or 3) with boundary $\Gamma = \partial\Omega$.
- ω be a nonempty given subregion of Ω .
- $[0, t_f]$ with $t_f > 0$ a time measurement interval, we denote $Q = \Omega \times]0, t_f[$ and $\Sigma = \Gamma \times]0, t_f[$.
- A be a linear differential operator defined by

$$A = a_0 - \sum_{i,j=1}^n \frac{\partial}{\partial x_i} \left(a_{ij} \frac{\partial}{\partial x_j} \right) \quad (2.1)$$

where $a_0, a_{ij} \in \mathcal{D}'(\bar{\Omega} \times [0, t_f])$, the space of C^∞ functions with compact support in $\mathcal{D}'(\bar{\Omega} \times [0, t_f])$. We assume that A is elliptic; A^* is the adjoint operator of A .

We consider the system described by the state-space equation

$$\begin{cases} y' + Ay = 0 & \text{in } Q \\ y = 0 & \text{in } \Sigma \\ y(0) = y_0 \text{ supposed unknown} & \text{in } \Omega \end{cases} \quad (2.2)$$

and the output function

$$z(t) = C'y(t) \quad (2.3)$$

where

$$C': y \in L^2(0, t_f; L^2(\Omega)) \longrightarrow z \in L^2(0, t_f; Z). \quad (2.4)$$

Equation (2.3) gives measurements of the state of the system. These measurements can be obtained by pointwise or zone sensors which may be located in Ω or in Γ .

Let us recall that a sensor is defined by a couple (D, f) (see [1]) where:

- i) $D \subset \Omega$ is the support of the sensor in the zone case, while $D = \{b\}$ in the pointwise case; and
- ii) $f \in L^2(D)$ is the spatial distribution of the sensor in the zone case, while $f = \delta_b$ in the pointwise case (δ_b is the Dirac mass in b).

Let

$$y_0 = \begin{cases} y_0^1 & \omega \text{ to be estimated} \\ y_0^2 & \Omega \setminus \omega \text{ undesired} \end{cases} \quad (2.5)$$

The problem consists of reconstructing y_0^1 with the knowledge of (2.2) and (2.3). From (2.2)–(2.3) we can write $z = Ky_0$ where K is as an operator: $L^2(\Omega) \rightarrow L^2(0, t_f; Z)$. We recall the following definitions.

Definition 2.1:

- 1) System (2.2) with output (2.3) is weakly observable if $\ker K = \{0\}$. The sensor is then said to be strategic [2].
- 2) System (2.2) with output (2.3) is weakly regionally observable in $\omega \subset \Omega$ if $\ker K|_{\omega} = \{0\}$. In this case the sensor is said to be ω -strategic with

$$\begin{aligned} \chi_\omega: L^2(\Omega) &\longrightarrow L^2(\omega) \\ \chi_\omega z &= z|_\omega \end{aligned} \quad (2.6)$$

($z|_\omega$ is the restriction of z to ω .) the adjoint χ_ω^* of χ_ω

$$\chi_\omega^*: L^2(\omega) \longrightarrow L^2(\Omega) \quad (2.7)$$

is defined by

$$\omega f = \begin{cases} f & \omega \\ 0 & \Omega \setminus \omega \end{cases} \quad (2.8)$$

The concept of regional analysis has been recently developed by Jai and Zerrik, and various papers have been devoted to this new approach of distributed parameter systems [3], [4].

B. Reconstruction Method: Case of a Pointwise Sensor

In this case, system (2.2) is observed via the output

$$z(t) = y(b, t) \quad (2.9)$$

where $b \in \Omega$ is the sensor location. Consider the set

$$G = \{g \in L^2(\Omega) \mid g = 0 \text{ in } \Omega \setminus \omega\} \quad (2.10)$$

and

$$\tilde{G} = \{\tilde{g} \in L^2(\Omega) \mid \tilde{g} = 0 \text{ in } \omega\} \quad (2.11)$$

and denote $\langle \cdot, \cdot \rangle$ the $L^2(\Omega)$ scalar product. It is then easy to see that for $g \in G$ and $\tilde{g} \in \tilde{G}$

$$\langle g, \tilde{g} \rangle = \int_{\Omega} g \tilde{g} dx = \int_{\omega} g \tilde{g} dx + \int_{\Omega \setminus \omega} g \tilde{g} dx = 0. \quad (2.12)$$

For $\varphi^0 \in G$, consider the system

$$\begin{cases} \varphi' + A\varphi = 0 & Q \\ \varphi = 0 & \Sigma \\ \varphi(0) = \varphi^0 & \Omega \end{cases} \quad (2.13)$$

which has a unique solution $\varphi \in L^2(Q)$. Moreover φ is continuous on Q . Then we can consider the operator $\|\cdot\|_G$ defined by

$$\varphi^0 \in G \longrightarrow \|\varphi^0\|_G^2 = \int_0^t \varphi^2(b, t) dt \quad (2.14)$$

which is a semi-norm on G . Consider now the system

$$\begin{cases} -\psi' + A^* \psi = -\varphi(b, t) \delta(x - b) & Q \\ \psi = 0 & \Sigma \\ \psi(t_f) = 0 & \Omega \end{cases} \quad (2.15)$$

For $\varphi^0 \in G$, (2.13) gives $\varphi(b, t)$ and with (2.15) we can obtain a corresponding $\psi(0)$.

Let Λ be the operator defined by

$$\Lambda \varphi^0 = P_{G^\perp}(\psi(0)) \quad (2.16)$$

where P_{G^\perp} is the projection on \tilde{G}^\perp (\tilde{G}^\perp may be identified to the dual G' of G). Let \bar{Z} be defined by the solution of

$$\begin{cases} -\bar{Z}' + A^* \bar{Z} = -z(t) \delta(x - b) & Q \\ \bar{Z} = 0 & \Sigma \\ \bar{Z}(t_f) = 0 & \Omega \end{cases} \quad (2.17)$$

Finally for a convenient choice of φ^0 in G , (i.e., such that $\varphi(b, t) = z(t)$), system (2.15) is the adjoint of the observed system (2.2)–(2.9) and hence, the observation problem in the subregion ω will be naturally solved by the equation

$$\Lambda \varphi^0 = P_{\tilde{G}^\perp}(\bar{Z}(0)). \quad (2.18)$$

The considered approach is derived from Lions Hilbert uniqueness method [5] which has been developed for the usual controllability concept but here the context is somewhat different. We have the following result.

Proposition 2.2: If the sensor (b, h_b) is ω -strategic then (2.18) has a unique solution $\varphi^0 \in G$ which corresponds to the regional state y_0^1 to be observed in ω .

Proof:

- 1) Firstly we show that if the sensor (b, h_b) is ω -strategic then (2.14) defines a norm on G . For $\varphi^0 \in G$, $\|\varphi^0\|_G = 0 \iff \varphi(b, t) = 0$ for all $t \in [0, t_f]$. As the system is autonomous we have $\varphi^0 \in \ker K_{\omega}^*$ and as the sensor (b, h_b) is ω -strategic then $\varphi^0 = 0$ in Ω .
- 2) The uniqueness of (2.18) is immediate if Λ is an isomorphism from $G \longrightarrow \tilde{G}^\perp$.

We have

$$\begin{aligned} \langle \Lambda \varphi^0, \varphi^0 \rangle &= \langle P_{G^\perp}(\psi(0)), \varphi^0 \rangle \\ &= \langle \psi(0), \varphi^0 \rangle \end{aligned}$$

and a formal use of Green's formula gives, by multiplying (2.15) by φ and integrating by parts

$$\begin{aligned} \langle \psi(t_f), \varphi(t_f) \rangle &= \langle \psi(0), \varphi^0 \rangle \\ &\quad - \int_Q \psi(-\varphi' + A^* \varphi) dQ \\ &\quad + \int_{\Sigma} \varphi \frac{\partial \psi}{\partial \nu} d\Sigma - \int_{\Sigma} \psi \frac{\partial \varphi}{\partial \nu} d\Sigma \\ &= - \int_0^{t_f} \varphi(b, t)^2 dt \end{aligned}$$

where ν is the outward normal derivative to $\partial\Omega$ and, for the operator A defined in (2.1)

$$\frac{\partial f}{\partial \nu} = \sum_{i=1}^n a_{ij}(x, t) \frac{\partial f}{\partial x_j} \cos(\nu, x_i).$$

From boundary and initial conditions we have

$$\begin{aligned} \langle \Lambda \varphi^0, \varphi^0 \rangle &= \langle P_{G^\perp}(\psi(0)), \varphi^0 \rangle \\ &= \|\varphi^0\|_G^2. \end{aligned}$$

One deduces that Λ is an isomorphism from G to \tilde{G}^\perp (all this can be made completely rigorous without too much difficulty). Finally (2.18) has a unique solution $\varphi^0 = y_0^1$, which ensures the observation of the initial state in the subregion ω .

Remarks:

- 1) In [4] we show that (b, h_b) is ω -strategic $\iff \varphi_i(b) \neq 0$ for all i , where (φ_i) is the set of eigenfunctions of A , with Dirichlet boundary conditions, in $L^2(\omega)$ associated to the eigenvalues λ_i .
- 2) These results may be easily extended to other kinds of measurements [4].

III. NUMERICAL APPROACH

The numerical approach may be achieved very easily when one can calculate the eigenfunctions of the system: this is the case of invariant systems and will be developed in the next subsection. In the general case an adapted technique is given and detailed later.

We have seen that the solution of the regional observation problem is obtained by the solution of the equation

$$\Lambda \varphi^0 = P_{\tilde{G}^\perp}(\bar{Z}(0)) \varphi^0 \in G. \quad (3.1)$$

In the next sections we give an implementable approach for solving the above equation.

A. Invariant Systems Case

In this section we consider the case where the system is described by an equation with constant coefficients. The idea, in this case, is to calculate as shown below, in a suitable basis (φ_j) of $L^2(\Omega)$, the components $\Lambda_{i,j}$ of Λ .

We assume that A has in $L^2(\Omega)$ a complete set of eigenfunctions (φ_j) such that

$$\begin{cases} A\varphi_j = \lambda_j \varphi_j & \Omega \\ \varphi_j = 0 & \Gamma \\ \|\varphi_j\|^2 = 1 & \forall j \end{cases} \quad (3.2)$$

Without loss of generality we suppose that the eigenvalues λ_i of A are of multiplicity one. As the sensor is pointwise, we have

$$\langle \Lambda \varphi^0, \varphi^0 \rangle = \|\varphi^0\|_C^2 = \int_0^t \varphi(b, t)^2 dt \quad (3.3)$$

and with

$$\varphi(b, t) = \sum_{i=1}^{\infty} \langle \varphi^0, \varphi_i \rangle_{L^2(\omega)} \varphi_i(b) e^{\lambda_i t} \quad (3.4)$$

we have

$$\begin{aligned} \langle \Lambda \varphi^0, \varphi^0 \rangle &= \sum_{i,j} \langle \varphi^0, \varphi_i \rangle_{L^2(\omega)} \langle \varphi^0, \varphi_j \rangle_{L^2(\omega)} \\ &\quad \times \varphi_i(b) \varphi_j(b) \frac{e^{(\lambda_i + \lambda_j)t} - 1}{\lambda_i + \lambda_j}. \end{aligned} \quad (3.5)$$

One deduces

$$\Lambda = (\Lambda_{i,j}), \quad i, j = 1, \infty$$

with

$$\Lambda_{i,j} = \varphi_i(b) \varphi_j(b) \frac{e^{(\lambda_i + \lambda_j)t} - 1}{\lambda_i + \lambda_j} \quad (3.6)$$

hence, the regional observation problem is transformed in the linear system

$$\sum_{j=1}^M \Lambda_{i,j} \varphi_j^0 = \bar{Z}'(0) \quad i = 1, \dots, M \quad (3.7)$$

where $\bar{Z}'(0)$ (respectively, φ_j^0) are the components of $\psi \bar{Z}(0)$ (respectively, φ^0) in the basis (φ_j) . Let us remark that by construction, the observed state y_0^1 will vanish in $\Omega \setminus \omega$.

B. General Case

In the general case, it is not easy to calculate the eigenfunctions of the operator A . Here we shall give a direct approach which allows to overcome this difficulty and leads to the state to be estimated in ω .

We have seen that the regional observability is equivalent to finding φ^0 such that $\psi(0) = \bar{Z}(0)$ in ω , where $\psi(t)$ and $\bar{Z}(t)$ are solutions of (2.15) and (2.17). So the problem turns up naturally to find φ^0 which is the solution of the following problem

$$\begin{cases} \min \|\psi(0) - \bar{Z}(0)\|_{L^2(\omega)}^2 \\ \varphi^0 \in G \end{cases} \quad (3.8)$$

The resolution of this problem can easily be achieved by the direct minimization algorithm.

Fig. 1. Longitudinal section of the reactor

Algorithm.

- 1) Solve (2.17) ($\rightarrow \bar{Z}(0)$).
- 2) Initiate φ^0 in G .
- 3) Solve (2.13) ($\rightarrow \varphi(b, t)$).
- 4) Solve (2.15) ($\rightarrow \psi(0)$).
- 5) If $\|\psi(0) - \bar{Z}(0)\|_{L^2(\omega)} > \epsilon$ return to Step 2).
- 6) The observed state on the subregion ω is given by $y_0^1 = \varphi^0$.

Remark The choice of φ^0 can be made by an optimization process which does not need the calculus of the gradient [9]. The initial choice of φ^0 must be as close as possible to the state suggested by the real system. But any arbitrary choice will lead to the same result, with more computations. This is applied to the thermal considered problem.

IV. APPLICATION TO THE THERMAL DEPOSITION PROBLEM

A. System Description

The deposition phenomenon is produced in a reactor with cold walls where a substrate is placed. The temperature is controlled by the energy supplied by electric current (Joule effect) between two electrodes maintained at a constant temperature (they are thermally controlled by a refrigerating fluid circulation). The Joule effect produces a temperature elevation in the substrate which exchanges heat with the surroundings essentially in the radiative form (around a temperature of 1300 degrees C). The deposition concerns only a subregion $\omega \subset \Omega$. See Fig. 1.

The substrate is first steered to the deposition temperature, and then the covering process starts. The surface of the substrate is modified, its emissivity evolves, and then thermal exchanges start. The modification of the thermal profile is to be compensated with action on the electric current. Then it is important to know the variation of this profile around the previous equilibrium state. One of the difficulties is due to the fact that only the temperature out of the deposition zone ω can be measured by optical pyrometry. In view of this, we have to conceive a precise estimator of the temperature profile in the sensitive subregion. This is made by the regional observation techniques developed in the previous sections.

B. Thermal Model

The modelization of the thermal deposition problem can be carried out in one-dimensional space with $\Omega =]0, \ell[$. Let $\omega \subset \Omega$ be the deposition zone. The radiative phenomenon introduces a nonlinear term in the thermal balance which takes the conductive exchange

Fig. 2. Comparison of the real state $T_0(x)$ (supposed to be unknown) and the estimated state $T_0(x)$ on the deposition subregion $\omega = [0.3, 0.7]$.

Fig. 3. Zoom of the real and estimated states in the deposition subregion.

into account. This leads to the following modelization of the system

$$\begin{cases} mc_p \frac{\partial T(x, t)}{\partial t} \\ = \lambda \left(c \frac{\partial^2 T(x, t)}{\partial x^2} \right) - 2 \cdot \sigma (t + \epsilon) T^4(x, t) + \frac{\rho}{\epsilon} I^2 &]0, \ell[\times]0, t_f[\\ T(0, t) = T_1 &]0, t_f[\\ T(\ell, t) = T_2 &]0, t_f[\\ T(x, 0) = T_0(x) &]0, \ell[\end{cases} \quad (4.1)$$

where

x : space variable, t : time variable.
 m : mass element by unit length, c_p : calorific heat element.
 λ : thermal conductivity, ρ : electric sensitivity.
 ϵ : emissivity, ℓ : length of the element.
 ϵ : depth of the element, σ : Stephan-Boltzman constant.
 T : temperature of the element, I : current intensity.

C. Linearized Model

The previous model is nonlinear but the nature of the problem allows the study to be made in a linear context. Indeed the deposition is produced around a temperature T_0 . The modification of the thermal profile has to be compensated with a control of the electric current around T_0 . Therefore (4.1) can be linearized around T_0 corresponding to current intensity $I = I_0$.

Let $\Delta T = T - T_0$, $\Delta I = I - I_0$. The linearized model is then

$$\begin{cases} \frac{\partial \Delta T(x, t)}{\partial t} \\ = \alpha \frac{\partial^2 \Delta T(x, t)}{\partial x^2} + \beta T_0^3 \Delta T(x, t) + \gamma &]0, \ell[\times]0, t_f[\\ \Delta T(0, t) = \Delta T(\ell, t) = 0 &]0, t_f[\\ \Delta T(x, 0) = 0 &]0, \ell[\end{cases} \quad (4.2)$$

where α , β , and γ are given by

$$\alpha = \frac{\lambda \ell \epsilon}{mc_p}; \quad \beta = \frac{-8\pi\sigma(t + \epsilon)}{mc_p}; \quad \gamma = \frac{\rho}{mc_p \ell \epsilon} \Delta I \quad (4.3)$$

where ΔI is the control variable and $\lambda, m, c_p, \ell, \epsilon, \sigma, \rho, I_0$ are constants to be specified for numerical simulation.

The problem is to determine the variation of the temperature profile only on the deposition subregion around the previous equilibrium rating. The measurements are given by the output function

$$z(t) = \Delta T(b, t) \quad (4.4)$$

where b is the sensor location, $b \in]0, \ell[\setminus \omega$.

D. Simulation

For numerical simulations we consider the following values for the different parameters

$$\begin{aligned} \Omega &=]0, 1[& \omega &= [\frac{1}{3}, \frac{2}{3}] \\ T_1 &= T_2 = 900^\circ\text{C} & I_0 &= 38 \text{ A} \\ \ell &= 0.510^{-2} \text{ m} & \epsilon &= 10^{-3} \text{ m} \\ z &= 0.2 & c_p &= 61.10^{-3} \text{ J Kg}^{-1} \text{ K}^{-1} \\ \lambda &= 1.03210^2 \text{ W m}^{-1} \text{ K}^{-1} & m &= 1.6 \text{ Kg m}^{-1} \\ \sigma &= 5.7110^{-8} \text{ W m}^{-2} \text{ K}^{-4} & \rho &= 2.8710^{-4} \Omega \text{ m}^{-1}. \end{aligned} \quad (4.5)$$

The sensor is located out of the deposition zone with $b = 0.85$.

Using the algorithm of Section III-B, we obtain the following results: Fig. 2 gives the estimated state (dashed line) and the real state (continuous line).

The regional state in the deposition subregion is estimated with a good accuracy

$$\frac{\|T_0 - T_0\|_{L^2(\omega)}^2}{\|T_0\|_{L^2(\omega)}^2} \simeq 1.410^{-4}. \quad (4.6)$$

Towards a Generalized Regulation Scheme for Oscillatory Systems via Coupling Effects

Kevin L. Tuer, M. Farid Golnaraghi, and David Wang

Abstract—The vibration suppression laws presented in this work utilize an energy transfer phenomena that is evident in some linearly and nonlinearly coupled systems. The first iteration of the formulation is presented in this paper. These control laws are unique in that the states approach the operating point on the order of a cosine function, the nonlinear control law renders a unidirectional control input, and the intuition associated with the energy transfer analogy aids the controller design.

I. INTRODUCTION

Many techniques have been formulated to suppress oscillations in both linear and nonlinear systems. The standard linear time-invariant state-space representation of a system has the form

$$\begin{aligned}\dot{x} &= Ax + Bu \\ y &= Cx + Du\end{aligned}\quad (1)$$

where $A \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times m}$, $C \in \mathbb{R}^{p \times n}$ and $D \in \mathbb{R}^{p \times m}$. In contrast, a typical nonlinear system is represented by

$$\begin{aligned}\dot{x} &= f(x, u) \\ y &= g(x, u)\end{aligned}\quad (2)$$

where $f: \mathbb{R}^{n+m} \rightarrow \mathbb{R}^n$ and $g: \mathbb{R}^{n+m} \rightarrow \mathbb{R}^p$. The corresponding control techniques can also be classified as linear or nonlinear. Included in the linear realm are techniques such as the standard PID control [1], pole-placement control [1], and linear quadratic (LQ) techniques [1]. The latter involves the minimization of a quadratic cost function to define the control law. More recently, the H_∞ optimal control technique [2] has been used quite extensively. It entails the selection of a controller from the set of all possible stabilizing controllers by minimizing the infinity operator norm of the transfer function between the exogenous inputs and exogenous outputs of a standard augmentation. Structurally similar approaches include the H_2 [2] and L_1 [3] control methods. The field of nonlinear control includes techniques such as the Lyapunov approach [4], the passivity formalism [4], and dissipative system theory [5]. These particular strategies have energy-based scenarios. The Lyapunov approach involves specifying a control input such that the candidate Lyapunov function is locally positive definite and its time derivative locally negative (semi) definite. A similar approach is taken using the passivity formalism which involves the use of a Lyapunov-like function that is an indicator of the energy content of the system at any point in time and space. The control input to the system is selected such that the system is passive and/or dissipative. In addition, closed-loop stability of a feedback system can be ascertained using the well known passivity theorem [4]. Dissipative system theory, in contrast, employs energy storage and supply functions to model the energy

based characteristics of a system. The control input to the plant is chosen to ensure that the closed-loop system is dissipative which translates to a decrease in the system energy. Other nonlinear control techniques involve the use of a variable feedback law including sliding mode [4] and gain scheduling [6]. For example, the former involves specifying a sliding surface in the state space and defining the appropriate control parameters such that a sliding mode exists and the surface is locally or globally attractive. Implementation typically involves high speed switching feedback which can induce spillover effects. Gain scheduling is similar except the transition between feedback structures is smoother [6]. Some nonlinear systems support the use of feedback linearization techniques [4]. Using this approach, the designer develops a feedback law that essentially linearizes the plant. Then, a wealth of linear control algorithms can be utilized to complete the control design. These techniques, however, tend to suffer from a lack of robustness in the presence of uncertainty. More recently, neural networks [7] and fuzzy logic [7] have been utilized for vibration suppression applications as well.

Implementation of the control techniques outlined above may render a system that is stable in an L_2 , L_∞ , or exponential sense. Stability in this sense, however, does not preclude the possibility of one or more of the states of the controlled system exhibiting an unacceptable rate of convergence to the desired state and/or unwanted oscillatory behavior. The techniques presented in this work are intended to reduce or eliminate these effects.

For the purposes of this paper, the investigation is conducted using a canonical second order system with a state-space model given by

$$\dot{x}_p = \begin{bmatrix} 0 & 1 \\ -\omega_p^2 & -2\zeta_p\omega_p \end{bmatrix} x_p + f_p(x_p) + \begin{bmatrix} 0 \\ b_{21} \end{bmatrix} u \quad (3)$$

where $\zeta_p, \omega_p \in \mathbb{R}^+$ are the damping coefficient and natural frequency respectively, $b_{21} \in \mathbb{R}$, $f_p(x)$ contains weak nonlinear terms and the state vector is $\{x_p\} = [x_1 \ x_2] = [x \ \dot{x}]$. Equation (3) can be considered as the model of one oscillatory mode of a multi-degree-of-freedom (MDOF) system. Thus, the intention is to develop the theory for a canonical oscillatory system with the ultimate goal of utilizing the theory for multi-mode oscillation suppression. For notational purposes, the system given in (3) will be denoted as the plant.

The essence of the proposed techniques is to exploit the energy link that can exist between two coupled, second order, oscillating systems. If one equation models a system to be controlled and the other models a controller, then it is plausible to alter the dynamic characteristics of the plant using the controller. Under this scenario, the plant and the controller dynamics are characterized by amplitude and/or phase modulation giving rise to a beat phenomenon. As a result, the envelope of the plant response is periodic and approaches a minimum at approximately the same rate as a cosine function. Subsequent controller action can then be instituted to "remove" energy from the entire system. Using the energy transfer analogy, the design is well directed and efficient. The designer is able to incorporate physical meaning with the mathematics to yield a control strategy that is intuitive and relatively easy to troubleshoot.

The use of coupling effects to suppress structural oscillations has been addressed recently in [8]–[14]. Golnaraghi was one of the first researchers to use modal coupling effects to control structural oscillations [8], [9]. Tuer *et al.* [10], Duquette *et al.* [11], Duquette [12], and Tuer [13] examined the use of coupling effects to control

Manuscript received March 12, 1993; revised April 20, 1994. This work was supported in part by the Natural Sciences and Engineering Research Council of Canada (NSERC).

Fig. 1. Experimental Responses [12]. (a) Coordinate coupling, (b) modal coupling.

oscillations in a flexible cantilever beam on both a theoretical and experimental level. The desired coupling effects were achieved via physical components. A DC motor was attached to the free end of the beam. A rigid beam-mass assembly was connected directly to the shaft of the motor. This assembly was designated the secondary link. The position of the secondary link was regulated at 90 degrees to the flexible beam via position and velocity feedback from the motor. Fig. 1(a) shows the experimental plot of the regulated response of the tip of the flexible beam using the coordinate coupling control law after subjecting the tip to an initial displacement. Similarly, Fig. 1(b) illustrates the tip response employing the modal coupling control law. Both strategies function very effectively. These experimental results illustrate that physical systems can exhibit both coordinate and modal coupling effects under the proper conditions. This investigation also showed that these phenomena can be used, rather effectively, for control purposes. This physical insight provides the primary motivation for the current research.

The disadvantage of the aforementioned work is the need for unconventional actuation devices to apply the necessary control. This problem has been addressed by Tuer *et al.* [14]. They have initiated the generalization of the use of modal coupling effects to control a canonical system using more conventional actuation devices. In this paper, both linear and nonlinear coupling effects are employed as paradigms in the development of control laws to regulate an oscillatory state of a system. As well, stability issues for both control strategies are addressed. A numerical example is presented to illustrate the use of the proposed techniques and corroborate the mathematical predictions.

II. CONTROLLER IMPLEMENTATION

To suppress the oscillations of a system of the form of (3) using the proposed techniques, a second system must be introduced to which the plant can be coupled using feedback. This is accomplished via the introduction of second-order differential equation with a linear structure similar to that of the plant. This system becomes the controller in the closed-loop system. Thus, the closed-loop system dynamics are dictated by equations of the form

$$\dot{x}_p = \begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -\omega_p^2 & -2\zeta_p\omega_p \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + f_p(x_p) + \begin{bmatrix} 0 \\ b_{21} \end{bmatrix} u \quad (4)$$

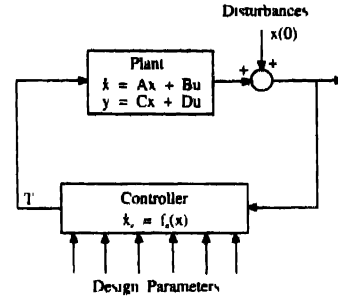

Fig. 2. Block diagram of controlled system.

$$\dot{x}_c = \begin{bmatrix} \dot{x}_1 \\ \dot{x}_1 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -\omega_c^2 & 0 \end{bmatrix} \begin{bmatrix} x_1 \\ x_1 \end{bmatrix} + \begin{bmatrix} 0 \\ C'(x_2, x_1) \end{bmatrix} + f_c(x_p, x_c) \quad (5)$$

where (4) models the plant, (5) models the controller and $\omega_c \in \mathbb{R}^+$ is the controller frequency. The function $C'(\cdot)$ is a damping mechanism utilized to effect control and $f_p(\cdot)$ contains the plant nonlinearities. The plant control input u , which takes the form of a state relation in the formulation, and $f_c(\cdot)$ are used to establish the coupling between the plant and the controller. The coefficient of the relation for u , the elements of $f_c(\cdot)$, the form of $C'(\cdot)$, and the controller frequency ω_c are the design parameters of the system. A block diagram of the closed-loop system is illustrated in Fig. 2. As evident from the figure, the disturbance is modelled by initial state conditions acting at the output of the plant.

The design of the controller is a two-stage process. The first step involves establishing the required coupling effects. The second step revolves around specifying the remaining design parameters to establish the frequency of amplitude modulation and defining the appropriate parameters of the energy removal mechanism such that the disturbance induced motion is quelled in accordance with the given design specifications.

A. Establishing Coupling Effects

The proposed technology hinges on both linear and nonlinear coupling effects to function. In the past, the phenomena resulting from coupling effects were examined primarily from an analysis standpoint. However, the focus of this work is to utilize the desirable features of these phenomena for control purposes.

1) *Coordinate Coupling*: In a mathematical sense, coordinate coupling refers to the nondiagonal nature of the inertia and/or stiffness matrices of a system of second order, ordinary differential equations of motion. In certain situations, the system response may exhibit periodic amplitude modulation or a beat phenomenon. Since the solutions of (4) and (5) are predominantly oscillatory, this amplitude modulated response must be the result of the superposition of "tuned" periodic functions. This can be illustrated using the analogy of the pointwise addition of two periodic functions with the same amplitude and nearly the same frequencies of oscillation. There are well-defined points in time where the two functions reinforce each other to yield a doubling of the amplitude. Conversely, there are points in time where the two functions act to cancel one another yielding a net amplitude of zero. On a physical level, this is analogous to a transfer of energy between the coordinates of the system.

The development of the control law based on coordinate coupling was conducted by first recognizing that a similar phenomena can be established between a second order, single-degree-of-freedom (SDOF) plant and second order, SDOF controller through the proper selection of the controller parameters and the control input to the

plant. That is, the control law was established so as to generate a closed-loop system with inertial coupling. To this end, the closed-loop equations have the form of (4) and (5) with

$$\begin{aligned} u &= -\dot{x}_1 \\ f_r(\cdot) &= -K\dot{x}_2 \\ f_p(\cdot) &= 0 \end{aligned} \quad (6)$$

where $K \in \mathbb{R}^+$. In general, the last condition in (6) need not be satisfied. It is implicitly assumed, however, that any nonlinearities contained in $f_p(\cdot)$ are at least one order of magnitude smaller than the linear terms of the closed-loop system equations. The solutions of (4) and (5) with (6) invoked, assuming zero damping, are readily found to have the form

$$\begin{bmatrix} x_1 \\ x_3 \end{bmatrix} = \begin{bmatrix} C_1 A_1^1 & C_2 A_1^2 \\ C_1 A_2^1 & C_2 A_2^2 \end{bmatrix} \begin{bmatrix} \cos(\omega_1 t + \Phi_1) \\ \cos(\omega_2 t + \Phi_2) \end{bmatrix} \quad (7)$$

where $A_j^i \in \mathbb{R}$ is the i th entry of the j th eigenvector corresponding to the j th natural frequency of the closed-loop system, $\omega_j \in \mathbb{R}^+$. The constants $C_j \in \mathbb{R}$ and $\Phi_j \in \mathbb{R}$ are defined by the initial conditions imposed on the system. The eigenvalues of the undamped system $\lambda_{1,2} \in \mathbb{C}$, are

$$\lambda_{1,2} = \frac{(\omega_p^2 + \omega_c^2) \pm \sqrt{-(\omega_p^2 + \omega_c^2)^2 - 4(1-K)(\omega_p^2 \omega_c^2)}}{2(1-K)} \quad (8)$$

The degree of coupling and frequency of amplitude modulation is contingent on the magnitude of K since this parameter dictates the proximity of the system's natural frequencies.

The first solution in (7) models the plant response whereas the second solution pertains to the controller response. Using the design parameter, K , the natural frequencies of the closed-loop system can be placed arbitrarily close to one another. Since the plant and controller responses are the result of the superposition of two periodic functions with nearly the same frequencies, a linear beat phenomenon can be established. Under these conditions, the periodic functions will completely cancel one another provided the amplitudes of the two functions are equivalent. In terms of the solution for the plant response, this translates to enforcing the condition $C_1 A_1^1 = C_2 A_1^2$ in (7). In [12], it was shown that this condition is satisfied if

$$\omega_c = \omega_p. \quad (9)$$

To ensure a relative plant energy minimum at a specific point in time, the parameter K is chosen so as to satisfy the relation [12]

$$n = \frac{\omega_2}{\omega_2 - \omega_1} \quad (10)$$

where the user-defined $n \in \mathbb{R} \setminus 0$ dictates the amplitude modulation frequency. Both (9) and (10) are necessary conditions to establish the desired amplitude modulated response. The time at which the first cancellation occurs, t_{fc} , can be shown to occur at [12]

$$t_{fc} = \frac{\pi}{\omega_2 - \omega_1}. \quad (11)$$

Thus, satisfying (9) ensures that $C_1 A_1^1 = C_2 A_1^2$ to foster complete cancellation at time t_{fc} , the value of which is dictated, primarily, by the magnitude of n as expressed by (10). That is, the parameter n is used to define the point in time where the position and velocity of the plant are simultaneously zero which corresponds to zero plant energy.

In the foregoing formulation, acceleration feedback was utilized to establish dynamic coupling effects. Analysis shows that a static coupling paradigm can also be utilized and that both (9) and (10) hold under this scenario as well [15], [16]. Since both types of coupling render the same characteristics, the remainder of the analysis is conducted for the dynamic coupling scenario only.

2) Modal Coupling: A nonlinear system may exhibit modal coupling effects if it is in a state of internal resonance. Internal resonance has its foundation in the field of nonlinear oscillations. Mathematically, a necessary but not sufficient condition for the existence of internal resonance is defined by the commensurability of the linear natural frequencies of the nonlinear equations of motion, ω , [17]. That is, there exist constants $\{\Psi_1, \dots, \Psi_n \in \mathbb{R} \setminus 0\}$ such that

$$\Psi_1 \omega_1 + \Psi_2 \omega_2 + \dots + \Psi_n \omega_n \approx 0. \quad (12)$$

Under such conditions, an energy bridge is formed between the commensurable modes of oscillation. If the left-hand side and right-hand side of (12) are identically equal, an exact commensurability condition exists which fosters a state of maximum energy transfer.

The type of internal resonance condition is contingent on the order of nonlinearities. For instance, if quadratic nonlinearities are present in the system, a 2:1 internal resonance condition may exist. The specific commensurability relation under this scenario is $\Psi_1 \omega_1 + \Psi_2 \omega_2 \approx 0$ where the associated constants are $\{\Psi_1 = \pm 2, \Psi_2 = \mp 1\}$ or $\{\Psi_1 = \pm 1, \Psi_2 = \mp 2\}$. A state of 2:1 internal resonance is employed in this paper.

As with the coordinate coupling-based control law presented in the previous section, the internal resonance-based control law was developed by recognising that a state of internal resonance can be established between a second order, SDOF plant and a second order, SDOF controller. Thus, using this paradigm, the closed-loop system equations are of the form given by equations (4) and (5) with

$$\begin{aligned} u &= -\gamma_1 x_1^2 \\ f_r(\cdot) &= \gamma_2 x_2 x_1 \\ f_p(\cdot) &= 0 \\ \omega_c &\approx \frac{1}{2} \omega_p \end{aligned} \quad (13)$$

where $\gamma_1, \gamma_2 \in \mathbb{R}^+$ are design parameters. In general, $f_p(\cdot)$ need not be zero. In this case, if the structure of the nonlinear terms, $f_p(\cdot)$, parallel the nonlinearity introduced by the control law, they can be used to effect the control. If these terms have a structure differing from that of the nonlinearities introduced by the control, they will not affect the integrity of the controller provided they are weak relative to the control law nonlinearities. Finally, the last condition in (13) is employed to satisfy the commensurability requirements and is necessary for establishing modal coupling effects.

Other forms of nonlinear feedback can be utilized in the formulation of the control law [15]. That is, the nonlinear terms remain quadratic but the individual terms may include position, velocity, and/or acceleration feedback. The analysis and resulting relations differ slightly but, nevertheless, have essentially the same structure. Therefore, as with the linear case, the potential to use other forms of feedback renders more freedom to the design. In this paper, the system given by (4), (5), and (13) is analyzed and discussed in detail.

To illustrate the modal transfer of energy and to derive a relation indicating the degree of energy transfer, a perturbation analysis technique known as the method of multiple scales is utilized [17]. Using this approach, an assumed solution for the undamped nonlinear system is constructed in the form of an asymptotic series. Several relations indicating the existence of internal resonance are derived in the process of formulating the exact form of the elements of the series solution. The system solution is of the form

$$\begin{aligned} x_1 &= x_{10}(T_0, T_1) + \epsilon x_{11}(T_0, T_1) + \dots \\ x_2 &= x_{20}(T_0, T_1) + \epsilon x_{21}(T_0, T_1) + \dots \end{aligned} \quad (14)$$

where T_i are new independent time scales and the corresponding asymptotic sequence is constructed using powers of $\{\epsilon \in \mathbb{R}^+ \mid 0$

Fig. 3. Undamped Modal Response. — : R_1 , - - - : R_2

$\epsilon \ll 1$. Substituting (14) into the undamped form of the nonlinear equations of motion yields a set of conditions that must be satisfied in order to satisfy the constraints implicit on the series solution. These are known as the secular terms or solvability conditions and can be expressed in terms of the modal amplitudes, R_1 , R_2 , and associated phases, α_1 , α_2 , of the system

$$\begin{aligned}\dot{R}_1 &= -0.0625\gamma_1\omega_p R_2^2 \sin(\phi) \\ \dot{R}_2 &= 0.25\gamma_2\omega_p R_1 R_2 \sin(\phi) \\ R_1 \dot{\phi} &= (0.5\gamma_2\omega_p R_1^2 - 0.0625\gamma_1\omega_p R_2^2) \cos(\phi) \\ \phi &= 2\alpha_2 - \alpha_1\end{aligned}\quad (15)$$

where the overdot () indicates differentiation with respect to the time variable T_1 . The variables R_1 and R_2 model the envelope of the response of the plant and controller, respectively. Equations (15) model the response of the envelopes of the modes of oscillation of the system. Simulation of these equations indicate that the desired transfer of energy between modes is indeed occurring as illustrated in Fig. 3. The corresponding parameter values are $\{\omega_p = 30, \gamma_1 = \gamma_2 = 0.5\}$. Equations (15) are used to generate an energy relation which has the form

$$1 \frac{\gamma_2}{\gamma_1} R_1^2 + R_2^2 = E \quad (16)$$

where $E \in \mathbb{R}^+$ is representative of the system energy and R_i^2 is indicative of the energy of mode i . Equation (16) shows that, provided R_1 is a periodic function, a continuous exchange of energy occurs in this conservative system. The secular term equations are further analyzed to generate a relation used as an indicator of the degree of energy transfer within the system. This relation takes the form

$$K_1 = \frac{4\gamma_2 [R_2(0)^2 R_1(0) \cos(\phi(0))]^2}{\gamma_1 [4 \frac{\gamma_2}{\gamma_1} R_1(0)^2 + R_2(0)^2]} \quad (17)$$

where $K_1 \in \mathbb{R}^+$. In general, the smaller the value of K_1 , the better the transfer of energy between modes. Perturbation analysis shows that $K_1 = 0$ corresponds to an unstable equilibrium point and is therefore inadmissible. It appears after extensive numerical analysis that (17) can be extrapolated to the full-order nonlinear system

$$\frac{4\gamma_2 [x_1(0)^2 x_3(0) \cos(\phi(0))]^2}{\gamma_1 [4 \frac{\gamma_2}{\gamma_1} x_1(0)^2 + x_3(0)^2]} \leq \frac{4\gamma_2 [x_3(0)^2 x_1(0)]^2}{\gamma_1 [4 \frac{\gamma_2}{\gamma_1} x_1(0)^2 + x_3(0)^2]} = K_1. \quad (18)$$

Thus, (18) illustrates the effect that the disturbance and the design parameters have on the degree of energy transfer. This is an important result because K_1 and (18) can be utilized in the formulation of the controller. To guarantee a particular level of energy transfer, K_1 is selected arbitrarily small and the design parameters are chosen to satisfy (18). In addition, actuator constraints can be incorporated into the design at this stage since a smaller value of K_1 translates to larger control effort. Further detail of the perturbation analysis and the derivation of (17) is contained in [14].

B. Achieving Vibration Suppression

To effect control over the system, the energy must be transferred from the plant to the controller and "removed" before it has an opportunity to transfer from the controller back to the plant. To accomplish this task, two fundamentally different approaches are proposed [14]. The first method is the disabled input method (DIM). Using this method, the existing energy bridge is severed once the energy has transferred from the plant by disabling the control signal to the plant. The second method is termed the dissipated energy method (DEM). This approach, in essence, dissipates the energy as it is transferred from the plant to the controller via a damping mechanism associated with the controller.

1) *Disabled Input Method (DIM)*: An outline of the design procedures for the coordinate and modal coupling controllers are delineated separately beginning with the former.

a) *Coordinate coupling controller*: Using this paradigm of control, the governing equations of the closed-loop system are given by (4)–(6) with $C(\cdot) \equiv 0$. The first step of the procedure is to set the controller frequency, ω_c , equal to the natural frequency of the plant, ω_p , to facilitate a maximum energy transfer. The desired response frequencies are established using the controller gain K since the natural frequencies of the closed-loop system are explicitly a function of K . The frequency of amplitude modulation and primary response frequency are

$$\left(\frac{\omega_2 - \omega_1}{2} \right), \left(\frac{\omega_2 + \omega_1}{2} \right) \quad (19)$$

respectively, where the former is an indication of the settling time of the system.

Since the proposed techniques hinge on energy transfer, it is necessary to construct an energy function for the plant to effect control. In general, the energy function has a quadratic form and is given by

$$\mathbf{x}_p^T Q \mathbf{x}_p \quad (20)$$

where Q is a real, diagonal, positive definite weighting matrix

$$Q = \begin{bmatrix} \frac{\omega_p^2}{2} & 0 \\ 0 & 1 \end{bmatrix}. \quad (21)$$

The final task of the design involves monitoring the plant's energy on a continuous basis and disabling the input to the plant when the magnitude of the energy function falls below a predetermined threshold value, $E_i^{DIM} \in \mathbb{R}^+$. That is

$$u = \begin{cases} -i_1, & \mathbf{x}_p^T Q \mathbf{x}_p > E_i^{DIM} \\ 0, & \mathbf{x}_p^T Q \mathbf{x}_p \leq E_i^{DIM} \end{cases} \quad (22)$$

b) *Modal coupling controller*: Under this scenario, the closed-loop dynamics are dictated by (4), (5), and (13). The procedure resembles the latter with a few fundamental differences. First of all, the frequency of the controller, ω_c , is set equal to one-half the natural frequency of the plant, ω_p . Next, with $(\frac{\gamma_2}{\gamma_1}) = 1$ and an arbitrarily small k , the required controller initial condition, $x_3(0)$, is calculated using (18). To attain the desired amplitude modulation frequency, maintain $(\frac{\gamma_2}{\gamma_1}) = 1$ and set γ_1, γ_2 such that the point at which the amplitude envelope achieves a minimum value corresponds to the desired settling time. At this point, double peak symmetry in the plant response is achieved to maximize the dwell time at the plant energy minimum thus rendering the system more robust to errors in disabling time. This is done by adjusting the parameter $x_3(0)$. Using this new value of $x_3(0)$ and the specified design parameters, the degree of modal energy transfer, K_1 , is recalculated using (18). If the energy transfer corresponding to this value of K_1 is insufficient, the value of K_1 is reduced and the previous steps are repeated. Otherwise,

the final stage of the design entails monitoring the system energy and disabling the input in a similar manner described in the previous section. That is

$$u = \begin{cases} -\gamma_1 x_4^2, & x_p^T Q x_p > E_t^{DIM} \\ 0, & x_p^T Q x_p \leq E_t^{DIM} \end{cases} \quad (23)$$

Although effective, this technique suffers from lack of robustness to errors in disabling time. When the input is disabled, the energy bridge between the plant and the controller is destroyed. Thus, whatever energy is in the plant mode when the input is disabled remains in the plant mode unless controller action is reinitiated.

b) Dissipated energy method (DEM): The design procedure for the DEM is similar to the DIM except for the means of oscillation suppression. Using this approach, a damping model is incorporated into the controller equation. The energy link facilitates the transfer of energy from the plant to the controller where it is dissipated through the controller's damping mechanism. This technique can be implemented in either a time invariant fashion or a time-varying fashion. The time invariant approach involves invoking the damping mechanism associated with the controller in conjunction with the disturbance. That is, given that the disturbance is applied at time t_d and the damping mechanism is invoked at time t_{imp} , then $t_{imp} = t_d$. Thus, the system approaches the operating point slower than a cosine function but quicker than an exponential function. The time-varying approach involves the use of a function that provides an on-line indication of the plant energy. Once this indicator function drops below a user-specified threshold, the damping effects are invoked. Thus, given that t_{min} denotes the time at which the plant reaches its first energy minimum, then $\{t_{imp} = t_{min} - d : 0 < d \leq (t_{min} - t_d), d \in \mathbb{R}^+\}$. Alternatively, the damping invoke condition can be energy based. That is

$$C(\cdot) = \begin{cases} 0, & x_p^T Q x_p > E_t^{DEM} \\ C_{d,s}(\cdot), & x_p^T Q x_p \leq E_t^{DEM} \end{cases} \quad (24)$$

where E_t^{DEM} is the user-specified energy threshold and $C_{d,s}(\cdot)$ is the tuned damping mechanism rendering the desired response. This implementation allows the envelope of the response to approach the operating point with the speed of a cosine function until the switching condition is invoked at which point the damping effects are implemented. From this time forward, the speed of approach becomes similar to that of the time invariant approach. The threshold, $E_t^{DEM} \in \mathbb{R}^+$, must be set at a value that guarantees that the damping effects are employed. That is, if the plant energy does not reach the threshold value, the damping effects will not be invoked and the desired response will not be achieved.

Unlike the DIM, the DEM technique is relatively robust. More details of the design procedure can be found in [14].

C. Stability Analysis

The stability of the closed-loop system can be ascertained for both the coordinate coupling and modal coupling scenarios. For the DEM, a viscous damping mechanism (i.e., $C(\cdot) = 2\zeta_c \omega_c x_4$) is implemented in the controller equation.

1) Coordinate Coupling Controller: System stability using the linear feedback approach is attained by examining the eigenvalues of the closed-loop system which, in the absence of damping ($\zeta_p = 0, \zeta_c = 0$) are dictated by (8). Thus, the undamped closed-loop system is globally stable provided $0 < K < 1$. If the time invariant DEM approach is utilized with $\zeta_p > 0, \zeta_c > 0$, it can be shown that the system is globally asymptotically stable provided $0 < K < 1$. Stability for the DIM and the time-varying DEM is more difficult to show. Since, however, the closed-loop system is stable when the control is applied and after the control is disabled using the DIM, it is

plausible to conjecture stability based on intuition. A similar stability conjecture can be made for the time-varying DEM since the closed-loop system is stable before and after the damping mechanism is invoked.

2) Modal Coupling Controller: The fundamental approach to ascertaining the stability of a nonlinear system is to use Lyapunov's indirect method [4]. In this case, the closed-loop system equations are linearized about the origin of the state-space. If the time invariant DEM is utilized and thus $\zeta_p > 0, \zeta_c > 0$, the system is asymptotically stable. If, however, $\zeta_c = 0$ and/or $\zeta_p = 0$, then the stability of the system cannot be ascertained since at least one of the eigenvalues acquires a zero real part. Thus, Lyapunov's direct method is adopted [4]. The existence of quadratic nonlinearities in the closed-loop system suggests the use of a candidate Lyapunov function of the form

$$V(x) = ax_1^2 + bx_2^2 + cx_3^2 + dx_4^2 \quad (25)$$

where $a, b, c, d \in \mathbb{R}^+$. Taking the time derivative of (25) and substituting the expressions for the derivatives of the state variables yields

$$\begin{aligned} \dot{V}(x) = & -4\zeta_p \omega_p x_2^2 - 4d\zeta_c \omega_c x_1^2 + (2a - 2b\omega_p^2)x_1 x_2 \\ & + (2d\gamma_2 - 2b\gamma_1)x_2 x_4^2 + (2c - 2d\omega_c^2)x_3 x_4. \end{aligned} \quad (26)$$

Selecting the variables of the candidate function to be

$$a = \omega_p^2, \quad b = 1, \quad c = \left(\frac{\gamma_1}{\gamma_2}\right)\omega_c^2, \quad d = \left(\frac{\gamma_1}{\gamma_2}\right) \quad (27)$$

induces the derivative of the Lyapunov function to take the form

$$\dot{V}(x) = -4\zeta_p \omega_p x_2^2 - 4\left(\frac{\gamma_1}{\gamma_2}\right)\zeta_c \omega_c x_1^2 \quad (28)$$

which shows that the closed-loop system is stable over the entire state-space provided

$$\zeta_p, \zeta_c \geq 0, \quad \omega_p, \omega_c, \left(\frac{\gamma_1}{\gamma_2}\right) > 0. \quad (29)$$

As with coordinate coupling, stability for the modal coupling DIM and the time-varying DEM is difficult to prove. Closed-loop stability can be conjectured based on a similar argument as given in the previous section.

Asymptotic stability for the nonlinear feedback configuration cannot be ascertained due to the fact that once the plant is motionless or the equation associated with the controller becomes inactive, the modal energy bridge is destroyed. The energy bridge can be regenerated at any time, however, provided both the plant and controller are active. Thus, it may be possible to prove asymptotic stability if a small, persistently exciting signal is applied to the controller equation for the duration of plant activity.

III. NUMERICAL EXAMPLES

In this section, the proposed control techniques are applied to a plant of the form

$$\dot{x} = \begin{bmatrix} 0 & 1 \\ -900 & 0 \end{bmatrix} x + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u \quad (30)$$

where $\zeta_p, f_p(\cdot) = 0$ have been assumed for convenience. The uncontrolled plant response is given in Fig. 4. If coordinate coupling effects are utilized, the control structure is

$$u = -\dot{x}_4, \quad f_c(\cdot) = -K\dot{x}_2, \quad \omega_c = \omega_p. \quad (31)$$

The plant and controller responses when (31) are enforced and $h = 0.0017$ are given in Fig. 5. Clearly, the desired transfer of energy is occurring. If the value of K is increased to $K = 0.005$, which corresponds to $n = 425$, the first energy minimum of the plant occurs

Fig. 4. Uncontrolled plant response.

(a)

(b)

Fig. 5 System response using coordinate coupling (a) Plant, (b) controller.

Fig. 6 Plant response, coordinate coupling, with desired amplitude modulation frequency

at approximately 1.5 seconds as illustrated in Fig. 6. Utilizing the DIM results in the controlled response and input profile illustrated in Fig. 7. The steady-state oscillation is an indication of the amount of energy in the plant when the input was disabled. If the DEM approach is adopted and a viscous damping mechanism is utilized, a time invariant implementation results in the plant response and input profile given in Fig. 8 whereas if the time-varying approach is utilized, the plant response and input profile are as given in Fig. 9.

If modal coupling effects are employed, the control parameters are

$$u = -\gamma_1 \dot{x}_1^2, f_1(\cdot) = \gamma_2 x_2^2 x_1, \omega_c = \frac{1}{2} \omega_p. \quad (32)$$

The corresponding plant and controller response with (32) invoked is illustrated in Fig. 10. The magnitudes of the nonlinear coefficients are then increased to render a plant response with the first energy minimum occurring at approximately 1.5 seconds (Fig. 11). To achieve symmetry in the response, the initial position condition

(b)

Fig. 7 DIM controller using coordinate coupling. (a) Plant response, (b) input.

(a)

(b)

Fig. 8 DEM time invariant controller using coordinate coupling. (a) Plant response, (b) input.

is increased. The resulting response is illustrated in Fig. 12. Finally, implementing the DIM control law yields the plant response and input profile given in Fig. 13. With the given choice of nonlinear feedback, the control input is always on one side of zero. This may be advantageous for some applications. If the plant is controlled using the time invariant DEM, the plant response and input profile are as given in Fig. 14. If the time-varying approach is implemented, however, the plant response and control input profile are as given in Fig. 15. Fig. 16 illustrates the controlled response and input profile of the plant subject to a proportional-derivative control law. These are included for comparison purposes. A complete list of parameters for the coordinate coupling and modal coupling controllers is contained in Tables I-III.

In all cases, the proposed control strategies function very effectively. Unlike many techniques, the controller design is aided by the

Fig. 11. Plant response, modal coupling, with desired amplitude modulation frequency.

intuition accompanying the energy transfer analogy upon which the derivation of the control laws were based. Thus, troubleshooting and fine tuning tasks are relatively easy to perform.

Fig. 12. Plant response, modal coupling, with desired symmetry.

Fig. 13. DIM controller using modal coupling. (a) Plant response, (b) input.

Fig. 14. DEM time invariant controller using modal coupling. (a) Plant response, (b) input.

IV. CONCLUSIONS

In this paper, new techniques were outlined to suppress the oscillations of a canonical second-order system. In general, the oscillation to be suppressed may result from the application of another control technique or may be disturbance induced.

Fig. 15. DEM time-varying controller using modal coupling. (a) Plant response, (b) input.

Fig. 16. PD controller. (a) Plant response, (b) input.

There are several advantages affiliated with these techniques. First of all, a great deal of intuition can accompany the mathematics in the formulation of the design as a result of the energy transfer analogy. This leads to more efficient controllers and renders troubleshooting relatively easy to perform. Secondly, the plant response approaches the operating point on the order of the cosine function whereas most existing techniques render responses that approach the operating point exponentially. Finally, the nonlinear feedback paradigm proposed in this paper yields either a positive or negative acting control input which may be useful for certain applications.

The work presented in this paper represents the first stage in the development of generalized vibration suppression laws using linear and nonlinear coupling effects. The extension to the multi-degree-of-freedom case involves the transformation of the plant equations to a form that facilitates the repeated application of the SDOF theory.

 μ -Synthesis of an Electromagnetic Suspension System

Masayuki Fujita, Toru Namerikawa,
Fumio Matsumura, and Kenko Uchida

Abstract—This paper deals with μ -synthesis of an electromagnetic suspension system. First, an issue of modeling a real physical electromagnetic suspension system is discussed. We derive a nominal model as well as a set of models in which the real system is assumed to reside. Different model structures and possible model parameter values are fully employed to determine unstructured additive plant perturbations, which directly yield uncertainty frequency weighting function. Second, based on the set of plant models, we setup robust performance control objectives. Third, we make use of the D - K iteration approach for the controller design. Finally, implementing the controller with a digital signal processor, experiments are carried out. With these experimental results, we show robust performance of the designed control system.

1. INTRODUCTION

Electromagnetic suspension systems can suspend objects without any contact. The increasing use of this technology in its various forms makes the research extremely active. The electromagnetic suspension technology has already applied to magnetically levitated vehicles, magnetic bearings, and so on. Recent advances on this field are shown in [1], and [5].

Feedback control is indispensable for magnetic suspension systems, since they are essentially unstable systems. To synthesis a feedback control system, a precise mathematical model for the plant is required. It is known, however, that a design model can not always express the behavior of the real physical plant. An ideal mathematical model has various uncertainties such as parameter identification errors, unmodeled dynamics, and neglected nonlinearities. The controller is required to have robustness for stability and performance against uncertainties on the model.

Recently, μ -synthesis, which is constructed with both H_∞ synthesis and μ -analysis, has been developed for the design of robust control systems [7], [8]. Beyond the singular value specifications, the μ -synthesis technique can put both robust stability and robust performance problems in a unified framework. Applications of the μ -synthesis method have been reported in [3]-[4], and [9]. This electromagnetic suspension system is a simple SISO system, but in [3] and [10], the authors also applied the H_∞/μ synthesis to a magnetic bearing, and the effectiveness of this design method was evaluated for a MIMO system. In the case of applications of H_∞/μ control to real physical systems, it is quite important to select appropriate design parameters. These parameters construct some parts of the generalized plant, e.g., uncertainty and performance weightings.

In this paper, we will evaluate μ -synthesis methodology experimentally with a real electromagnetic suspension system. We will model the additive uncertainties and decide the frequency weighting function for uncertainty accurately and reasonably. We will show that the closed-loop system with a μ controller achieves robust performance experimentally.

II. EXPERIMENTAL SETUP

A. Electromagnetic Suspension System

The structure of the electromagnetic suspension system is shown schematically in Fig. 1. The objective of our control experiments is to suspend an iron ball stably and firmly without any contact by controlling the attractive forces of an electromagnet. Note that this system is essentially unstable.

In Fig. 1, a cylindrical electromagnet as an actuator is located at the upper part of the experimental system. Mass of the iron ball is 1.75 kg, and it has a diameter of 77 mm. A gap sensor of our own producing is placed at the bottom of the system to measure the gap length between the iron ball and the electromagnet. The sensor is scaled for a gap of 2.4 mm per volt. It is a standard induction probe of eddy-current type. Physical parameters of this experimental machine are shown in Table I.

B. Digital Controller

The experimental machine is controlled by a digital controller using a DSP (digital signal processor). The experimental setup basically consists of the DSP which is sandwiched between A/D and D/A converters. Real-time control is implemented with a processor NEC μ PD77230, which can execute one instruction in 150 ns with 32-bit floating point arithmetic. This device has enough fast processing speed to stabilize a relatively simple magnetic suspension system in Fig. 1. The control algorithm is written in the assembly language for the DSP and a software development is assisted by a host personal computer NEC PC-9801 under the MS-DOS environment. The data acquisition board MSP-77230 consists of a 12-bit A/D converter and a 12-bit D/A converter with the maximum conversion speed of 10.5 μ s and 1.5 μ s, respectively.

The sensor outputs are filtered through an analog low-pass circuit and then converted to digital signals by A/D converters. The DSP calculates the control input signals. These digital signals are converted to analog signals by D/A converters with a range of ± 5 V. The converted signals and the steady current signals are added and amplified by 10 times to actuate the electromagnet. Steady-state voltage of the electromagnet is 24.6 V, and the maximum voltage of a regulated DC power supply is 70.0 V.

III. MODEL OF ELECTROMAGNETIC SUSPENSION SYSTEM

Our purpose in this section is to introduce an ideal mathematical model and an uncertainty weighting function for the system. See [4] for details.

TABLE I
PARAMETERS OF ELECTROMAGNETIC SUSPENSION SYSTEM

Parameter	Maximum Value	Nominal Value	Minimum Value
m [kg]	---	1.75	---
X [m]	5.50×10^{-3}	5.00×10^{-3}	4.50×10^{-3}
I [A]	1.18	1.06	0.93
x [m]	5.00×10^{-4}	0	-5.00×10^{-4}
i [A]	1.18×10^{-1}	0	-1.26×10^{-1}
L [H]	5.57×10^{-1}	5.08×10^{-1}	4.65×10^{-1}
R [Ω]	$2.37 \times 10^{+1}$	$2.32 \times 10^{+1}$	$2.27 \times 10^{+1}$
k [Nm ² /A ²]	3.35×10^{-4}	2.90×10^{-4}	2.53×10^{-4}
x_0 [m]	-3.32×10^{-4}	-6.41×10^{-4}	-9.42×10^{-4}
Q [Hm]	6.70×10^{-4}	5.79×10^{-4}	5.06×10^{-4}
X_- [m]	-3.32×10^{-4}	-6.41×10^{-4}	-9.42×10^{-4}
L_0 [H]	3.96×10^{-1}	3.75×10^{-1}	3.54×10^{-1}

A. Model Structures

We will employ four different model structures for the system depicted in Fig. 1. All of the models are finite-dimensional, linear, and time-invariant of the following state-space form

$$\begin{aligned} \dot{x} &= Ax + Bu, & y &= Cx \\ x &= [x \quad \dot{x} \quad i]^T, & u &= e, & y &= x. \end{aligned} \quad (3.1)$$

First, we introduce ideal mathematical models for the real electromagnetic suspension system. Due to the idealizing assumptions that we make, two types of ideal mathematical models can be derived hereafter, which are composed of nonlinear differential equations. We define them as Type[A] and Type[B], respectively.

Since the behavior of the electromagnetic force is nonlinear, we then employ the linearization procedure around an operating point. To account for the neglected nonlinearity, we derive two types of linear model, respectively. Thus, we will derive four linear models according to the following manners:

- *Model[A1]*: $L = \text{CONSTANT}$; and the nonlinearity of the electromagnetic forces are approximated up to the first-order term in the Taylor series expansion.
- *Model[A2]*: $L = \text{CONSTANT}$; and the nonlinearity of the electromagnetic forces are approximated up to the second-order term in the Taylor series expansion.
- *Model[B1]*: $L = L(x)$; and the nonlinearity of the electromagnetic forces are approximated up to the first-order term in the Taylor series expansion.
- *Model[B2]*: $L = L(x)$; and the nonlinearity of the electromagnetic forces are approximated up to the second-order term in the Taylor series expansion.

1) *Ideal Mathematical Model—Type[A]*: We will derive ideal mathematical models for the real electromagnetic suspension system, where the following assumptions on the electromagnet are considered.

- A.1) Magnetic permeability of the electromagnet is infinity.
- A.2) Magnetic flux density and magnetic field have not hysteresis, and they are not saturated.
- A.3) Eddy current in the magnetic pole can be neglected.

Using A.1) and A.2), we can treat the coil inductance L as a function of variable x . Then, the system can be written by the following nonlinear differential equations

$$\begin{aligned} m \frac{d^2 x}{dt^2} &= mg - f, & f &= k \left(\frac{i}{x + x_0} \right)^2 \\ e &= Ri = \frac{d}{dt} \{L(x)i\} \end{aligned} \quad (3.2)^*$$

where the coefficients k and x_0 in (3.2) are constants determined by identification experiments. Further, we introduce another assumption for Type[A].

A.A) The coil inductance is constant near an operating point. Furthermore, the electromotive forces due to the differential of gap can be neglected.

Then from (3.2), we get

$$e = Ri + L_c \frac{di}{dt}. \quad (3.3)$$

The ideal mathematical model: Type[A] is represented by (3.2) and (3.3).

Model[A1]: In view of (3.2) and (3.3), we can obtain the linear model (3.4)

$$\begin{aligned} A &= \begin{bmatrix} 0 & 1 & 0 \\ \frac{2kI^2}{m(X+x_0)^3} & 0 & -\frac{2kI}{m(X+x_0)^2} \\ 0 & 0 & -\frac{R}{L} \end{bmatrix}, \\ B &= \begin{bmatrix} 0 \\ 0 \\ \frac{1}{L} \end{bmatrix}, \quad C = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}^T \end{aligned} \quad (3.4)$$

Model[A2]: We can further obtain another linear model (3.5)

$$\begin{aligned} A &= \begin{bmatrix} 0 & 1 & 0 \\ \frac{2kI^2}{m(X+x_0)^3} \Delta y & 0 & -\frac{2kI}{m(X+x_0)^2} \Delta y \\ 0 & 0 & -\frac{R}{L} \end{bmatrix} \\ B &= \begin{bmatrix} 0 \\ 0 \\ \frac{1}{L} \end{bmatrix}, \quad C = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}^T \\ \Delta x &= \frac{x}{X+x_0}, \quad \Delta i = \frac{i}{I} \\ \Delta y &= 1 - \frac{3}{2} \Delta x + \frac{1}{2} \Delta i. \end{aligned} \quad (3.5)$$

In this way, we deal with the deviation x and i as fixed numbers, at the second-order term in the Taylor series expansion and include them in the matrix A as Δx , Δi and Δy .

2) Ideal Mathematical Model—Type[B]: For the ideal mathematical model Type[B], we also consider the assumptions A.1), A.2), A.3) and here in addition to them, we introduce the next assumption A.B) instead of A.A). Using this assumption, we can obtain more accurate model than one of Type[A].

A.B) The coil inductance L is a function of a gap x , and written as follows

$$L(x) = \frac{Q}{x + X_\infty} = L_0 \quad (3.6)$$

where the coefficients Q , X_∞ and L_0 are also the constants determined by identification experiments. For any given current i in a coil with inductance L , the magnetic co-energy is shown as $\frac{1}{2} Li^2$. Hence electromagnetic forces between the electromagnet and the iron ball in (3.2) is equal to the change rate of co-energy with respect to the distance x , i.e.,

$$\begin{aligned} f &= \frac{\partial}{\partial x} \left\{ \frac{1}{2} L(x) i^2 \right\} = \frac{1}{2} i^2 \frac{\partial L(x)}{\partial x} \\ &= \frac{Q}{2} \left(\frac{i}{x + X_\infty} \right)^2. \end{aligned} \quad (3.7)$$

Comparing (3.2) with (3.7)

$$X_\infty = x_0, \quad Q = 2k. \quad (3.8)$$

Then from (3.2), (3.6) and (3.8), we get

$$e = Ri - \frac{2ki}{(x+x_0)^2} \frac{dx}{dt} + \left(\frac{2k}{x+x_0} + L_0 \right) \frac{di}{dt}. \quad (3.9)$$

Now we obtained the ideal mathematical model: Type[B] which is constructed with (3.2) and (3.9).

Model[B1]: From (3.2) and (3.9), the linear model (3.10) (as shown at the bottom of the page) is derived.

Model[B2]: Moreover, the linear model (3.11) can be derived, as shown at the bottom of the page.

Thus, now we obtained four linear model structures: Model[A1], Model[A2], Model[B1], and Model[B2].

$$\begin{aligned} A &= \begin{bmatrix} 0 & 1 & 0 \\ \frac{2kI^2}{m(X+x_0)^3} & 0 & -\frac{2kI}{m(X+x_0)^2} \\ 0 & \frac{2kI}{(X+x_0)\{2k+L_0(X+x_0)\}} & -\frac{R(X+x_0)}{2k+L_0(X+x_0)} \end{bmatrix}, \\ B &= \begin{bmatrix} 0 \\ 0 \\ \frac{X+x_0}{2k+L_0(X+x_0)} \end{bmatrix}, \quad C = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}^T \end{aligned} \quad (3.10)$$

$$\begin{aligned} A &= \begin{bmatrix} 0 & 1 & 0 \\ \frac{2kI^2}{m(X+x_0)^3} \Delta y & 0 & -\frac{2kI}{m(X+x_0)^2} \Delta y \\ 0 & \frac{2kI(1-2\Delta x+\Delta i)}{(X+x_0)\{2k(1-\Delta x)+L_0(X+x_0)\}} & -\frac{R(X+x_0)}{2k(1-\Delta x)+L_0(X+x_0)} \end{bmatrix}, \\ B &= \begin{bmatrix} 0 \\ 0 \\ \frac{X+x_0}{L_0(X+x_0)+2k(1-\Delta x)} \end{bmatrix}, \quad C = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}^T. \end{aligned} \quad (3.11)$$

B. Model Parameters

To account for unpredictable perturbations in the model parameters, we will set the nominal value as well as the possible max./min. value of each parameter in every linear model. To obtain the possible max./min. value of each parameter, consider the steady-state gap $X = 5.0$ mm (nominal). Now let us perturb it with $X = 4.5$ mm and $X = 5.5$ mm (perturbed ± 0.5 mm). And, for these cases, we measured the three sets of the parameter values. The results of measurements are shown in Table II.

C. Nominal Model

We will form the nominal model using the simplest Model[A1] structure and the nominal model parameter ($X = 5.0$ mm case). Its state-space form is then of the following form

$$A_{nom} = \begin{bmatrix} 0 & 1 & 0 \\ 4481 & 0 & -18.43 \\ 0 & 0 & -45.69 \end{bmatrix}, \quad B_{nom} = \begin{bmatrix} 0 \\ 0 \\ 1.969 \end{bmatrix}, \quad C_{nom} = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}^T. \quad (3.12)$$

And the corresponding nominal transfer function is

$$G_{nom} = \frac{-36.27}{(s + 66.94)(s - 66.94)(s + 45.69)}. \quad (3.13)$$

Fig. 2. Uncertainty weighting.

D. Modeling Unstructured Uncertainty

To account for unstructured uncertainties, we should consider not only a nominal model but also a set of plant models in which the real system is assumed to reside. Considering only unstructured uncertainties, we get all unstructured uncertainties together into one-full block uncertainty.

To estimate the quantities of additive model perturbations, we employ differences of gain between the nominal transfer function and the perturbed transfer function with only one parameter changed and the others fixed, where we did not consider that plural parameters change together. In such a way, 24 perturbed models have been employed. They are shown in Table II. With these notations, we can define the corresponding perturbed transfer functions \hat{G}_{ij} in an obvious way

$$\Delta_{ij} := \hat{G}_{ij} - G_{nom} \quad (1 \leq i \leq 12, j = a, b). \quad (3.14)$$

Frequency responses of these additive perturbations $|\Delta_{ij}(j\omega)|$ are plotted in Fig. 2, with 24 dotted lines. Now let us consider the set of plant models. Here we assume the following form

$$G := \{G_{nom} + \Delta_{add}W_{add} : \|\Delta_{add}\|_{\infty} \leq 1\} \quad (3.15)$$

in which the real plant is assumed to reside. All of the uncertainties are captured in the normalized, unknown transfer function Δ_{add} . It is natural to choose the uncertainty weighting W_{add} as follows (shown in Fig. 2). Here it should be noted that the magnitude of the uncertainty weighting W_{add} covers all the model perturbations shown in Fig. 2

$$W_{add} = \frac{1.4 \times 10^{-5} (1 + s/8)(1 + s/170)(1 + s/420)}{(1 + s/30)(1 + s/35)(1 + s/38)}. \quad (3.16)$$

IV. DESIGN

A. Control Objectives

Electromagnetic suspension system is essentially unstable. We must design a robust controller to stabilize the closed-loop system; furthermore, we would like to design a controller to maintain the performance against unpredictable disturbances and the uncertainties.

Let us consider the feedback structure shown in Fig. 3. The box represents the set of the models: G of the real system. Robust stability requirement for the additive uncertainty can be evaluated using the closed-loop transfer function $K S$, where $S := (I + GK)^{-1}$. Hence robust stability test for $G \in \mathcal{G}$ is equivalent to

$$\|W_{add} K (I + G_{nom} K)^{-1} W_{add}\|_{\infty} < 1. \quad (4.1)$$

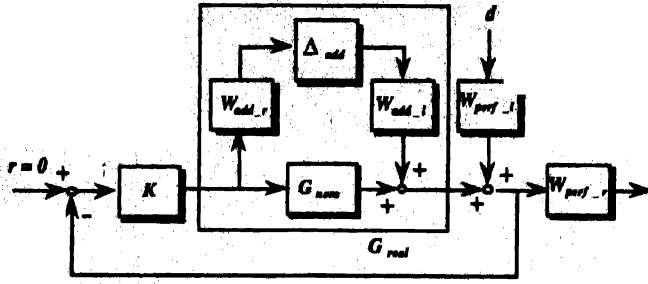

Fig. 3. Feedback structure.

It is noted in Fig. 3 that we factor the uncertainty weighting as $W_{add} = W_{add_l} \times W_{add_r}$, where

$$W_{add_l} = 1.0 \times 10^{-5},$$

$$W_{add_r} = \frac{1.4 \times (1 + s/8)(1 + s/170)(1 + s/420)}{(1 + s/30)(1 + s/35)(1 + s/38)}. \quad (4.2)$$

To reject the disturbances at low frequency band, the performance weighting W_{perf} is now chosen as

$$W_{perf} = \frac{200.0}{1 + s/0.1}. \quad (4.3)$$

We also factor the performance weighting as $W_{perf} = W_{perf_l} \times W_{perf_r}$, where

$$W_{perf_l} = 1.0 \times 10^{-5}, \quad W_{perf_r} = \frac{2.0 \times 10^7}{1 + s/0.1}. \quad (4.4)$$

In practical situation, however, we would like to achieve this performance specification for all the possible plant $G \in \mathbf{G}$. A necessary and sufficient condition for this robust performance is

$$\|W_{perf_r}(I + GK)^{-1}W_{perf_l}\|_{\infty} < 1, \quad \forall G \in \mathbf{G}. \quad (4.5)$$

Now the control objective is to find a stabilizing controller K which achieves the following two conditions

- The closed-loop system remains internally stable for every plant model $G \in \mathbf{G}$,
- The weighted sensitivity function satisfies the performance test (4.5) for every plant $G \in \mathbf{G}$.

The design objectives have been specified as the requirements for particular closed loop transfer functions with the frequency weighting functions W_{add} and W_{perf} . The above control objectives exactly fit in the μ -synthesis framework by introducing a fictitious uncertainty block Δ_{perf} . Rearranging the feedback structure in Fig. 3, we can build the interconnection structure shown in Fig. 4.

B. μ -Synthesis

We first define a block structure Δ_P as

$$\Delta_P := \left\{ \begin{bmatrix} \Delta_{add} & 0 \\ 0 & \Delta_{perf} \end{bmatrix} : \Delta_{add} \in \mathbf{C}, \Delta_{perf} \in \mathbf{C} \right\}. \quad (4.6)$$

Next, consider a generalized plant P partitioned as

$$P = \begin{bmatrix} P_{11} & P_{12} \\ P_{21} & P_{22} \end{bmatrix}. \quad (4.7)$$

Fig. 4. Interconnection structure.

Obviously in Fig. 4, we can get a lower linear fractional transformation $\mathcal{F}_l(P, K)$ on P by K

$$\mathcal{F}_l(P, K) := P_{11} + P_{12}K(I - P_{22}K)^{-1}P_{21}. \quad (4.8)$$

Finally, robust performance condition is equivalent to the following structured singular value μ test

$$\sup_{\omega \in \mathbf{R}} \mu_{\Delta_P}(\mathcal{F}_l(P, K)(j\omega)) < 1. \quad (4.9)$$

The complex structured singular value μ_{Δ_P} is defined as

$$\mu_{\Delta_P}(M) := \frac{1}{\min \{ \bar{\sigma}(\Delta) : \Delta \in \Delta, \det(I - M\Delta) = 0 \}} \quad (4.10)$$

unless no $\Delta \in \Delta$ makes $I - M\Delta$ singular, in which case $\mu_{\Delta}(M) := 0$. In this case a matrix M in (4.10) belongs to $\mathbf{C}^{2 \times 2}$.

C. D-K iteration

Unfortunately, it is not known how to obtain a controller K achieving the structured singular value test (4.9) directly. But we can obtain the lower and upper bounds of μ . Our approach taken here is the so-called D - K iteration procedure.

The D - K iteration involves a sequence of minimizations over either K or D while holding the other fixed, until a satisfactory controller is constructed. First, for $D = I$ fixed, the controller K_1 is synthesized using the well-known state-space H_{∞} optimization method. Let $P_1 = P$ denote the given open-loop interconnection structure in Fig. 4, and $\mathcal{F}_l(P, K)$ be the closed-loop transfer function from the disturbances w to the errors z .

Then, solving the following H_{∞} control problem

$$\|\mathcal{F}_l(P_1, K_1)\|_{\infty} < \gamma_1, \quad \gamma_1 = 1.3. \quad (4.11)$$

The problem (4.11) yields the central controller K_1 as shown in (4.12) found at the bottom of the page.

$$K_1 = \frac{-5.22 \times 10^8 (s + 12.46)(s + 30.0)(s + 35.0)(s + 38.0)(s + 45.69)(s + 66.94)}{(s + 0.10)(s + 31.6 - j5.12)(s + 31.6 + j5.12)(s + 39.77)(s + 315.2 - j329.6)(s + 315.2 + j329.6)(s + 734.7)} \quad (4.12)$$

Fig. 5. σ and μ plot of the first D - K iteration.Fig. 6. σ and μ plot of the second D - K iteration.

Here we try to assess robust performance of this closed-loop system using μ -analysis associated with the block structure (4.6). The maximum singular value and μ upper bound of the closed-loop transfer function $\mathcal{F}_l(P_1, K_1)$ are plotted in Fig. 5. It is noteworthy to point out that the peak value of the upper bound μ plot is not less than one. This reveals that the closed-loop system with this H_∞ controller K_1 does not achieve robust performance condition.

Next, the above calculations of μ produce a scaling matrix at each frequency. In this design, we try to fit the curve using a first-order transfer function.

Now, let P_2 denote the new open-loop interconnection structure absorbing the scaling matrix D . This time, from the following H_∞ control problem

$$\|\mathcal{F}_l(P_2, K_2)\|_\infty < \gamma_2, \quad \gamma_2 = 1.0 \quad (4.13)$$

we can calculate the controller K_2 as found in (4.14) as shown at the bottom of the page.

The maximum singular value and μ upper bound of this closed-loop system are plotted in Fig. 6. Since the value of μ is less than one in Fig. 6, robust performance condition is now achieved.

V. EXPERIMENTAL RESULTS

The designed controllers K_1 and K_2 are continuous-time systems. To implement these two controllers with the digital controller, we discretized them via the well known Tustin transform. The controllers K_1 and K_2 are discretized at the sampling period of $45\mu\text{s}$ and $60\mu\text{s}$, respectively.

Fig. 7. Response to step disturbance with K_1 (-17.15N).Fig. 8. Response to step disturbance with K_2 (-17.15N).Fig. 9. Response to step disturbance with K_1 (-34.30N).

We succeeded in the stable suspension of the iron ball using both of the controllers K_1 and K_2 . In the Section IV, robust stability and robust performance objectives were considered as the control problems. The obtained H_∞ controller K_1 achieves robust stability condition, and μ controller K_2 achieves not only robust stability but also robust performance specification. Hence, we will evaluate robust performance as well as robust stability of the closed-loop systems with responses against various external disturbances.

There the disturbances are added to the experimental system as an applied voltage in the electromagnet. It is noted that there are four types of disturbances. Taking account that the steady-state force of the electromagnet is equal to 17.15 N, we added the following disturbance forces to the floating iron ball

$$\text{downward } 17.15 \text{ N}, \quad \text{downward } 34.30 \text{ N}.$$

These disturbances are large enough to evaluate the robustness of both these two controllers. Experimental results are shown in Figs. 7–10.

First of all, these experimental results in Figs. 7–10 show that the iron ball is suspended. Responses in Fig. 9 are vibrating extremely, however, their vibration get on the decrease. This shows the closed-loop systems with both the controllers K_1 and K_2 remain stable against these disturbances. Comparing Fig. 7 with Fig. 9, the responses with K_1 deteriorate extremely against relatively large disturbances. While in Fig. 8 and Fig. 10, the responses with the controller K_2 maintain good transient responses against these disturbances. Now we can see the following observation.

$$K_2 = \frac{-8.01 \times 10^9 (s + 10.54)(s + 15.75)(s + 30.0)(s + 35.0)(s + 38.0)}{(s + 0.10)(s + 19.59 - j5.32)(s + 19.59 + j5.32)(s + 38.48 - j2.70)(s + 38.48 + j2.70)} \\ \times \frac{(s + 45.69)(s + 66.94)(s + 169.6)}{(s + 176.6)(s + 420.1 - j272.8)(s + 420.1 + j272.8)(s + 8180)} \quad (4.14)$$

Fig. 10. Response to step disturbance with K_2 ($-34.30N$).

- The closed-loop system with the μ controller K_2 achieves robust performance, while the closed-loop system with the H_∞ controller K_1 does not.

VI. CONCLUSIONS

In this paper, we experimentally evaluated a controller designed by μ -synthesis methodology with an electromagnetic suspension system. We have obtained a nominal mathematical model as well as a set of plant models in which the real system is assumed to reside. With this set of the models we designed the control system to achieve robust performance objective utilizing μ -synthesis method.

First, four types of different model structures were derived based on the several idealizing assumptions for the real system. Second, for every model, the nominal value as well as the possible maximum and minimum values of each model parameter was determined by measurements and/or experiments. Third, a nominal model was naturally chosen. This model has the simplest model structure of all four models and makes use of nominal parameter values. Then, model perturbations were defined to account for additive unstructured uncertainties from such as neglected nonlinearities and model parameter errors. Fourth, we defined a family of plant models where the unstructured additive perturbation was employed. The method to model the plant as belonging to a family or set plays a key role for systematic robust control design. Fifth, we setup robust performance objective as a structured singular value test. Next, for the design, the D - K iteration approach was employed. Finally, the experimental results showed that the closed-loop system with the μ -controller achieves not only nominal performance and robust stability, but in addition robust performance.

Parameter-Dependent Lyapunov Functions and the Popov Criterion in Robust Analysis and Synthesis

Wassim M. Haddad and Dennis S. Bernstein

Abstract—Many practical applications of robust feedback control involve constant real parameter uncertainty, whereas small gain or norm-bounding techniques guarantee robust stability against complex, frequency-dependent uncertainty, thus entailing undue conservatism. Since conventional Lyapunov bounding techniques guarantee stability with respect to time-varying perturbations, they possess a similar drawback. In this paper we develop a framework for parameter-dependent Lyapunov functions, a less conservative refinement of "fixed" Lyapunov functions. An immediate application of this framework is a reinterpretation of the classical Popov criterion as a parameter-dependent Lyapunov function. This result is then used for robust controller synthesis with full-order and reduced-order controllers.

I. INTRODUCTION

The analysis and synthesis of robust feedback controllers entails a fundamental distinction between parametric and nonparametric uncertainty. Parametric uncertainty refers to plant uncertainty that is modeled as constant real parameters, whereas nonparametric uncertainty refers to uncertain transfer function gains modeled as complex frequency-dependent quantities. In the time domain, nonparametric uncertainty is manifested as time-varying uncertain real parameters.

The distinction between parametric and nonparametric uncertainty is critical to the achievable performance of feedback control systems. For example, in the problem of vibration suppression for flexible space structures, if stiffness matrix uncertainty is modeled as nonparametric uncertainty, then perturbations to the damping matrix will inadvertently be allowed. Predictions of stability and performance for given feedback gains will consequently be extremely conservative, thus limiting achievable performance [1]. Alternatively, this problem can be viewed by considering the classical analysis of Hill's equation (e.g., the Mathieu equation) which shows that time-varying parameter variations can destabilize a system even when the parameter variations are confined to a region in which constant variations are nondestabilizing. Consequently, a feedback controller designed for time-varying parameter variations will unnecessarily sacrifice performance when the uncertain real parameters are actually constant.

The above distinction can also be illustrated by considering the central result of feedback control theory, namely, the small gain theorem, which guarantees robust stability by requiring that the loop gain (including desired weighting functions for loop shaping) be less than unity at all frequencies. The small gain theorem, however, does not make use of phase information in guaranteeing stability. In fact, the small gain theorem allows the loop transfer function to possess arbitrary phase at all frequencies, although in many applications at least some knowledge of phase is available [2]. Thus, small gain techniques such as H_∞ theory are generally conservative when phase information is available. More generally, since $|e^{j\omega}| = 1$ regardless of the phase angle ϕ , it can be expected that any robustness theory based upon norm bounds will suffer from the same shortcoming. Of course, every real parameter can be viewed as a complex parameter with phase angle $\phi = 0$ degrees or $\phi = 180$ degrees.

To some extent, phase information is accounted for by means of positivity theory [3]–[15] which is widely used to model passive systems such as flexible structures [16], [17]. In this theory, a positive real plant and strictly positive real uncertainty are both assumed to have phase less than 90 degrees so that the loop transfer function has less than 180 degrees of phase shift, hence guaranteeing robust stability in spite of gain uncertainty. Both gain and phase properties can be simultaneously accounted for by means of the circle criterion [15], [18]–[22] which yields the small gain theorem and positivity theorem as special cases. It is important to note that since positivity theory and the circle criterion can be obtained from small gain conditions by means of suitable transformations, they can be viewed as equivalent results from a mathematical point of view. The engineering ramifications of the ability to include phase information, however, can be significant [1].

The above discussion is further illuminated by means of Lyapunov function theory in [15]. Specifically, as pointed out in [15], a serious defect of conventional or fixed Lyapunov bounding theory is the fact that stability is guaranteed even if the plant uncertainty ΔA is a function of t . This observation follows from the fact that the Lyapunov derivative $\dot{V}(x(t)) = V_x(x(t))(A + \Delta A(t))x(t)$ need only be negative for each fixed value of t [15], [23]. Although this feature is desirable if ΔA is time varying, as discussed above, it leads to conservatism when ΔA is actually constant. This defect can be remedied, however, by utilizing an alternative approach, which is consistent with Lyapunov function bounding techniques, based upon parameter-dependent Lyapunov functions. The idea behind parameter-dependent Lyapunov functions is to allow the Lyapunov function to be a function of the uncertainty ΔA . In the usual case, $V(x) = x^T P x$, P is a single, fixed matrix, whereas the parameter-dependent Lyapunov function $V_{\Delta A}(x) = x^T P(\Delta A)x$ represents a family of Lyapunov functions.

The concept of a parameter-dependent Lyapunov functions is not new to this paper. Specifically, a parameter-dependent Lyapunov function of the form $V(x) = x^T P(\lambda_1, \dots, \lambda_r)x$, where $P(\lambda_1, \dots, \lambda_r) = \sum_{i=1}^r \lambda_i P_i$, is considered in [24]. In this case the matrices P_i correspond to the vertices of a polytope of uncertain matrices with vertices A_1, \dots, A_r . More recently, [25] considers a Lyapunov function with matrix $P(\sigma_1, \dots, \sigma_s) = P_0 + \sum_{i=1}^s \sigma_i P_i$, where P_0 corresponds to the nominal system and the P_i are "first-order perturbations" of P_0 . Numerical techniques are used to determine P_i and the range of robust stability. Both [24] and [25] discuss potential advantages of parameter-dependent Lyapunov functions over fixed Lyapunov functions.

The goal of the present paper is to develop robust analysis and synthesis techniques that exploit the fact that the classical Popov criterion [26] is based upon a parameter-dependent Lyapunov

function. Indeed, recall that the Popov criterion is based upon the Lur'e-Postnikov Lyapunov function

$$V_\phi(x) = x^T P x + N \int_0^y \phi(\sigma) d\sigma \quad (1.22)$$

where $y = Cx$ and $\phi(\cdot)$ is a scalar memoryless time-invariant nonlinearity in the sector $[0, k]$, that is, $0 \leq \phi(y)y \leq ky^2$. Specializing to the linear uncertainty case $\phi(y) = Fy$, where $0 \leq F \leq k$, yields

$$\begin{aligned} V_F(x) &= x^T P x + N \int_0^y F \sigma d\sigma = x^T P x + NF \frac{y^2}{2} \\ &= x^T [P + \frac{1}{2} N F C^T C] x = x^T P(F)x. \end{aligned}$$

This form appears in [10, pp. 84–89] and was discussed in the context of robust analysis in [15].

For practical purposes the form of the parameter-dependent Lyapunov function $V_F(x)$ is useful since the presence of F restricts the allowable time-varying uncertain parameters [27]. That is, if $F(t)$ were permitted, then terms involving $\dot{F}(t)$ would arise and potentially subvert the negative definiteness of $\dot{V}_F(x)$.

This paper has four specific goals: 1) to provide a general framework for parameter-dependent Lyapunov functions; 2) to obtain a generalized multivariable version of the Popov criterion for linear matrix uncertainty ΔA (the classical Popov criterion is limited to scalar or diagonal nonlinearities) along with H_2 robust performance bounds; 3) to provide explicit uncertainty bounds for the multivariable Popov criterion in terms of a single Riccati equation that can be used for robust controller synthesis; and 4) to develop robust controller synthesis techniques based upon the multivariable Popov criterion with applications to full-order and reduced-order controllers.

II. ROBUST STABILITY AND PERFORMANCE PROBLEMS: ANALYSIS

Let $\mathcal{U} \subset \mathbb{R}^{n \times n}$ denote a set of perturbations ΔA of a given nominal dynamics matrix $A \in \mathbb{R}^{n \times n}$. Within the context of robustness analysis, it is assumed that A is asymptotically stable and $0 \in \mathcal{U}$. We begin by considering the stability of $A + \Delta A$ for all $\Delta A \in \mathcal{U}$.

Robust Stability Problem: Determine whether the linear system

$$\dot{x}(t) = (A + \Delta A)x(t), \quad t \in [0, \infty) \quad (2.1)$$

is asymptotically stable for all $\Delta A \in \mathcal{U}$.

To consider the problem of robust performance, we introduce an external disturbance model involving white noise signals as in standard LQG (H_2) theory. The robust performance problem concerns the worst-case H_2 norm, that is, the worst-case over \mathcal{U} of the expected value of a quadratic form involving outputs $z(t) = Ex(t)$, where $E \in \mathbb{R}^{q \times n}$, when the system is subjected to a standard white noise disturbance $w(t) \in \mathbb{R}^d$ with weighting $D \in \mathbb{R}^{n \times d}$.

Robust Performance Problem: For the disturbed linear system

$$\dot{x}(t) = (A + \Delta A)x(t) + Dw(t), \quad t \in [0, \infty). \quad (2.2)$$

$$z(t) = Ex(t) \quad (2.3)$$

where $w(\cdot)$ is a zero-mean d -dimensional white noise signal with intensity I_d , determine a performance bound β satisfying

$$J(\mathcal{U}) \triangleq \sup_{\Delta A \in \mathcal{U}} \limsup_{t \rightarrow \infty} \mathbb{E}\{\|z(t)\|_2^2\} \leq \beta. \quad (2.4)$$

In Section VI, (2.2) will denote a control system in closed-loop configuration subjected to external white noise disturbances and for which $z(t)$ denotes the state and control regulation error.

Next, we express the H_2 performance measure in terms of the observability Gramian for the pair $(A + \Delta A, E)$. For convenience define the $n \times n$ nonnegative-definite matrices $R \triangleq E^T E$, $V \triangleq DD^T$.

Lemma 2.1: Suppose $A + \Delta A$ is asymptotically stable for all $\Delta A \in \mathcal{U}$. Then

$$J(\mathcal{U}) = \sup_{\Delta A \in \mathcal{U}} \text{tr} P_{\Delta A} V = \sup_{\Delta A \in \mathcal{U}} \|G_{\Delta A}(s)\|_2^2 \quad (2.5)$$

where $P_{\Delta A} \in \mathbb{R}^{n \times n}$ is the unique, nonnegative-definite solution to

$$0 = (A + \Delta A)^T P_{\Delta A} + P_{\Delta A} (A + \Delta A) + R \quad (2.6)$$

and $G_{\Delta A}(s) \triangleq E[sI - (A + \Delta A)]^{-1}D$.

III. ROBUST STABILITY AND PERFORMANCE VIA PARAMETER-DEPENDENT LYAPUNOV FUNCTIONS

The key step in obtaining robust stability and performance is to bound the uncertain terms $\Delta A^T P_{\Delta A} + P_{\Delta A} \Delta A$ in the Lyapunov equation (2.6) by means of a parameter-dependent bounding function $\Omega(P, \Delta A)$ which guarantees robust stability by means of a family of Lyapunov functions. This procedure corresponds to the construction of a parameter-dependent Lyapunov function which constrains the class of allowable time-varying uncertainties. The following result forms the basis for all later developments.

Theorem 3.1. Let $\Omega_0: \mathbb{N}^n \rightarrow \mathbb{S}^n$ and $P_0: \mathcal{U} \rightarrow \mathbb{S}^n$ be such that

$$\Delta A^T P + P \Delta A \leq \Omega_0(P) - [(A + \Delta A)^T P_0(\Delta A) + P_0(\Delta A)(A + \Delta A)], \quad \Delta A \in \mathcal{U}, P \in \mathbb{N}^n \quad (3.1)$$

and suppose there exists $P \in \mathbb{N}^n$ satisfying

$$0 = A^T P + P A + \Omega_0(P) + R \quad (3.2)$$

and such that $P + P_0(\Delta A)$ is nonnegative definite for all $\Delta A \in \mathcal{U}$. Then

$$(A + \Delta A, E) \text{ is detectable, } \Delta A \in \mathcal{U} \quad (3.3)$$

if and only if

$$A + \Delta A \text{ is asymptotically stable, } \Delta A \in \mathcal{U}. \quad (3.4)$$

In this case

$$P_{\Delta A} \leq P + P_0(\Delta A), \quad \Delta A \in \mathcal{U} \quad (3.5)$$

where $P_{\Delta A}$ is given by (2.6). Therefore

$$J(\mathcal{U}) \leq \text{tr} P V + \sup_{\Delta A \in \mathcal{U}} \text{tr} P_0(\Delta A) V. \quad (3.6)$$

If, in addition, there exists $\tilde{P}_0 \in \mathbb{S}^n$ such that

$$P_0(\Delta A) \leq \tilde{P}_0, \quad \Delta A \in \mathcal{U} \quad (3.7)$$

then

$$J(\mathcal{U}) \leq \text{tr}[(P + \tilde{P}_0)V]. \quad (3.8)$$

Proof: Note that in (3.1), P denotes an arbitrary element of \mathbb{N}^n , whereas in (3.2) P denotes a specific solution of the modified Lyapunov equation (3.2). This minor abuse of notation considerably simplifies the presentation. Now, note that for all $\Delta A \in \mathbb{R}^{n \times n}$, (3.2) is equivalent to

$$0 = (A + \Delta A)^T P + P(A + \Delta A) + \Omega_0(P) - (\Delta A^T P + P \Delta A) + R. \quad (3.9)$$

Adding and subtracting $(A + \Delta A)^T P_0(\Delta A) + P_0(\Delta A)(A + \Delta A)$ to (3.9) yields

$$\begin{aligned} 0 = & (A + \Delta A)^T (P + P_0(\Delta A)) + (P + P_0(\Delta A))(A + \Delta A) \\ & + \Omega_0(P) - [(A + \Delta A)^T P_0(\Delta A) + P_0(\Delta A)(A + \Delta A)] \\ & - (\Delta A^T P + P \Delta A) + R. \end{aligned} \quad (3.10)$$

Hence, by assumption, (3.10) has a solution $P \in \mathbb{N}^n$ for all $\Delta A \in \mathbb{R}^{n \times n}$. If ΔA is restricted to the set \mathcal{U} , then, by (3.1), $\Omega_0(P) - [(A + \Delta A)^T P_0(\Delta A) + P_0(\Delta A)(A + \Delta A)] - (\Delta A^T P + P \Delta A)$ is nonnegative definite. Thus if condition (3.3) holds for all $\Delta A \in \mathcal{U}$, then Theorem 3.6 of [28] implies $(A + \Delta A, [R + \Omega(P, \Delta A) - (\Delta A^T P + P \Delta A)]^{1/2})$ is detectable for all $\Delta A \in \mathcal{U}$, where

$$\Omega(P, \Delta A) \triangleq \Omega_0(P) - [(A + \Delta A)^T P_0(\Delta A) + P_0(\Delta A)(A + \Delta A)]. \quad (3.11)$$

It now follows from (3.10) and Lemma 12.2 of [28] that $A + \Delta A$ is asymptotically stable for all $\Delta A \in \mathcal{U}$. Conversely, if $A + \Delta A$ is asymptotically stable for all $\Delta A \in \mathcal{U}$, then (3.3) is immediate. Now, subtracting (2.6) from (3.10) yields

$$\begin{aligned} 0 = & (A + \Delta A)^T (P + P_0(\Delta A) - P_{\Delta A}) + (P + P_0(\Delta A) - P_{\Delta A})(A + \Delta A) \\ & \times (A + \Delta A) + \Omega_0(P) - [(A + \Delta A)^T P_0(\Delta A) + P_0(\Delta A)(A + \Delta A)] \\ & \times (A + \Delta A) - (\Delta A^T P + P \Delta A), \quad \Delta A \in \mathcal{U} \end{aligned} \quad (3.12)$$

or, equivalently, since $A + \Delta A$ is asymptotically stable for all $\Delta A \in \mathcal{U}$

$$\begin{aligned} P + P_0(\Delta A) - P_{\Delta A} &= \int_0^\infty e^{(A + \Delta A)^T t} [\Omega(P, \Delta A) \\ &\quad - (\Delta A^T P + P \Delta A)] e^{(A + \Delta A) t} dt \\ &\geq 0, \quad \Delta A \in \mathcal{U} \end{aligned} \quad (3.13)$$

which implies (3.5). The performance bounds (3.6) and (3.8) are now an immediate consequence of (2.5), (3.5), and (3.7) \square

Note that with $\Omega(P, \Delta A)$ defined by (3.11) condition (3.1) can be written as

$$\Delta A^T P + P \Delta A \leq \Omega(P, \Delta A), \quad \Delta A \in \mathcal{U}, \quad P \in \mathbb{N}^n \quad (3.1)'$$

where $\Omega(P, \Delta A)$ is a function of the uncertainty ΔA . For convenience we shall say that $\Omega(\cdot, \cdot)$ is a parameter-dependent Ω -bound, which is consistent with [29]. One can recover the standard guaranteed cost bound or parameter-independent Ω -bound by setting $P_0(\Delta A) \equiv 0$ so that $\Omega(P, \Delta A) \equiv \Omega_0(P)$ and therefore $\Delta A^T P + P \Delta A \leq \Omega_0(P)$ for all $\Delta A \in \mathcal{U}$. Finally, since we do not assume that $P_0(0) = 0$, it follows that $\Omega_0(P)$ need not be nonnegative definite. If, however, $P_0(0) = 0$, then it follows from (3.1) with $\Delta A = 0$ that $\Omega_0(P) \geq 0$ for all nonnegative-definite P . To apply Theorem 3.1, we first specify functions $\Omega_0(\cdot)$ and $P_0(\cdot)$ and an uncertainty set \mathcal{U} such that (3.1)' holds. If the existence of a nonnegative-definite solution P to (3.2) can be determined analytically or numerically and the detectability condition (3.3) is satisfied, then robust stability is guaranteed and the performance bound (3.8) can be computed.

Finally, we show that a parameter-dependent Ω -bound establishing robust stability is equivalent to the existence of a parameter-dependent Lyapunov function which also establishes robust stability. To show this, assume there exists a positive-definite solution to (3.2), let

$P_0: \mathcal{U} \rightarrow \mathbb{N}^n$, and define the parameter-dependent Lyapunov function $V_{\Delta A}(x) \triangleq x^T (P + P_0(\Delta A))x$. Note that since P is positive definite and $P_0(\Delta A)$ is nonnegative definite, $V_{\Delta A}(x)$ is positive definite. The corresponding Lyapunov derivative is given by

$$\dot{V}_{\Delta A}(x) = -x^T [\Omega_0(P) - \{\Delta A^T P + P \Delta A + (A + \Delta A)^T \times P_0(\Delta A) + P_0(\Delta A)(A + \Delta A)\} + R]x. \quad (3.14)$$

Thus, using (3.1) it follows that $\dot{V}_{\Delta A}(x) \leq 0$ so that $A + \Delta A$ is stable in the sense of Lyapunov. Asymptotic stability follows from the invariant set theorem.

IV. CONSTRUCTION OF PARAMETER-DEPENDENT LYAPUNOV FUNCTIONS

We now assign explicit structure to the uncertainty set \mathcal{U} and the parameter-dependent bounding function $\Omega(\cdot)$. Specifically, let

$$\mathcal{U} \triangleq \{\Delta A \in \mathbb{R}^{n \times n} \mid \Delta A = B_0 F C_0, F \in \mathcal{F}\} \quad (4.1)$$

where \mathcal{F} satisfies

$$\mathcal{F} \subseteq \mathcal{F} = \{F \in \mathbb{R}^{m_0 \times m_0} \mid 0 \leq F \leq M\} \quad (4.2)$$

and where $B_0 \in \mathbb{R}^{n \times m_0}$, $C_0 \in \mathbb{R}^{m_0 \times n}$ are fixed matrices denoting the structure of the uncertainty, $F \in \mathbb{R}^{m_0 \times m_0}$ is an uncertain symmetric matrix, and $M \in \mathbb{R}^{m_0 \times m_0}$ is a given positive-definite matrix. Note that \mathcal{F} may be equal to \mathcal{F} , although, for generality, \mathcal{F} may be a specified proper subset of \mathcal{F} . For example, \mathcal{F} may consist of block-structured matrices $F = \text{block-diag}(F_1, F_2, \dots, F_r)$ where $F_i = \text{block-diag}(F_{i1}, F_{i2}, \dots, F_{im_i})$ and $M = \text{block-diag}(M_1, M_2, \dots, M_r)$, then $0 \leq F_i \leq M_i$, $i = 1, \dots, r$. Finally, we assume that $0 \in \mathcal{F}$ and $M \in \mathcal{F}$.

Next, we provide an equivalent characterization of the set \mathcal{F} .

Lemma 4.1 Let $F \in \mathbb{S}^{m_0}$ and $M \in \mathbb{P}^{m_0}$. Then $F M^{-1} F \leq I$ if and only if $0 \leq F \leq M$.

For \mathcal{U} given by (4.1), the parameter-dependent bound $\Omega(\cdot)$ satisfying (3.12) can now be given a concrete form. Since the elements ΔA in \mathcal{U} are parameterized by the elements F in \mathcal{F} , we shall write $P_0(F)$ in place of $P_0(\Delta A)$. Finally, we define the sets \mathcal{N}_s and \mathcal{N}_{nd} such that the product of the transpose of every matrix in \mathcal{N}_s (resp., \mathcal{N}_{nd}) and every matrix in \mathcal{F} is symmetric (respectively, nonnegative definite) by

$$\mathcal{N}_s \triangleq \{N \in \mathbb{R}^{m_0 \times m_0} \mid F N = N^T F, F \in \mathcal{F}\}$$

and

$$\mathcal{N}_{nd} \triangleq \{N \in \mathcal{N}_s \mid F N \geq 0, F \in \mathcal{F}\}$$

Finally, Lemma 4.1 of [30] implies that there exists $\mu \in \mathbb{N}^{m_0}$ such that $F N \leq \mu$ for all $F \in \mathcal{F}$.

Proposition 4.1 Let $N \in \mathcal{N}_s$ and

$$(M^{-1} - N C_0 B_0) + (M^{-1} - N C_0 B_0)^T > 0 \quad (4.3)$$

Furthermore, let \mathcal{U} be defined by (4.1) and define $\Omega_0(\cdot)$ and $P_0(\cdot)$ by

$$\Omega_0(P) = (C_0 + N C_0 A + B_0^T P)^T [(M^{-1} - N C_0 B_0) + (M^{-1} - N C_0 B_0)^T]^{-1} (C_0 + N C_0 A + B_0^T P) \quad (4.4)$$

and

$$P_0(F) = C_0^T F N C_0 \quad (4.5)$$

Then (3.1) is satisfied

Proof Since by (4.3) $(M^{-1} - N C_0 B_0) + (M^{-1} - N C_0 B_0)^T$ is positive definite and by Lemma 4.1 $F - F M^{-1} F$ is nonnegative definite, it follows that

$$\begin{aligned} 0 &\leq [(C_0 + N C_0 A + B_0^T P) - [(M^{-1} - N C_0 B_0) \\ &\quad + (M^{-1} - N C_0 B_0)^T] F C_0]^T [(M^{-1} - N C_0 B_0) \\ &\quad + (M^{-1} - N C_0 B_0)^T]^{-1} [(C_0 + N C_0 A + B_0^T P) \\ &\quad - [(M^{-1} - N C_0 B_0) + (M^{-1} - N C_0 B_0)^T] F C_0] \\ &\quad + 2 C_0^T [F - F M^{-1} F] C_0 \\ &= \Omega_0(P) - C_0^T F (C_0 + N C_0 A + B_0^T P) \\ &\quad - (C_0^T + A^T C_0^T N^T + P B_0) F C_0 + C_0^T F [(M^{-1} - N C_0 B_0) \\ &\quad + (M^{-1} - N C_0 B_0)^T] F C_0 + 2 C_0^T [F - F M^{-1} F] C_0 \\ &= \Omega_0(P) - C_0^T F B_0^T P - P B_0 F C_0 \\ &\quad - C_0^T F N C_0 A - A^T C_0^T N^T F C_0 \\ &\quad - C_0^T F N C_0 B_0 F C_0 - C_0^T F B_0^T C_0^T N^T F C_0 \\ &= \Omega_0(P) - [(A + \Delta A)^T P_0(F) + P_0(F)(A + \Delta A)] \\ &\quad - [\Delta A^T P + P \Delta A] \end{aligned}$$

which proves (3.1) with \mathcal{U} given by (4.1) \square

Next, using Theorem 3.1 and Proposition 4.1 we have the following immediate result

Theorem 4.1 Let $N \in \mathcal{N}_{nd}$ and assume (4.3) is satisfied. Furthermore, suppose there exists a nonnegative-definite matrix P satisfying

$$0 = A^T P + P A + (C_0 + N C_0 A + B_0^T P)^T [(M^{-1} - N C_0 B_0) + (M^{-1} - N C_0 B_0)^T]^{-1} (C_0 + N C_0 A + B_0^T P) + R \quad (4.6)$$

Then

$$(A + \Delta A, E) \text{ is detectable, } \Delta A \in \mathcal{U} \quad (4.7)$$

if and only if

$$A + \Delta A \text{ is asymptotically stable, } \Delta A \in \mathcal{U} \quad (4.8)$$

In this case, if $\mu \in \mathbb{N}^{m_0}$ satisfies $F N \leq \mu$ for all $F \in \mathcal{F}$, then

$$J(\mathcal{U}) \leq \text{tr}[(P + C_0^T \mu C_0) V] \quad (4.9)$$

Proof The result is a direct specialization of Theorem 3.1 using Proposition 4.1 with $P_0(\Delta A) = C_0^T F N C_0$. Since by assumption, $F N \geq 0$ for all $F \in \mathcal{F}$, it follows that $P + P_0(F)$ is nonnegative definite for all $F \in \mathcal{F}$ as required by Theorem 3.1 \square

Note that asymptotic stability in Theorem 4.1 is guaranteed by the parameter-dependent Lyapunov function $V_{\Delta A}(x) = x^T (P + C_0^T F N C_0)x$.

Remark 4.1 The condition $F N = N^T F, F \in \mathcal{F}$ is analogous to the commuting assumption between the D -scales and Δ blocks in μ -analysis which accounts for structure in the uncertainty F . Note that there always exists such a matrix N even if $F \in \mathcal{F}$ is not diagonal. For example, if $F = F_1 I_{m_0}$, where F_1 is a scalar uncertainty, then N can be an arbitrary symmetric matrix. Alternatively, if F is nondiagonal, then one can choose $N = N_0 I_{m_0}$, where N_0 is a scalar. Finally, F and N may be block diagonal with commuting blocks situated on the diagonal. Characterization of the optimal multiplier N for robust controller analysis and synthesis is given in Section VI.

Remark 4.2 Standard loop-shifting techniques [31] can be used to consider uncertainties with upper and lower bounds of the form $M_1 \leq F \leq M_2$, where $F \in \mathcal{F}$ and $M_1, M_2 \in \mathbb{S}^{m_0}$. In this case, Proposition 4.1 holds with F, A , and M replaced by $F - M_1, A + B_0 M_1 C_0$, and $M_2 - M_1$, respectively. Similar modifications can be made to Theorem 4.1.

Next, we use results from positivity theory to guarantee the existence of a positive-definite solution to (4.6). Let $G(s) \sim \begin{bmatrix} A & B \\ C & D \end{bmatrix}$ denote a state space realization of a transfer function $G(s)$, that is, $G(s) = C(sI - A)^{-1}B + D$. The notation " \sim " denotes a minimal realization:

Lemma 4.2. (Positive Real Lemma [4], [9]):

$$G(s) \sim \begin{bmatrix} A & B \\ C & D \end{bmatrix}$$

is positive real if and only if there exist matrices P, L , and W with P positive definite such that

$$0 = A^T P + PA + L^T L, \quad (4.10)$$

$$0 = PB - C^T + L^T W, \quad (4.11)$$

$$0 = D + D^T - W^T W. \quad (4.12)$$

Next, we show that if $D + D^T > 0$ then (4.10)-(4.12) yield a single Riccati equation characterizing positive realness. For the statement of this result recall that a square transfer function $G(s)$ is strongly positive real if it is strictly positive real [15] and $D + D^T > 0$.

Lemma 4.3 [14]. Let $G(s) \sim \begin{bmatrix} A & B \\ C & D \end{bmatrix}$. Then $G(s)$ is strongly positive real if and only if $D + D^T > 0$ and there exist positive-definite matrices P and R such that

$$0 = A^T P + PA + (C - B^T P)^T (D + D^T)^{-1} (C - B^T P) + R. \quad (4.13)$$

We now use Lemma 4.3 to obtain a sufficient condition for the existence of a solution to (4.6).

Theorem 4.2. Let

$$\mathcal{G}(s) \sim \begin{bmatrix} A & -B_0 \\ C_0 + NC_0 A & M^{-1} - NC_0 B_0 \end{bmatrix}.$$

Then $\mathcal{G}(s)$ is strongly positive real if and only if there exist positive definite matrices P and R satisfying (4.6).

Finally, we specialize Proposition 4.1 and Theorem 4.1 to the case in which $N = 0$ and $M = D_0^{-1}$, where $D_0 + D_0^T > 0$. In this case we have the following result.

Proposition 4.2: Let $D_0 \in \mathbb{R}^{m_0 \times m_0}$ be such that $D_0 + D_0^T > 0$. Furthermore, let \mathcal{U} be defined by (4.1) with $M = D_0^{-1}$, let $P_0(F) = 0$, and define $\Omega_0(\cdot)$ by

$$\Omega_0(P) = (C_0 + B_0^T P)^T (D_0 + D_0^T)^{-1} (C_0 + B_0^T P). \quad (4.14)$$

Then (3.1) is satisfied.

Since $P_0(F) = 0$, the case $N = 0$ corresponds to a parameter-independent Ω -bound. Hence, it follows from Theorem 3.1 that if there exists a nonnegative-definite matrix P satisfying

$$0 = A^T P + PA + (C_0 + B_0^T P)^T (D_0 + D_0^T)^{-1} (C_0 + B_0^T P) + R \quad (4.15)$$

then $(A + \Delta A, E)$ is detectable for all $\Delta A \in \mathcal{U}$ if and only if $A + \Delta A$ is asymptotically stable for all $\Delta A \in \mathcal{U}$. Furthermore, it follows from Lemma 4.3 that the existence of a positive-definite matrix P satisfying (4.15) implies that

$$G(s) \sim \begin{bmatrix} A & -B_0 \\ C_0 & D_0 \end{bmatrix}$$

is strongly positive real. Hence the parameter-independent Ω -bound (4.14) guarantees robust stability in the presence of positive real (but otherwise unknown) plant uncertainty. The situation is analogous to H_∞ bounded real theory, which also depends upon a parameter independent Ω -bound.

V. CONNECTIONS TO THE POPOV CRITERION

In this section we demonstrate connections between the parameter-dependent Lyapunov function obtained in Section 4 and the classical multivariable Popov criterion. Traditionally, the Popov criterion is stated for component-decoupled time-invariant sector-bounded nonlinearities $\phi(y)$. We state the Popov criterion for this case and then specialize to the case of linear uncertainty. Hence let $M \in \mathbb{R}^{m_0 \times m_0}$ be a given positive-definite matrix and define

$$\Phi \triangleq \{ \phi : \mathbb{R}^{m_0} \rightarrow \mathbb{R}^{m_0} : \phi^T(y)[M^{-1}\phi(y) - y] \leq 0, y \in \mathbb{R}^{m_0}, \text{ and } \phi(y) = [\phi_1(y_1), \phi_2(y_2), \dots, \phi_{m_0}(y_{m_0})]^T \}. \quad (5.1)$$

If $M = \text{diag}(M_1, \dots, M_{m_0})$ is diagonal, then the sector condition characterizing Φ is implied by the scalar sector conditions $0 \leq \phi_i(y_i)y_i \leq M_i y_i^2, y_i \in \mathbb{R}, i = 1, \dots, m_0$.

Theorem 5.1. (The Popov Criterion) [15]: Suppose there exists a nonnegative-definite matrix $N = \text{diag}(N_1, \dots, N_{m_0})$ such that $M^{-1} + (I + N\kappa)G(s)$ is strongly positive real, where $G(s) \sim \begin{bmatrix} A & B \\ C & 0 \end{bmatrix}$. Then, for all $\phi(\cdot) \in \Phi$, the negative feedback interconnection of $G(s)$ and $\phi(\cdot)$ is asymptotically stable with Lyapunov function

$$V_\phi(x) = x^T P x + 2 \sum_{i=1}^{m_0} \int_0^{y_i} \phi_i(\sigma) N_i d\sigma. \quad (5.2)$$

Next, we specialize Theorem 5.1 to the case of constant linear parameter uncertainty. Specifically, consider the system $\dot{x}(t) = (A + \Delta A)x(t)$, where $\Delta A \in \mathcal{U}$ and \mathcal{U} is defined by

$$\mathcal{U} \triangleq \{ \Delta A : \Delta A = -BFC, \quad F = \text{diag}(F_1, F_2, \dots, F_{m_0}), \quad 0 \leq F_i \leq M_i, \quad i = 1, \dots, m_0 \}.$$

By setting $\phi(y) = Fy = FCx$ Theorem 5.1 guarantees that $A + \Delta A$ is asymptotically stable for all $\Delta A \in \mathcal{U}$.

It has thus been shown that in the special case that F and N are diagonal nonnegative-definite matrices, Theorem 4.1 (with B_0 replaced by $-B_0$) specializes to the Popov criterion when applied to linear parameter uncertainty. This is not surprising since the Lyapunov function (5.2) that establishes robust stability has the form

$$V_F(x) = x^T P x + 2 \sum_{i=1}^{m_0} \int_0^{y_i} F_i \sigma N_i d\sigma, \quad y_i = (C_0 x)_i, \quad (5.3)$$

or, equivalently

$$V_F(x) = x^T P x + x^T C_0^T F N C_0 x = x^T P x + \sum_{i=1}^{m_0} F_i N_i x^T C_0^T C_0 x \quad (5.4)$$

which is a specialization of the parameter-dependent Lyapunov function considered in Section IV to the case of diagonal uncertainty F . The results of Section IV, however, allowed nondiagonal uncertain matrices F , which cannot be addressed by means of the nonlinear theory. Finally, note that the uncertain parameters F are not allowed to be arbitrarily time-varying, which is consistent with the fact that the Popov criterion is restricted to time-invariant nonlinearities.

VI. ROBUST CONTROLLER SYNTHESIS VIA PARAMETER-DEPENDENT LYAPUNOV FUNCTIONS: FIXED-ORDER DYNAMIC COMPENSATION

In this section we consider robust stability and performance with dynamic output-feedback controllers. For generality, the compensator dimension n_c may be less than the plant order n . Define $\hat{n} \triangleq n + n_c$, where $n_c \leq n$.

Dynamic Robust Stability and Performance Problem Given the n th-order stabilizable and detectable plant with constant structured real-valued plant parameter variations

$$\dot{x}(t) = (A + \Delta A)x(t) + Bu(t) + D_1w(t), t \geq 0, \quad (6.1)$$

$$y(t) = Cx(t) + D_2u(t) \quad (6.2)$$

where $u(t) \in \mathbb{R}^m$, $x(t) \in \mathbb{R}^d$, and $y(t) \in \mathbb{R}^l$, determine an n th-order dynamic compensator

$$\dot{v}(t) = A_c v(t) + B_c y(t), \quad (6.3)$$

$$u(t) = C_c v(t) \quad (6.4)$$

that satisfies the following design criteria

- i) The closed-loop system (6.1)-(6.4) is asymptotically stable for all $\Delta A \in \mathcal{U}$ and
- ii) The performance functional

$$J(A, B, C) \triangleq \sup_{\Delta A \in \mathcal{U}} \limsup_{t \rightarrow \infty} \frac{1}{t} E \left\{ \int_0^t [v^T(s) R_1 v(s) + u^T(s) R_2 u(s)] ds \right\} \quad (6.5)$$

is minimized

For each uncertain variation $\Delta A \in \mathcal{U}$, the closed-loop system (6.1)-(6.4) can be written as

$$\dot{x}(t) = (A + \Delta A)x(t) + Du(t) \quad t \geq 0 \quad (6.6)$$

where

$$x(t) = \begin{bmatrix} x(t) \\ v(t) \end{bmatrix}, A \triangleq \begin{bmatrix} A & BC \\ B_c C & A_c \end{bmatrix}, \Delta A = \begin{bmatrix} \Delta A & 0_{n \times n} \\ 0_{n \times n} & 0_{n \times n} \end{bmatrix}$$

and where the closed loop disturbance $Du(t)$ has intensity $V = DD^T$ where $D = \begin{bmatrix} D_1 \\ B, D_2 \end{bmatrix}$, $V \triangleq \begin{bmatrix} V_1 & 0 \\ 0 & B, V_2 B_c^T \end{bmatrix}$, $V_1 = D_1 D_1^T$, $V_{1,2} = D_1 D_2^T = 0$, $V_2 = D_2 D_2^T$. The closed-loop system uncertainty ΔA has the form $\Delta A = B_0 \Gamma C_0$ where $B_0 = \begin{bmatrix} B_0 \\ 0_{n_c \times m_0} \end{bmatrix}$, $C_0 \triangleq [C_0 \ 0_{m_0 \times l}]$. Finally, if $A + \Delta A$ is asymptotically stable for all $\Delta A \in \mathcal{U}$ for a given compensator (A_c, B_c, C_c) , then it follows from Lemma 2.1 that the performance functional (6.5) is given by

$$J(A, B, C) = \sup_{\Delta A \in \mathcal{U}} \text{tr} P_{\Delta A} V \quad (6.7)$$

where $P_{\Delta A}$ satisfies the $n \times n$ Lyapunov equation

$$0 = (A + \Delta A)^T P_{\Delta A} + P_{\Delta A} (A + \Delta A) + R \quad (6.8)$$

where

$$R = [E_1 \ E_2 C_c^T], \quad R = E^T F = \begin{bmatrix} R_1 & 0 \\ 0 & C_c^T R_2 C_c \end{bmatrix}$$

Next, we apply Theorem 4.1 to controller synthesis. Specifically, we replace the Lyapunov equation (6.8) for the dynamic problem with a Riccati equation that guarantees that the closed-loop system is robustly stable. Thus, for the dynamic output feedback problem, Theorem 4.1 holds with A, R, V replaced by $\hat{A}, \hat{R}, \hat{V}$. This leads to the following problem

Dynamic Auxiliary Minimization Problem Determine $N \in \mathcal{N}_{nd}$ and controllable and observable (A_c, B_c, C_c) that minimize

$$\mathcal{J}(A_c, B_c, C_c, N) \triangleq \text{tr}(P + C_0^T \mu C_0) V \quad (6.9)$$

where $P \in \mathbb{N}^n$ satisfies

$$0 = \hat{A}^T P + P \hat{A} + (C_0 + \lambda C_0 A + B_0^T P)^T [(M^{-1} - N \tilde{C}_0 B_0) + (M^{-1} - \lambda C_0 B_0)^T]^{-1} (C_0 + \lambda C_0 A + B_0^T P) + R \quad (6.10)$$

Necessary conditions for the dynamic auxiliary minimization problem will provide fixed-order dynamic output feedback controllers with guaranteed robust stability and performance. The following result is required for the statement of the main theorem

Lemma 6.1 [32] Let Q, P be $n \times n$ nonnegative-definite matrices and suppose that $\text{rank } QP = n$. Then there exist $n \times n$ matrices G, Γ and an $n_c \times n_c$ invertible matrix M , unique except for a change of basis in \mathbb{R}^{n_c} , such that

$$QP = G^T \Gamma M \quad \Gamma G^T = I_{n_c} \quad (6.11)$$

Furthermore, the $n \times n$ matrices $\tau \triangleq G^T \Gamma$ and $\tau_{\perp} \triangleq I_n - \tau$ are idempotent and have rank n_c and $n - n_c$, respectively

To state the main result of this section let $P, Q \in \mathbb{R}^{n \times n}$ and define the notation

$$R_0 \triangleq (M^{-1} - \lambda C_0 B_0) + (M^{-1} - \lambda C_0 B_0)^T$$

$$C \triangleq C_0 + \lambda C_0 A, \quad A_c \triangleq A + B_0 R_0^{-1} C,$$

$$B_{c,c} \triangleq B_2 + B^T C_0^T \lambda^T R_0^{-1} \lambda C_0 B,$$

$$P_c \triangleq B^T P + B^T C_0^T \lambda^T R_0^{-1} (C + B_0^T P)$$

$$\Sigma \triangleq C^T \lambda_2^{-1} C, \quad \lambda_P \triangleq A_P - Q \Sigma + B_0 R_0^{-1} B_0^T P$$

$$A_Q \triangleq A_c + B_0 R_0^{-1} B_0^T P - (I + B_0 R_0^{-1} \lambda C_0) B R_{2a}^{-1} P_a$$

Theorem 6.1 Let $n_c \leq n$ assume $R_0 > 0$, and assume $V \in \mathcal{N}_{nd}$. Furthermore, suppose there exist $n \times n$ nonnegative-definite matrices P, Q, P_c, Q_c satisfying

$$0 = A_P^T P + P A_P + R_1 + C^T R_0^{-1} C + P B_0 R_0^{-1} B_0^T P - P^T R_{2,c}^{-1} P_c + \tau_{\perp}^T P_c^T R_{2,c}^{-1} P_c \tau_{\perp} \quad (6.12)$$

$$0 = (A_c + B_0 R_0^{-1} B_0^T [P + P_c]) Q + Q (A_P + B_0 R_0^{-1} B_0^T [P + P_c])^T + V_1 - Q \Sigma Q + \tau_{\perp} Q \Sigma Q \tau_{\perp}^T \quad (6.13)$$

$$0 = A_c^T P + P A_c + P B_0 R_0^{-1} B_0^T P + P_c^T R_{2,c}^{-1} P_c - \tau_{\perp}^T P_c^T R_{2,c}^{-1} P_c \tau_{\perp} \quad (6.14)$$

$$0 = A_Q Q + Q A_Q^T + Q \Sigma Q - \tau_{\perp} Q \Sigma Q \tau_{\perp}^T \quad (6.15)$$

$$\text{rank } Q = \text{rank } P = \text{rank } QP = n_c \quad (6.16)$$

and let A_c, B_c, C_c be given by

$$A_c = \Gamma [A_Q - Q \Sigma] G^T, \quad B_c = \Gamma Q C^T \lambda_2^{-1}, \quad C_c = -R_{2,c}^{-1} P_c G^T \quad (6.17)$$

Then $(A + \Delta A, E)$ is detectable for all $\Delta A \in \mathcal{U}$ if and only if $A + \Delta A$ is asymptotically stable for all $\Delta A \in \mathcal{U}$. In this case the performance of the closed-loop system (6.7) satisfies the bound

$$J(A_c, B_c, C_c) \leq \text{tr}[(P + \hat{P}) V_1 + P Q \Sigma Q + C_0^T \mu C_0 V_1] \quad (6.18)$$

Proof: The proof is constructive in nature and is similar to the proofs given in [14] and [33]. Specifically, first we obtain necessary conditions for the Dynamic Auxiliary Minimization Problem and then show by construction that these conditions serve as sufficient conditions for robust stabilization and provide a worst-case H_2 performance bound. \square

Theorem 6.1 provides constructive sufficient conditions that yield dynamic feedback gains A_c, B_c, C_c for robust stability and performance. When solving (6.12)–(6.15) numerically, the matrices M and N and the structure matrices B_0 and C_0 appearing in the design equations can be adjusted to examine tradeoffs between performance and robustness. Finally, to further reduce conservatism, one can view the multiplier matrix N as a free parameter and optimize the worst-case H_2 performance bound \mathcal{J} with respect to N . In particular, setting $\partial \mathcal{J} / \partial N = 0$ yields

$$0 = \frac{1}{2} M \tilde{C}_0 \tilde{C}_0^T + [(M^{-1} - N \tilde{C}_0 \tilde{B}_0) + (M^{-1} - N \tilde{C}_0 \tilde{B}_0)^T]^{-1} \times (\tilde{C}_0 + N \tilde{C}_0 \tilde{A} + \tilde{B}_0^T \tilde{P}) \tilde{Q} \tilde{A}^T \tilde{C}_0^T + [(M^{-1} - N \tilde{C}_0 \tilde{B}_0) + (M^{-1} - N \tilde{C}_0 \tilde{B}_0)^T]^{-1} (\tilde{C}_0 + N \tilde{C}_0 \tilde{A} + \tilde{B}_0^T \tilde{P}) \tilde{Q} (\tilde{C}_0 + N \tilde{C}_0 \tilde{A} + \tilde{B}_0^T \tilde{P})^T [(M^{-1} - N \tilde{C}_0 \tilde{B}_0) + (M^{-1} - N \tilde{C}_0 \tilde{B}_0)^T]^{-1} \tilde{B}_0^T \tilde{C}_0^T \quad (6.19)$$

where \tilde{Q} satisfies

$$0 = (\tilde{A} + \tilde{B}_0 R_0^{-1} N \tilde{C}_0 \tilde{A} + \tilde{B}_0 R_0^{-1} \tilde{C}_0 + \tilde{B}_0 R_0^{-1} \tilde{B}_0^T \tilde{P}) \tilde{Q} + \tilde{Q} (\tilde{A} + \tilde{B}_0 R_0^{-1} N \tilde{C}_0 \tilde{A} + \tilde{B}_0 R_0^{-1} \tilde{C}_0 + \tilde{B}_0 R_0^{-1} \tilde{B}_0^T \tilde{P})^T + \tilde{V}. \quad (6.20)$$

By using (6.19) within a numerical search algorithm, the optimal compensator and multiplier N can be determined simultaneously, thus avoiding the need to iterate between controller design and optimal multiplier evaluation.

Remark 6.1: Several special cases can immediately be discerned from Theorem 6.1. For example, in the full-order case, set $n_c = n$ so that $\tau = G = \Gamma = I_n$ and $\tau_1 = 0$. In this case the last term in each of (6.12)–(6.15) is zero and (6.15) is superfluous. Alternatively, letting $B_0 = 0, C_0 = 0$ and retaining the reduced-order constraint $n_c \leq n$ yields the result of [32].

VII. NUMERICAL ALGORITHM AND ILLUSTRATIVE RESULTS

In this section we describe a numerical algorithm for solving the Riccati equation (6.10) along with the expression (6.19) for the optimal multiplier N . We also present numerical results for controller synthesis via an illustrative example.

To synthesize dynamic compensators, we let $\mu = (M_2 - M_1)N$ in (6.9) and determine (A_c, B_c, C_c, N) to minimize $\mathcal{J}(A_c, B_c, C_c, N)$ subject to (6.10) with $\tilde{P} \in \mathbb{N}^n$. To do this we form the Lagrangian

$$\mathcal{L}(A_c, B_c, C_c, N, \tilde{P}, \tilde{Q}) = \text{tr}[(P + \tilde{C}_0^T (M_2 - M_1) N \tilde{C}_0) \tilde{V} + \{(\tilde{A} + \tilde{B}_0 M_1 \tilde{C}_0)^T \tilde{P} + \tilde{P} (\tilde{A} + \tilde{B}_0 M_1 \tilde{C}_0) + [\tilde{C}_0 + N \tilde{C}_0 (\tilde{A} + \tilde{B}_0 M_1 \tilde{C}_0) + \tilde{B}_0^T \tilde{P}]^T \cdot \tilde{R}_0^{-1} [\tilde{C}_0 + N \tilde{C}_0 (\tilde{A} + \tilde{B}_0 M_1 \tilde{C}_0) + \tilde{B}_0^T \tilde{P}] + \tilde{R} \} \tilde{Q}] \quad (7.1)$$

where

$$\tilde{R}_0 \triangleq [(M_2 - M_1)^{-1} - N \tilde{C}_0 \tilde{B}_0] + [(M_2 - M_1)^{-1} - N \tilde{C}_0 \tilde{B}_0]^T \quad (7.2)$$

and $\tilde{Q} \in \mathbb{R}^{n \times n}$ is a Lagrange multiplier. The partial derivatives of \mathcal{L} are then used in the search procedure. Note that the shifted version of (6.10) discussed in Remark 4.2 is used in (7.1) to address uncertainties with upper and lower bounds of the form $M_1 \leq F \leq M_2$.

Fig. 1. Three-mass system.

Fig. 2. Performance vs. robustness trade-off for LQG and Popov controllers

A quasi-Newton search algorithm was initialized with $N = 0$ and the LQG gains. For given values of the robustness bounds M_1 and M_2 , the search algorithm was used to find A_c, B_c, C_c and N satisfying the necessary conditions. After each iteration, M_1 and M_2 were increased and the current design was used as the initial step for the next iteration. Since the optimal compensator and multiplier are found simultaneously, there is no need to iterate between controller design and optimal multiplier evaluation.

Consider the three-mass, two-spring system shown in Fig. 1 with $m_1 = m_2 = m_3 = 1$ and an uncertain spring stiffness k_2 . A control force acts on mass 3 while the position of mass 1 is measured resulting in a noncollocated control problem. The nominal dynamics, with state variables defined in Fig. 1, are given by

$$A = \begin{bmatrix} 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ -k_1 & k_1 & 0 & 0 & 0 & 0 \\ k_1 & -(k_1 + k_{2nom}) & k_{2nom} & 0 & 0 & 0 \\ 0 & k_{2nom} & -k_{2nom} & 0 & 0 & 0 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 1 \end{bmatrix}, \quad C = [1 \ 0 \ 0 \ 0 \ 0 \ 0], \quad D_1 = \begin{bmatrix} 0 & 0 \\ 0 & 0 \\ 0 & 0 \\ 1 & 0 \\ 0 & 0 \\ 0 & 0 \end{bmatrix}$$

$D_2 = [0 \ 1]$, and $k_1 = k_{2nom} = 1$. The actual spring stiffness of the second spring can be written as $k_2 = k_{2nom} + \Delta k$ so that the actual dynamics are given by $A(\Delta k) = A + B_0 \Delta k C_0$, where $B_0 = [0 \ 0 \ 0 \ 0 \ 1 \ 1]^T$ and $C_0 = [0 \ 1 \ 0 \ 0 \ 0 \ 0]$. Furthermore, let

$$E_1 = \begin{bmatrix} 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}, \quad E_2 = \begin{bmatrix} 0 \\ 1 \end{bmatrix}.$$

Fig. 3. Popov (dashed) and LQG (solid) controllers.

Two full-order ($n_c = n$) Popov compensators were designed. Fig. 2 compares performance versus robustness trade-offs of the Popov compensators (dashed) with the normalized LQG design (solid). Fig. 3 shows the magnitude and phase of both a Popov design and the LQG design. Note that the Popov design robustified the LQG controller notch by increasing both the width and the depth of the notch.

Design of L-Q Regulators for State Constrained Continuous-Time Systems

Carlos E. T. Dórea and Basilio E. A. Milani

Abstract—A new methodology to the design of L-Q regulators for continuous-time systems subject to linear state constraints is proposed, consisting of two parts. In the first one, the positive invariance of the polyhedron defined by the constraints in the state space is imposed, guaranteeing thereby that the constraints will not be violated. Furthermore, the admissible constrained controllers are parameterized via the determination of the elements which are fixed in the state feedback matrix. This parameterization enables in a second part the L-Q regulator to be obtained from the solution of a parameter optimization problem subject to linear constraints, for which it is proposed a specialized feasible directions method.

I. INTRODUCTION

In most of engineering applications, linear systems subject to state and input constraints are frequently found, since such constraints are generally associated to physical limitations in the course of the variables or to the validation domain of the linearization of nonlinear models. The controllers to be designed for such systems should therefore be capable to attain their performance specifications without violating the constraints.

Due to its known attractive properties, a classical control systems design specification which is widely used is the optimal linear-quadratic (L-Q) regulation, which aims to achieve a compromise between the speed of convergence to the zero state and the magnitude of the input amplitudes necessary to that, by minimizing a quadratic performance index [1]. The problem of L-Q regulation of systems under constraints has been treated to present in the framework of optimal control theory by means of variational calculus techniques, of difficult application because complex, generally resulting, moreover, in an open-loop "bang-bang" control law (see e.g., [2]). Other techniques are based on the choice of weighting matrices for which the solution of the unconstrained optimal L-Q regulator problem results in a control law that respects the constraints [3], [4]. Such techniques imply clearly in a limitation to the designer, since the weighting matrices cannot be freely chosen in order to satisfy performance requirements.

The forthcoming of new techniques to the design of controllers for linear constrained systems has been propelled lately by the development of the theory of positively invariant polyhedra, that are domains from which the state vector trajectories cannot escape (see e.g., [5], [6] and references therein). The basic idea behind the techniques derived from this theory is to determine a control law that imposes the positive invariance of the polyhedron defined in the state space by the linear constraints on the state vector. In order to solve this problem, Castelan and Hennet [7], by interpreting geometrically the positive invariance conditions, have proposed elaborate eigenstructure assignment techniques.

The aim of this paper is to develop a new methodology to the design of L-Q regulators for continuous-time systems under linear state constraints, applying to this end results from the invariant polyhedra theory and parameter optimization techniques. This objective

is achieved in two stages. In the first one, by an appropriate change in the state-space representation of the system and the utilization of results from the geometric theory of control systems [8], the conditions for positive invariance are transformed into a set of linear constraints on the elements of state feedback matrices, which are thereby parameterized. As a consequence of this parameterization, the problem of positive invariance of an unbounded polyhedron with simultaneous closed-loop stability is split into two distinct ones for lower order systems: a stabilization problem and a problem of positive invariance of a bounded polyhedron. In the second stage, the original problem of state constrained L-Q regulation is reformulated as a parameter optimization problem subject to the constraints defined in the first stage. To solve this problem, it is proposed a specialized feasible directions method which is initialized with a point obtained from the solution of an auxiliary linear programming problem.

This paper is organized as follows. Section II contains preliminaries. In Section III the positive invariance of the polyhedron defined by the constraints is achieved together with the parameterization of the controllers. Section IV presents the design of the constrained L-Q regulators. An example in Section V illustrates the application of the proposed design and some conclusions are found in Section VI.

II. PRELIMINARIES

Consider the linear, time-invariant, continuous-time system

$$\dot{x}(t) = Ax(t) + Bu(t) \quad (1)$$

where $x(t) \in \mathbb{R}^n$ is the state vector, $u(t) \in \mathbb{R}^m$ is the input vector and the system is supposed to be stabilizable. Under a state feedback control law, $u(t) = Fx(t)$, it can be written as

$$\dot{x}(t) = (A + BF)x(t). \quad (2)$$

Definition 1 [5]: A nonempty set Ω is a positively invariant set of system (2) if and only if for any initial state $x(0) \in \Omega$ the state vector trajectory remains in Ω .

Assume now that system (2) is subject to symmetrical linear constraints, $[-\rho \leq Gx(t) \leq \rho]$, where $G \in \mathbb{R}^{r \times n}$, $r \leq n$ is a full rank matrix and the elements ρ_i of vector $\rho \in \mathbb{R}^r$ are such that $\rho_i > 0$. These constraints define in the state space the convex symmetrical polyhedron

$$S[G, \rho] = \{x \in \mathbb{R}^n / -\rho \leq Gx \leq \rho\} \quad (3)$$

where the inequalities are componentwise. For $r < n$, $S[G, \rho]$ is clearly unbounded.

Proposition 1: The symmetrical polyhedron (see also [6]) $S[G, \rho]$ is a positively invariant set of system (2) if and only if there exist matrices H and $K \in \mathbb{R}^{r \times n}$, with $H_{ij} \geq 0$ for $i \neq j$ and $K_{ij} \geq 0$ for any i, j such that

$$(H - K)G = G(A + BF) \quad (4)$$

$$(H + K)\rho \leq 0. \quad (5)$$

Proof: Let $R[T, \omega]$ be a general, not necessarily symmetrical convex polyhedron defined by

$$R[T, \omega] = \{x \in \mathbb{R}^n / Tx \leq \omega\} \quad (6)$$

IEEE Log Number 9407227.

where $T \in \mathbb{R}^{n \times n}$ and $\omega \in \mathbb{R}^n$, $\omega_i > 0$. In [5] and [6] it is shown that $R[T, \omega]$ is positively invariant for system (2) if and only if there exists a matrix $J \in \mathbb{R}^{n \times n}$, with $J_{ij} \geq 0$ for $i \neq j$ such that

$$JT = T(I + BF) \quad (7)$$

$$J\omega \leq 0 \quad (8)$$

The polyhedron $S[G, \rho]$ can be written as a generic one (6). One only needs to consider

$$T = \begin{bmatrix} G \\ -G \end{bmatrix} \quad \omega = \begin{bmatrix} \rho \\ \rho \end{bmatrix} \quad (9)$$

$$J = \begin{bmatrix} H & K \\ I & M \end{bmatrix} \quad (10)$$

with $H_{ij}, M_{ij} \geq 0$ for $i \neq j$ and $K_{ij}, I_{ij} \geq 0$ for any i, j . Substituting (9)–(10) in (7)–(8) one arrives to (4)–(5) and two other redundant equations. \square

III POSITIVE INVARIANCE OF $S[G, \rho]$

This section is concerned with the obtention of a proportional state feedback law $u = Fx$ for which the symmetrical polyhedron $S[G, \rho]$ is positively invariant and the closed loop system (2) is asymptotically stable. Consider then the following change of basis in the system (1)

$$x = Qz \quad (11)$$

where $Q \in \mathbb{R}^{n \times n}$ is an orthogonal matrix such that

$$G_+ - G_-Q = \begin{bmatrix} 0 & G_- \end{bmatrix} \quad G_- \in \mathbb{R}^{n \times n} \quad (12)$$

The new representations of system (1) and polyhedron $S[G, \rho]$ are

$$\dot{z} = A_1 z + B_1 u \quad (13)$$

$$A = Q^{-1}AQ = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix} \quad A \in \mathbb{R}^{n \times n} \quad (14)$$

$$B = Q^{-1}B = \begin{bmatrix} B_1 \\ B_2 \end{bmatrix} \quad B \in \mathbb{R}^{n \times m} \quad (15)$$

$$S[G, \rho] = \{z \in \mathbb{R}^n / -\rho \leq G_+ z \leq \rho\} \quad (16)$$

Proposition 2 The polyhedron $S[G, \rho]$ is positively invariant for system (2) if and only if

- 1) There exists a matrix $F_1 \in \mathbb{R}^{m \times n}$ such that

$$A_{11} + B_1 F_1 = 0 \quad (17)$$

- 2) There exist matrices $F_2 \in \mathbb{R}^{m \times n}$, $H \in \mathbb{R}^{n \times n}$, with $H_{ij} \geq 0$ for $i \neq j$ and $K_{ij} \geq 0$ for any i, j such that

$$(H - K)G_2 = G_2(A_{22} + B_2 F_2) \quad (18)$$

$$(H + K)\rho \leq 0 \quad (19)$$

Proof Consider the state feedback matrix in the transformed system (13)

$$F = FQ = [F_1 \ F_2] \quad F_2 \in \mathbb{R}^{m \times n} \quad (20)$$

Its substitution together with G_+ (12), A (14) and B (15) in (4) yields

$$[0 \ (H - K)G_-] = [G_2(A_{21} + B_2 F_1) \ G_2(A_{22} + B_2 F_2)] \quad (21)$$

To satisfy this equation it is necessary that $G_2(A_{21} + B_2 F_1) = 0$. Since G_+ (12) has linearly independent columns, this condition holds if and only if (17) holds. Condition 2 may be directly verified from (5) and (21). \square

Considering (17) satisfied, it can be noted from (18)–(19) that the original problem of positive invariance of $S[G, \rho]$ for the system represented by the pair (A, B) has been reduced to the positive invariance of the bounded polyhedron $S[G_+, \rho]$ for a lower order system represented by the pair (A_{22}, B_2) . This reduction becomes significative mainly for large dimensions systems subject to few constraints, since redundant equalities are eliminated.

It is easy to verify that condition (17) is equivalent to the (A, B) -invariance of $\ker(G_-)$, the null space of the matrix G_- , result firstly obtained by Castelan and Hennet [7]. This interpretation enabled them to apply results from the so called geometric approach to control systems [8] in the analysis of stabilizability and controllability of state constrained systems, and to reformulate the design problem as an eigenstructure assignment problem.

In this paper, geometric theory results will be applied in a quite different manner. Suppose that (17) holds. In closed loop one has

$$A_1 = A + BF = \begin{bmatrix} A_{11} + B_1 F_1 & A_{12} + B_1 F_2 \\ 0 & A_{22} + B_2 F_2 \end{bmatrix} \quad (22)$$

The eigenvalues of A_1 are therefore those of submatrices $A_{11} = A_{11} + B_1 F_1$ and $A_2 = A_{22} + B_2 F_2$. The positive invariance of $S[G, \rho]$ implies certain spectral properties for A_{11} [5]–[6]. In particular, if the inequalities (19) are strictly satisfied, A_1 is asymptotically stable. The problem of positive invariance of $S[G, \rho]$ with closed loop stability can therefore be summarized as follows:

- Find F_1 such that (17) holds and the eigenvalues of $A_{11} + B_1 F_1$ have negative real parts.
- Find F_2 such that (18) holds and (19) holds with strict inequalities.

The stabilization of A_{11} , which represents the map of A_F restricted to $\ker(G_-)$, is dependent upon the maximal controllability subspace contained in $\ker(G_-)$ [8], here denoted as R^* . This subspace defines what can be controlled in $\ker(G_-)$ by matrices F that satisfy (17). An efficient and numerically stable method for its computation has been presented in [9] (see also [10]). It consists in finding orthogonal transformation matrices which change the coordinate basis of the system in such a way that the structure of the desired subspace is made evident. In particular, it is always possible to compute changes of basis [9]

$$u = Zu \quad z = Q_R z \quad (23)$$

such that the system (13) is represented as follows

$$\dot{z} = A_1 z + B_1 u \quad (24)$$

$$\hat{A} = Q'_R \hat{A} Q_R = \begin{bmatrix} \hat{A}_{11} & \hat{A}_{12} & \hat{A}_{13} \\ \hat{A}_{21} & \hat{A}_{22} & \hat{A}_{23} \\ \hat{A}_{31} & \hat{A}_{32} & \hat{A}_{33} \end{bmatrix}; \quad \hat{A}_{11} \in \mathbb{R}^{c \times c} \quad (25)$$

$$\hat{B} = Q'_R \hat{B} Z = \begin{bmatrix} \hat{B}_{11} & \hat{B}_{12} \\ \hat{B}_{21} & 0 \\ \hat{B}_{31} & 0 \end{bmatrix}; \quad \hat{B}_{11} \in \mathbb{R}^{c \times b} \quad (26)$$

where $\hat{B}_{31} \in \mathbb{R}^{r \times b}$ has full column rank

$$\hat{F} = Z' \hat{F} Q_R = \begin{bmatrix} \hat{F}_{11} & \hat{F}_{12} & \hat{F}_{13} \\ \hat{F}_{21} & \hat{F}_{22} & \hat{F}_{23} \end{bmatrix}; \quad \hat{F}_{11} \in \mathbb{R}^{b \times c} \quad (27)$$

$$\hat{G} = \hat{G} Q_R = [0 \quad 0 \quad \hat{G}_3]; \quad \hat{G}_3 \in \mathbb{R}^{r \times r} \quad (28)$$

$$\hat{\mathcal{R}}^* = \text{Im} \begin{bmatrix} I_c \\ 0 \\ 0 \end{bmatrix} \quad \ker(\hat{G}) = \begin{bmatrix} I_c & 0 \\ 0 & I_{n-(c+r)} \\ 0 & 0 \end{bmatrix} \quad (29)$$

where I_n denotes the identity matrix of order n

$$\hat{S}[\hat{G}, \rho] = \{\hat{x} \in \mathbb{R}^n / -\rho \leq \hat{G}\hat{x} \leq \rho\}. \quad (30)$$

Let \mathbf{F} be the set of matrices F for which $\ker(G)$ is (A, B) -invariant. Since \hat{B}_{31} has linearly independent columns, the set $\hat{\mathbf{F}}$ is uniquely defined by

$$\hat{\mathbf{F}} \equiv \left\{ \hat{F} / [\hat{A}_{31} \quad \hat{A}_{32}] + \hat{B}_{31} [\hat{F}_{11} \quad \hat{F}_{12}] = 0 \right\} \quad (31)$$

and in closed loop, for $\hat{F} \in \hat{\mathbf{F}}$

$$\hat{A}_F = \hat{A} + \hat{B}\hat{F} = \begin{bmatrix} \hat{A}_{F11} & \hat{A}_{F12} & \hat{A}_{F13} \\ 0 & \hat{A}_{F22} & \hat{A}_{F23} \\ 0 & 0 & \hat{A}_{F33} \end{bmatrix} \quad (32)$$

where the eigenvalues of \hat{A}_{F11} may be freely assigned while those of \hat{A}_{F22} cannot be modified by any $\hat{F} \in \hat{\mathbf{F}}$. If one considers the output equation $y(t) = Gx(t)$, the eigenvalues of \hat{A}_{F22} are the so-called transmission zeros (invariant zeros for some authors) [8], [10]. Therefore, if any of them has positive or null real part, the positive invariance of $S[G, \rho]$ with simultaneous closed-loop asymptotical stability cannot be achieved. In this case, a possible solution is to add adequately constraints to the states so as to assign only the eigenvectors corresponding to the stable eigenvalues of \hat{A}_{F22} to the null space of the new matrix G [7], [11].

Assuming henceforth that the eigenvalues of \hat{A}_{F22} have negative real parts, it can be observed from the representation (24)-(31) that the original problem of positive invariance of $S[G, \rho]$ with stability can be split into two distinct problems as follows:

Problem 1: Given \hat{F}_{11} and \hat{F}_{12} fixed by (31), find \hat{F}_{21} such that the eigenvalues of $\hat{A}_{11} + \hat{B}_{11}\hat{F}_{11} + \hat{B}_{12}\hat{F}_{21}$ have negative real parts.

Problem 2: Find $\hat{F}_{13} \in \mathbb{R}^{b \times r}$ such that there exist H and K which satisfy

$$(H - K)\hat{G}_3 = \hat{G}_3(\hat{A}_{33} + \hat{B}_{31}\hat{F}_{13}) \quad (33)$$

$$(H + K)\rho < 0 \quad (34)$$

with $H_{ij} \geq 0$ for $i \neq j$ and $K_{ij} \geq 0$ for any i, j .

Any stabilization procedure may be used to solve Problem 1. Regarding Problem 2, a simple and efficient approach to handle it is to formulate a linear program (LP) having conditions (33), (34) as constraints. A scheme similar to that proposed in [12], where the objective function is chosen so as to increase the rate of convergence of the state to the equilibrium, cannot be applied here because there are no bounds on the gains of \hat{F}_{13} . This difficulty can be removed by choosing as objective function to be minimized, for instance, the sum of the absolute values of the elements of \hat{F}_{13} . The solution of Problem 2 can therefore be obtained from the following LP

$$\min_{\hat{F}_{13}, H, K, W} \sum_{i=1}^b \sum_{j=1}^r (\hat{F}_{13,ij} + 2W_{ij}) \quad (35)$$

sub.to: $(H - K)\hat{G}_3 = \hat{G}_3(\hat{A}_{33} + \hat{B}_{31}\hat{F}_{13})$

$$(H + K)\rho \leq -\sigma\rho$$

$$\hat{F}_{13} + W \geq 0$$

$$H_{ij} \geq 0 \text{ for } i \neq j; K_{ij} \geq 0; W_{ij} \geq 0.$$

In view of the constraints involved, it can be easily verified that the minimization of the objective function yields $W_{ij} = 0$ for $\hat{F}_{13,ij} \geq 0$ and $W_{ij} = -\hat{F}_{13,ij}$ for $\hat{F}_{13,ij} \leq 0$. Therefore, at the optimum, $\hat{F}_{13,ij} + 2W_{ij} = |\hat{F}_{13,ij}|$.

The small positive number σ must be chosen so as to guarantee the strict satisfaction of inequalities (34) as well as to avoid an excessive proximity to the origin of the eigenvalues of $(\hat{A}_{33} + \hat{B}_{31}\hat{F}_{13})$. In fact, it can be easily shown [12] that $-\sigma$ defines an upper bound on the real part of such eigenvalues.

Before continuing, it should be remarked that the preceding development has been motivated by the case $r = \text{rank}(G) < n$. When $r = n$ the polyhedron $S[G, \rho]$ is bounded and the changes of basis (11), (23) are not required. In this case, a stabilizing F for which $S[G, \rho]$ is positively invariant may be directly obtained from the resolution of (35) using the corresponding matrices of system (2) and constraints (3), in their original basis. The same is applicable to the L-Q regulator design, to be treated in the next section.

IV. CONSTRAINED L-Q REGULATOR DESIGN

The resolution of Problems 1 and 2 defined in last section provides, if possible, a controller such that $S[G, \rho]$ is positively invariant and the closed-loop system is asymptotically stable. In a typical control system design, however, performance specifications are also included and among them the optimal L-Q regulation is widely used. Consider then the quadratic performance index

$$J(u(t)) = \mathbf{E} \left\{ \int_0^\infty [x(t)' S_1' x(t) + u(t)' S_2 u(t)] dt \right\} \quad (36)$$

where \mathbf{E} is the mathematical expectation operator; S_1 and S_2 are constant real matrices; S_2 is positive definite; $x_0 = x(0)$ is a random vector with $\mathbf{E}\{x_0\} = 0$ and $\mathbf{E}\{x_0 x_0'\} = X_0' X_0$.

The objective of the state constrained L-Q regulator problem to be solved here is to find a state feedback law $u = Fx$ such that $S[G, \rho]$ is positively invariant and the performance index (36) is simultaneously minimized. Consider then the changes of basis (11), (23) which lead the system to the form (24)-(31). Considering also the state feedback law $\hat{u} = \hat{F}\hat{x}$, the index (36) may be rewritten as

$$J(\hat{F}) = \mathbf{E} \left\{ \int_0^\infty \hat{x}(t)' [\hat{S}_1' \hat{S}_1 + \hat{F}' \hat{S}_2 \hat{F}] \hat{x}(t) dt \right\} \quad (37)$$

where $S_1 = S_1(QQ_R)$, $S_2 = Z'S_2Z$, $E\{x_0\} = 0$ and $E\{x_0x_0'\} = (QQ_R)X_0'X_0(QQ_R)' = X_0'X_0$. The performance index $J(F)$ is given by [13]

$$J(F) = T_1(\lambda_0' \lambda_0 I) \quad (38)$$

$$(\hat{A} + \hat{B}F)'T + T(\hat{A} + BF) + S_1'S_1 + F'S_2F = 0 \quad (39)$$

We are now in position to formulate the state constrained LQ regulator design problem

$$\begin{aligned} \min_{F \in \mathbf{F}} J(F) \\ \text{subject to } (H - K)G_1 &= G_1(A_{11} + B_{11}F_{11}) \\ (H + K)\rho &\leq 0 \\ F \in \mathbf{F}, H_{ij} &\geq 0 \text{ for } i \neq j, K_{ij} \geq 0 \end{aligned} \quad (40)$$

Matrices $F \in \mathbf{F}$ (31) have fixed and free elements. Let $\underline{\alpha}$ be a vector composed by the free elements of $F \in \mathbf{F}$ together with the elements of H and K . The problem (41) can therefore be rewritten as the following standard linearly constrained minimization problem

$$\min J(\underline{\alpha}) \quad (41)$$

$$\text{subject to } C\underline{\alpha} \leq \underline{f} \quad (42)$$

Without considering the constraints (42) $\min J(\underline{\alpha})$ (41) corresponds to a parameter optimization problem in LQ regulators subject to structural constraints. For solution of this kind of problem Dorca and Milani [13] proposed a specialized hybrid descent optimization procedure composed by a sequence of steps of Modified Newton, Newton's, and Quasi Newton methods. For obtaining a good trade off between the cost per step and the convergence rate the methods are chosen along the descent process considering their expected computational effort per step, an evaluation of the convergence rate of the descent sequence and the proximity to the optimal point.

To solve the parameter optimization problem with linear constraints (41) (42) the method proposed in [13] is transformed into a feasible directions optimization method [14] described in the sequel.

Assuming

$\nabla J(\underline{\alpha})$ gradient vector of $J(\underline{\alpha})$

$H(\underline{\alpha})$ hessian matrix of $J(\underline{\alpha})$

$H_+(\underline{\alpha})$ positive definite approximation to $H(\underline{\alpha})$

$H_d(\underline{\alpha})$ matrix obtained from the diagonal scaling of $H(\underline{\alpha})$ fulfilling the secant condition of Quasi Newton methods,

as defined in [13], the following active set based procedure [14] is proposed to solve the constrained minimization problem (41), (42), starting from a feasible point $\underline{\alpha}_0$

1) Initialization

- Define the tolerance ϵ
- Set

$$l = 0 \quad \underline{\alpha}_l = \underline{\alpha}_0$$

2) Active set computations

- Construct C'_A , the active constraints matrix composed by the lines C'_i of C' (42) such that

$$C'_i \underline{\alpha}_l = f_i$$

3) Computation of the projection matrix

- Compute the orthogonal matrix V by performing the following QR factorization [14]

$$C'_A = VU = [V_1 \quad V_2] \begin{bmatrix} U_1 \\ 0 \end{bmatrix}$$

where the matrix U_1 has full row rank

4) Test for convergence

- Compute the reduced gradient vector

$$q(\underline{\alpha}_l) = V_2' \nabla J(\underline{\alpha}_l)$$

- If $\|q(\underline{\alpha}_l)\| > \epsilon$ go to step 5. Otherwise compute the Lagrange multipliers vector λ by solving the system of equations

$$U_1 \lambda = V_1' \nabla J(\underline{\alpha}_l)$$

- If $\lambda \geq 0$ STOP and take $\underline{\alpha}_l$ as the solution. Otherwise eliminate the row of C'_A correspondent to the most negative component of λ and return to step 3.

5) Computation of a feasible search direction

- Based on the directions proposed in [13] select the descent method and define a positive definite matrix $L(\underline{\alpha}_l)$ considering the following alternatives

$$L(\underline{\alpha}_l) = \begin{cases} H(\underline{\alpha}_l) & \text{modified Newton} \\ H(\underline{\alpha}_l) & \text{Newton's} \\ H_d(\underline{\alpha}_l) & \text{Quasi Newton} \end{cases}$$

- Compute

$$M(\underline{\alpha}_l) = V_2 L(\underline{\alpha}_l) V_2'$$

- Solve the linear system of equations

$$M(\underline{\alpha}_l) p_l = -q(\underline{\alpha}_l)$$

- Compute

$$\underline{d}_l = V_2 p_l$$

6) Solution update

- Find a step size γ such that

$$\underline{\alpha}_{l+1} = \underline{\alpha}_l - \gamma \underline{d}_l \text{ is feasible}$$

$$J(\underline{\alpha}_{l+1}) < J(\underline{\alpha}_l)$$

- Set

$$l = l + 1$$

- Return to step 2

Remarks

- 1) The existence of γ in step 6 is assured by the positive definiteness of matrices $L(\underline{\alpha}_l)$, $M(\underline{\alpha}_l)$, in step 5 [15]. Due to the non convexity of $J(\underline{\alpha})$ it is not possible to assure that the attained minimum point in step 4 is the global one. To the author's knowledge, a convex programming approach to problems with the structural constraints present in (41), is not available to date.

- 2) The optimal state feedback matrix F^* in the original basis (2) is obtained from the optimal solution $F(\underline{\alpha}^*)$ by

$$F^* = ZF(\underline{\alpha}^*)(QQ_R)'$$

V. NUMERICAL EXAMPLE

The following example has been borrowed from [5]. Consider the system for which

$$A = \begin{bmatrix} 9.10 & 0.47 & -6.33 \\ 7.62 & 0 & 7.56 \\ 2.62 & -3.28 & 9.91 \end{bmatrix} \quad B = \begin{bmatrix} 1.82 & 3.61 \\ 1.24 & -3.77 \\ -4.91 & 0 \end{bmatrix}.$$

The state constraints are defined by

$$G = \begin{bmatrix} 5.69 & 1.97 & -1.68 \\ 2.24 & -1.68 & 5.59 \end{bmatrix} \quad \rho = \begin{bmatrix} 8.75 \\ 10.50 \end{bmatrix}.$$

The system is transformed into the representation (24)-(31) yielding

$$\hat{A} = \begin{bmatrix} 1.7936 & 1.8674 & 12.9823 \\ & 11.1206 & -2.1901 \\ -1.6275 & 1.1278 & 6.0957 \end{bmatrix}$$

$$\hat{B} = \begin{bmatrix} -1.1843 & -4.1421 \\ & 3.4836 \\ 4.6808 & 0 \end{bmatrix} \quad \hat{G} = \begin{bmatrix} 0 & 6.2514 & 0.0017 \\ 0 & 0.0055 & 6.2520 \end{bmatrix}.$$

The matrices $\hat{F} \in \hat{\mathcal{F}}$ are given by

$$\hat{F} = \begin{bmatrix} 0.3477 & X & X \\ 1.0678 & X & X \end{bmatrix}$$

where the elements X are free to assume any value. For such matrices, it can be readily verified that the closed-loop system will have -3.0399 as a fixed eigenvalue.

Using $S_1 = I_3$; $S_2 = I_2$; $X_0'X_0 = \frac{1}{3}I_3$ and starting from the solution of the LP (34) with $\sigma = 0.1$, the resolution of the parameter optimization problem (42) yields

$$J(\hat{F}^*) = 4.1255$$

$$\hat{F}^* = \begin{bmatrix} 0.3477 & -2.5595 & -4.6649 \\ 1.0678 & -7.4796 & -1.9137 \end{bmatrix}.$$

In the original basis,

$$F^* = \begin{bmatrix} -0.2561 & -1.0943 & 3.2597 \\ -8.7191 & -0.3818 & -1.0603 \end{bmatrix}.$$

The optimal solution of the unconstrained L-Q regulator problem is $J^* = 1.1228$. However, for $x(0) = [0.6161 \ 5.4503 \ 3.2695]'$, it can be seen in Fig. 1 that the state vector trajectory resulting from this solution violates the imposed constraints.

VI. CONCLUSION

In this paper a new approach has been proposed to the design of L-Q regulators for state constrained continuous-time systems. The design problem has been stated as a parameter optimization problem subject to linear constraints. The respect to the constraints has been guaranteed by achieving closed-loop positive invariance of the polyhedron defined by them. By appropriately changing the state-space representation of the system, the positive invariance of an unbounded polyhedron with simultaneous closed-loop stability has been achieved by solving two distinct problems for lower order systems: a stabilization problem and a problem of positive invariance of a bounded polyhedron, which can be solved by properly defining a linear programming problem. Moreover, the admissible constrained controllers have been parameterized by means of the determination of the fixed elements in the state feedback matrix. The conditions

Fig. 1. Trajectories in projection $(Gx)_1 \times (Gx)_2$ for the constrained (..) and unconstrained (-) L-Q regulator.

for existence of such controllers are directly verified from structural properties of the matrices of the system at each step of the design. A specialized feasible directions method has been proposed to solve the resulting constrained parameter optimization problem. The proposed design makes no assumptions, other than the usual ones, on the weighting matrices and is very simple when compared to other approaches available in the literature.

The Finite Inclusions Theorem

Richard D. Kaminsky and Theodore E. Djaferis

Abstract—This paper presents a novel, necessary and sufficient condition for a polynomial to have all its roots in an arbitrary convex region of the complex plane. The condition may be described as a variant of Nyquist's stability theorem; however, unlike this theorem it only requires knowledge of the polynomial's value at finitely many points along the region's boundary. A useful corollary, the Finite Inclusions Theorem (FIT), provides a simple sufficient condition for a family of polynomials to have its roots in a given convex region. Since FIT only requires knowledge of the family's value set at finitely many points along the region's boundary, this corollary provides a new convenient tool for the analysis and synthesis of robust controllers for parametrically uncertain systems.

1 INTRODUCTION

With regards to linear time invariant (LTI) systems there are now two well established ways to model system uncertainty: either parametrically or through H_∞ norm bounded classes of transfer functions. In the former case, which we are mainly interested in here, both robust stability and performance questions often reduce to showing that a certain parametric family of polynomials (or matrices) has its zeros (eigenvalues) in a given region of the complex plane. As engineers, we would like to have efficient numerical methods for verifying this inclusion. While many good methods and interesting results have come to light, our optimism in seeking a general solution to this problem, especially one that will permit us to conveniently synthesize robust controllers, must be tempered by the fact that there are certain fundamental mathematical difficulties in relating a polynomial's coefficients to its zeros.

Many if not all of the major results connecting a polynomial's coefficients with its zeros can be derived from the argument principle (aka Nyquist's theorem). Among them, the fact that a degree n polynomial has precisely n zeros (counting multiplicities), the algebraic root clustering criteria of Routh, Hurwitz, Schur, Cohn, and Jury, the Hermite-Biehler theorem, and Kharitonov's theorem. The purpose of this paper is to present a novel variant of the argument principle which is useful in solving robust parametric control problems.

Recall that Nyquist's theorem (i.e., the argument principle) states the following: Let $D \subset \mathbb{C}$ be an open, simply connected set, $f: D \rightarrow \mathbb{C}$ be a function analytic on D except for finitely many poles, and $\Gamma \subset D$ be a counterclockwise, closed, rectifiable, Jordan curve on which f has neither poles nor zeros. Further, let λ and λ_p be the number of zeros and poles of f inside Γ , and let λ be the net number of counterclockwise encirclements about the origin made by the curve $f(\Gamma)$. Then $\lambda - \lambda_p = \lambda$.

As a numerical method for determining pole/zero locations, Nyquist's theorem is flawed because it requires evaluating $f(\cdot)$ at the infinitely many points Γ . In practice, of course, we often choose finitely many points $\{s_k\} \subset \Gamma$ and from a plot of $\{f(s_k)\}$ make an educated guess as to the number of counterclockwise encirclements that $f(\Gamma)$ makes about the origin. Despite the room for error here, this procedure usually works quite well, yet it raises the question,

Fig. 1. A closed Jordan curve with convex interior.

Can λ ever be rigorously determined from some finite set of points $\{f(s_k)\}$?

The main result of this paper is that when f is a polynomial of degree $\leq n$ and the interior of Γ is convex, one can determine whether or not $\lambda = \lambda_p = n$ from an appropriately chosen set of points $\{f(s_k)\}$. This result, the finite Nyquist theorem (Theorem 1), leads naturally to a very useful sufficient condition for a family of polynomials to have all its zeros inside Γ , namely the finite inclusions theorem (Theorem 2).

Section II derives the finite Nyquist theorem and Section III derives the finite inclusions theorem. The case of Hurwitz stability was dealt with in [1]. For an application of these results to robust control analysis and synthesis problems, see [2]; the complete version of this paper.

II THE FINITE NYQUIST THEOREM

Let us introduce some notation. Let \mathbb{C} , \mathbb{R} , \mathbb{R}_+ , and \mathbb{Z} be the sets of complex, real, positive real, and integer numbers, respectively. Let $\arg \cdot$ be the argument of $\cdot \in \mathbb{C} \setminus \{0\}$ and $\text{Arg} \cdot$ the principle argument of $\cdot \in \mathbb{C} \setminus \{0\}$ with range $(-\pi, \pi]$. Let \cdot^* denote the complex conjugate of $\cdot \in \mathbb{C}$. Let $\text{ext } \Gamma$ be the exterior of a closed Jordan curve Γ , $\text{int } \Gamma$ the interior of a closed Jordan curve Γ , $\text{co } S$ the convex hull of S , and $\text{ext } Q$ the set of extreme points of a convex set Q .

Nyquist's theorem states that an n th degree polynomial p has all its zeros inside a counterclockwise closed Jordan curve Γ if and only if the point $p(s)$ revolves a net $2\pi n$ radians counterclockwise about the origin as s traverses Γ . An inconvenient feature of Nyquist's theorem is that $p(s)$ must be evaluated at the infinitely many points Γ . The following novel theorem states that when $\text{int } \Gamma$ is convex, $p(s)$ need only be evaluated at finitely many points. After this paper was accepted for publication, it was brought to our attention that a similar result was stated in [4].

Theorem 1—Finite Nyquist Theorem. Let $p(s) = \sum_{j=0}^n \alpha_j s^j$ where $n \geq 0$ and $\alpha_j \in \mathbb{C}$, and let $\Gamma \subset \mathbb{C}$ be a closed Jordan curve such that $\text{int } \Gamma$ is convex (see Fig. 1). Then, p is of degree n (i.e., $\alpha_n \neq 0$) and has all its zeros in $\text{int } \Gamma$ if and only if there exist $m \geq 1$ angles $\theta_k \in \mathbb{R}$ and a counterclockwise sequence of points $s_k \in \Gamma$, $1 \leq k \leq m$, such that

$$\forall 1 \leq k < m, |\theta_{k+1} - \theta_k| < \pi \quad (1a)$$

$$|2\pi n + \theta_1 - \theta_m| < \pi \quad (1b)$$

$$\forall 1 \leq k < m, p(s_k) \neq 0 \quad (1c)$$

$$\forall 1 \leq k < m, \arg p(s_k) \equiv \theta_k \pmod{2\pi} \quad (1d)$$

Fig. 2. A closed Jordan curve with convex interior.

Proof: The proof requires several preliminary definitions. First, let $I = [0, 1)$ and define the total variation [3, p. 328] of a function $f: I \rightarrow \mathbb{R}$ to be

$$Vf = \sup_{\substack{n \geq 1 \\ 0 \leq x_1 < x_2 < \dots < x_n < 1}} \sum_{j=1}^{n-1} |f(x_{j+1}) - f(x_j)|.$$

Intuitively, Vf is the total "vertical distance" through which f oscillates on I . Note, Vf is a nonnegative (possibly infinite) quantity, and by the elementary inequality $|\alpha + \beta| \leq |\alpha| + |\beta|$, $\alpha, \beta \in \mathbb{R}$, we have:

Lemma 1: For arbitrary $f, g: I \rightarrow \mathbb{R}$, $V(f + g) \leq Vf + Vg$.

Second, let us parameterize the closed Jordan curve Γ (see Fig. 1) by a continuous function $\Gamma: I \rightarrow \mathbb{C}$ where $\Gamma(0) = s_1$. For convenience both the curve and function will be denoted by Γ , and the left-hand limit $\lim_{t \rightarrow 1^-} \Gamma(t)$ will be denoted by $\Gamma(1^-)$. The above adjective closed refers to the property $\Gamma(0) = \Gamma(1^-)$ while the adjective Jordan refers to the property $\forall x \neq y, \Gamma(x) \neq \Gamma(y)$ (i.e., Γ does not intersect itself). Note, an intuitive—but difficult to prove—fact is that any closed Jordan curve Γ partitions the plane into two regions: a bounded, open region $\text{int } \Gamma$ and an unbounded, open region $\text{ext } \Gamma$.

Last, let us define the notion of a phase function $\phi: I \rightarrow \mathbb{R}$ which, simply put, describes the phase of the first degree polynomial $s - z$ as s traverses Γ . Specifically, for $z \notin \Gamma$ define $\phi: I \rightarrow \mathbb{R}$ to be any continuous function such that

$$\phi(t) \equiv \arg(\Gamma(t) - z) \pmod{2\pi}. \quad (2)$$

For $z \in \Gamma \setminus \{\Gamma(0)\}$ take this same definition but at $t' \in (0, 1)$ where $\Gamma(t') - z = 0$, only require ϕ to be right continuous and $\lim_{t \rightarrow t'^-} \phi(t) - \phi(t') \in [0, 2\pi)$. This minor complication arises, of course, because (2)'s right-hand side is undefined at $t = t'$. For technical reasons ϕ will be left undefined in the $z = \Gamma(0)$ case.

From Fig. 2 it should be apparent that when $\text{int } \Gamma$ is convex at least one phase function ϕ —and actually, infinitely many phase functions differing by multiples of 2π —exists for any given $z \neq \Gamma(0)$. Further, ϕ will have certain properties that depend only on whether z is inside, on, or outside Γ .

Case 1: $z \in \text{int } \Gamma$. Here ϕ increases continuously and monotonically by 2π (consider $z = z_-$ in Fig. 2). Hence, $V\phi = 2\pi$ and $\phi(1^-) - \phi(0) = 2\pi$.

Case 2: $z \in \Gamma \setminus \{\Gamma(0)\}$. ϕ increases continuously and monotonically by some amount $\theta_0 \leq \pi$ except at the point $t' \in (0, 1)$, $\Gamma(t') - z = 0$, where it makes a downward jump of height θ_0 (consider $z = z_0$ in Fig. 2). Hence, $V\phi = 2\theta_0 \leq 2\pi$ and $\phi(1^-) - \phi(0) = 0$.

Case 3: $z \in \text{ext } \Gamma$. ϕ increases continuously and monotonically by some amount $\theta_+ < \pi$ over a portion of the interval I (consider $z = z_+$ and the counterclockwise $B \rightarrow A$ portion of Γ in Fig. 2) while on the other portion it decreases continuously and monotonically by θ_+ (consider the $A \rightarrow B$ portion of Γ). Hence, $V\phi = 2\theta_+ < 2\pi$ and $\phi(1^-) - \phi(0) = 0$.

Now, from these observations we can prove the "if" part of Theorem 1. Let p be of degree $0 \leq d \leq n$ and have (not necessarily distinct) zeros $\{z_k\}$; so

$$p(s) = \sum_{j=0}^n \alpha_j s^j = \alpha_d \prod_{k=1}^d (s - z_k).$$

Substituting $\Gamma(t)$ for s and letting ϕ_k be an arbitrary phase function associated with z_k , we see

$$\begin{aligned} \arg p(\Gamma(t)) &\equiv \arg \alpha_d + \sum_{k=1}^d \arg(\Gamma(t) - z_k) \\ &\equiv \Phi(t) \pmod{2\pi} \end{aligned}$$

$$\text{where } \Phi(t) = \arg \alpha_d + \sum_{k=1}^d \phi_k(t).$$

Let $0 = t_1 < t_2 < \dots < t_m < 1$ be such that $\Gamma(t_k) = s_k$, $1 \leq k \leq m$, and note (1c) implies $\{\Gamma(t_k)\} \cap \{z_k\} = \emptyset$; so, (1d) implies for all k and some $\zeta_k \in \mathbb{Z}$, $\Phi(t_k) = \theta_k + 2\pi\zeta_k$. Thus, $\Phi(1^-) = \Phi(0) + 2\pi N = \theta_1 + 2\pi(N + \zeta_1)$ where N is the number of zeros z_k lying in $\text{int } \Gamma$. Now, observe

$$2\pi n = 2\pi n + \theta_1 - \theta_m + \sum_{k=1}^{m-1} \theta_{k+1} - \theta_k \quad (3)$$

$$\leq |2\pi n + \theta_1 - \theta_m| + \sum_{k=1}^{m-1} |\theta_{k+1} - \theta_k| \quad (4)$$

$$\begin{aligned} &\leq |2\pi n + \theta_1 - \theta_m + 2\pi(N + \zeta_1 - \zeta_m - n)| \\ &\quad + \sum_{k=1}^{m-1} |\theta_{k+1} - \theta_k + 2\pi(\zeta_{k+1} - \zeta_k)| \end{aligned} \quad (5)$$

$$= |\Phi(1^-) - \Phi(t_m)| + \sum_{k=1}^{m-1} |\Phi(t_{k+1}) - \Phi(t_k)| \quad (6)$$

$$\begin{aligned} &\leq V\Phi \leq \sum_{k=1}^d V\phi_k \\ &\leq 2\pi d \leq 2\pi n \end{aligned} \quad (7)$$

where in going from (4) to (5) we used (1a), (1b) and the fact n , N , and ζ_k are integers. Since the left-hand side of (3) and right-hand side of (7) are equal, we would have a contradiction if the inequality between (4) and (5) were strict. Hence, necessarily $N + \zeta_1 - \zeta_m - n = 0$ and $\zeta_{k+1} - \zeta_k = 0$, $1 \leq k < m$. Summing these equations shows $N = n$. Thus, as we set out to prove, p is of degree n and has all its zeros in Γ .

It now simply remains to prove the "only if" part of Theorem 1. Let p be of degree n and have all of its zeros in $\text{int } \Gamma$. If $n = 0$ trivially $p(s) = \alpha_0 \neq 0$, and Theorem 1 is satisfied for $m = \theta_1 = \arg \alpha_0$, and any $s_1 \in \Gamma$. So, suppose $n > 0$. By Nyquist theorem, the point $p(s)$ will revolve $2\pi n$ radians counterclockwise about the origin as s traverses Γ . Hence, if we choose $m = 2n + 1$ and $\theta_k = \pi(1 - 1/3n)(k - 1)$, $1 \leq k \leq m$, by the continuity of $p(s)$ we will be able to determine $\{s_k\}$ satisfying the theorem. A

interesting point here is that $m = 2n + 1$ is the smallest m for which the theorem can be satisfied. Q.E.D.

With little effort Theorem 1 and its proof can be generalized to certain, nonconvex, simply connected regions as follows. Suppose Γ is an arbitrary closed Jordan curve and $\nu > 0$ a constant such that for each $z \neq \Gamma(0)$ there exists a phase function ϕ with $\forall \phi \leq \nu$ (note, ϕ may not exist if $z \in \Gamma$ and in some neighborhood of z , Γ "oscillates too rapidly"). When $\text{int } \Gamma$ is convex, we saw there always exists a ϕ with $\forall \phi \leq \nu = 2\pi$. When $\text{int } \Gamma$ is not convex, however, we must take $\nu > 2\pi$. Now, to make the above proof go through, the right-hand sides of (1ab) must be replaced by some $\kappa > 0$ where κ, ν , and n satisfy the inequality $\nu n - 2\pi n \leq 2\pi - 2\kappa$. For then, noting that the right-hand side of (7) is νn , we must conclude $N + \zeta_1 - \zeta_m - n = 0$ and $\zeta_{k+1} - \zeta_k = 0$, $1 \leq k < m$, to avoid making the gap between (4) and (5) so large as to yield a contradiction. As before, summing these equations shows $N = n$.

The above inequalities imply $n \leq (2\pi - 2\kappa)/(\nu - 2\pi)$ and $\kappa < \pi$ (when $n > 0$). So, generalizing Theorem 1 in this way requires placing an upper bound on the degree n of p (perhaps requiring $n = 0$) and making the right-hand sides of (1ab) strictly less than π . In our opinion, these conditions are rather ugly, and so, as matter of aesthetics, we chose to state Theorem 1 for only convex regions.

Note, a more useful generalization of Theorem 1 is to unbounded convex regions. This is readily accomplished by approximating a given unbounded region by a suitably large bounded region as was done in [2]. Also, in certain cases where conjugate symmetry is present Theorem 1 can be specialized to require roughly half as many evaluations of p as would otherwise be needed [1], [2].

III. THE FINITE INCLUSIONS THEOREM

A problem of fundamental importance in robust control theory is that of proving a family of linear differential equations has only solutions which decay and/or oscillate within a prescribed range of rates. Via the Laplace transform this problem can be reduced to proving a family of polynomials has all its zeros inside a prescribed region of the complex plane. With this problem in mind we now state the following, very useful corollary to Theorem 1.

Theorem 2—Finite Inclusions Theorem: Let $p(s; q) = \sum_{j=0}^n \alpha_j (q)s^j$, $q \in Q$, where Q is an arbitrary set, $n \geq 0$, and $\alpha_j: Q \rightarrow \mathbb{C}$. Further, let $\Gamma \subset \mathbb{C}$ be a closed Jordan curve such that $\text{int } \Gamma$ is convex (see Fig. 1). Then, for all $q \in Q$, $p(\cdot; q)$ is of degree n and has all its zeros in $\text{int } \Gamma$ if there exist $m \geq 1$ intervals $(a_k, b_k) \subset \mathbb{R}$ and a counterclockwise sequence of points $s_k \in \Gamma$, $1 \leq k \leq m$, such that

$$\forall_{1 \leq k < m} \max\{b_{k+1} - a_k, b_k - a_{k+1}\} \leq \pi \quad (8a)$$

$$\max\{b_m - (a_1 + 2\pi n), (b_1 + 2\pi n) - a_m\} \leq \pi \quad (8b)$$

$$\forall_{1 \leq k \leq m} p(s_k; Q) \subset S_k = \{re^{i\theta} | r > 0, \theta \in (a_k, b_k)\}. \quad (8c)$$

Proof: For each $q \in Q$, (8c) implies for all k , $p(s_k; q) \neq 0$ and there exist $\theta_k \in (a_k, b_k)$ such that $\arg p(s_k; q) \equiv \theta_k \pmod{2\pi}$. Further, from the inequality

$$\forall_{\substack{\theta \in (a,b) \\ \theta' \in (c,d)}} |\theta - \theta'| < \sup_{\substack{\theta \in (a,b) \\ \theta' \in (c,d)}} |\theta - \theta'| = \max\{d - a, b - c\}$$

we see conditions (8a), (8b) imply $\forall_{1 \leq k < m} |\theta_{k+1} - \theta_k| < \pi$ and $2\pi n + \theta_1 - \theta_m < \pi$. Hence, for each $q \in Q$ Theorem 1 implies $p(\cdot; q)$ is of degree n and has all its zeros in $\text{int } \Gamma$. Q.E.D.

For a convex region $\text{int } \Gamma$ Theorem 2 roughly says that if we can find a sequence of open sectors S_k "spaced" no more than π radians apart and revolving a net $2\pi n$ radians about the origin and if we

can find a counterclockwise sequence of points $s_k \in \Gamma$ such that the value sets $p(s_k; Q) = \{p(s_k; q), q \in Q\}$ lie in these sectors, then each member of the family of polynomials $p(\cdot; q)$, $q \in Q$, is of degree n and has all its zeros in $\text{int } \Gamma$.

In general, it should be noted that Theorem 2 is only a sufficient condition for a family of polynomials to have its zeros in a given, convex region. When $p(s; q)$ is continuous and affine in $q \in Q$ and Q is a compact, convex set, however, it is also necessary (i.e., the word "if" in Theorem 2 may be replaced by "if and only if.") To see this, suppose $p(s; q)$ is continuous and affine in q , Q is a compact, convex set, and for all $q \in Q$, $p(\cdot; q)$ is a degree n polynomial with all its zeros in $\text{int } \Gamma$. First note, $p(s; Q)$ is a compact, convex set that revolves n times counterclockwise about the origin without touching the origin as s traverses Γ (since for arbitrary $q \in Q$, $p(s; q)$ revolves in this fashion). By the above facts and the continuous deformation of $p(s; Q)$ as s traverses Γ , we may define two continuous functions $a, b: [0, 1] \rightarrow \mathbb{R}$, such that for all $t \in I$, $\{re^{i\theta} | r > 0, \theta \in [a(t), b(t)]\}$ is the smallest sector containing $p(\Gamma(t); Q)$, and so, $0 \leq b(t) - a(t) < \pi$, $a(1) = a(0) + 2\pi n$, and $b(1) = b(0) + 2\pi n$. Since a continuous function defined on a compact set achieves its supremum and is uniformly continuous on that set, we see that $c = \sup b(t) - a(t) = \max b(t) - a(t) < \pi$ and that a and b are uniformly continuous. Thus, for an arbitrary $0 < \epsilon < (\pi - c)/2$ we can choose a sufficiently fine partition $\{t_k\}$ of I such that conditions (8a), (8b) are satisfied with $a_k = a(t_k) - \epsilon$ and $b_k = b(t_k) + \epsilon$, and by construction, (8c) is satisfied with $s_k = \Gamma(t_k)$.

Further Results on Rational Approximations of \mathcal{L}^1 Optimal Controllers

Zi-Qin Wang, Mario Sznajder, and Franco Blanchini

Abstract—The continuous-time persistent disturbance rejection problem (\mathcal{L}^1 optimal control) leads to nonrational compensators, even for SISO systems [4], [7], [8]. As noted in [4], the difficulty of physically implementing these controllers suggests that the most significant applications of the continuous time \mathcal{L}^1 theory is to furnish bounds for the achievable performance of the plant. Recently, two different rational approximations of the optimal \mathcal{L}^1 controller were developed by Ohta *et al.* [6] and by Blanchini and Sznajder [1]. In this paper we explore the connections between these two approximations. The main result of the paper shows that both approximations belong to the same subset Ω_τ of the set of rational approximations, and that the method proposed in [1] gives the best approximation, in the sense of providing the tightest upper bound of the approximation error, among the elements of this subset. Additionally, we exploit the structure of the dual to the \mathcal{L}^1 optimal control problem to obtain rational approximations with approximation error smaller than a prespecified bound.

I. INTRODUCTION

A large number of control problems involve designing a controller capable of stabilizing a given linear time invariant system while minimizing the worst case response to some exogenous disturbances. This problem is relevant for instance for disturbance rejection, tracking and robustness to model uncertainty (see [2] and references therein). When the exogenous disturbances are modeled as bounded energy signals and performance is measured in terms of the energy of the output, this problem leads to the well known \mathcal{H}_∞ theory. The case where the signals involved are persistent bounded signals leads to the \mathcal{L}^1 optimal control theory, formulated and further explored by Vidyasagar [7], [8] and solved by Dahleh and Pearson both in the discrete- [3], [5] and continuous-time [4] cases.

The \mathcal{L}^1 theory is appealing because it directly incorporates time-domain specifications. Moreover, it furnishes a complete solution to the robust performance problem (see [2] for a good tutorial and a list of relevant references). However, in contrast with the discrete time l^1 theory, the solution for the continuous-time \mathcal{L}^1 optimal control problem leads to nonrational compensators, even for SISO systems. As noted in [4], the difficulty of physically implementing these controllers suggests that the most significant application of the continuous time \mathcal{L}^1 theory is to provide performance bounds for the plant. Recently, two rational approximations to the optimal \mathcal{L}^1 controller were developed independently [6], [1]. Although these approximations are based upon different techniques ([6] follows an algebraic approach while [1] exploits the properties of the Euler approximating set), they seem to be strongly connected [1]. Noteworthy, they yield closed-loop plants with the same pole structure.

In this paper we explore the connection between these approaches. The main result of the paper shows that both belong to the same subset Ω_τ of the set of admissible rational approximations, and that the method proposed in [1] gives the best approximation (in the sense of providing the tightest upper bound of the error) among the elements of this set. Additionally, by exploiting the structure of the dual to

the \mathcal{L}^1 optimal control problem we furnish a procedure to compute rational approximations with error smaller than a prespecified bound ϵ , and we show that the approximation error $\rightarrow 0$ as $O(\tau)$.

The paper is organized as follows. In Section II we introduce the notation to be used and we restate the main results concerning the \mathcal{L}^1 problem and its rational approximations. Section III contains the majority of the theoretical results. Here we compare the two approximation methods and we show that, in a sense, the method proposed in [1] yields the best rational approximation. In Section IV we present a simple design example and we compare the optimal \mathcal{L}^1 controller with its rational approximations. Finally, in Section V we summarize our results.

II. PRELIMINARIES

A. Notation and Definitions

R_+ denotes the set of nonnegative real numbers. $\mathcal{L}^\infty(R_+)$ denotes the space of measurable functions $f(t)$ equipped with the norm: $\|f\|_\infty = \text{ess} \cdot \sup_{R_+} |f(t)|$. $\mathcal{L}^1(R_+)$ denotes the space of Lebesgue integrable functions on R_+ equipped with the norm $\|f\|_1 \triangleq \int_0^\infty |f(t)| dt < \infty$. Similarly, l_1 denotes the space of absolutely summable sequences $h = \{h_i\}$ equipped with the norm $\|h\|_1 \triangleq \sum_{i=0}^\infty |h_i| < \infty$. \mathcal{RL}^1 denotes the subspace of \mathcal{L}^1 formed by matrices with real rational Laplace transform. A denotes the space whose elements have the form

$$h = h^L(t) + \sum_{k=0}^\infty h_k^I \delta(t - t_k)$$

where $h^L(t) \in L_1(R_+)$, $\{h_k^I\} \in l_1$ and $t_k \geq 0$, equipped with the norm $\|h\|_A \triangleq \|h^L\|_{L_1} + \|h^I\|_{l_1}$. Given a function $f(t) \in \mathcal{L}^1$ we denote its Laplace transform by $F(s) \in \mathcal{L}_\infty$; similarly, given $h \in A$, we denote its Laplace transform by $H(s)$. By a slight abuse of notation, we denote as $\|F(s)\|_1 \triangleq \|f(t)\|_1$ and $\|H(s)\|_A = \|h\|_A$. Throughout the paper we use packed notation to represent state-space realizations, i.e.,

$$G(s) = C(sI - A)^{-1}B + D \triangleq \left(\begin{array}{c|c} A & B \\ \hline C & D \end{array} \right).$$

Definition 1: Consider the continuous time system $G(s)$. Its Euler approximating system (EAS) is defined as the following discrete time system

$$G^E(z, \tau) = \left(\begin{array}{c|c} I + \tau A & \tau B \\ \hline C & D \end{array} \right). \quad (1)$$

From this definition it is easily seen that we can obtain the EAS of $G(s)$ by the simple variable transformation $s = (z - 1)/\tau$, i.e.,

$$G^E(z, \tau) = G\left(\frac{z-1}{\tau}\right).$$

On the other hand, for any given τ we can relate a discrete time system to a continuous system by the inverse transformation $z = 1 + \tau s$. It is obvious that the discrete time system is, in fact, the EAS of the continuous time system obtained in this form.

Definition 2: Consider a system of the form

$$\Phi(s) = T_1(s) + T_2(s)Q(s)$$

where $T_2(s)$ has all its zeros $\{z_1, z_2, \dots, z_n\}$ in the open right-half plane and where, for simplicity, we assume that all the zeros are

distinct. $\Phi(s)$ is said to be admissible if it is stable and satisfies the interpolation conditions

$$\Phi(z_k) = T_1(z_k), \quad k = 1, \dots, n.$$

B. The \mathcal{L}^1 Optimal Control Problem

Consider the system shown in Fig. 1, where S represents the system to be controlled; the scalar signals $\omega \in \mathcal{L}^\infty$ and u represent an exogenous disturbance and the control action respectively; and where ζ and y represent the output subject to performance constraints and the measurements available to the controller, respectively. As usual we will assume, without loss of generality, that any weights have been absorbed in the plant S . Then, the \mathcal{L}^1 optimal control problem can be stated as: Given the system (S) find an internally stabilizing controller $u(s) = K(s)y(s)$ such that the worst case (over the set of all $\omega(t) \in \mathcal{L}^\infty$, $\|\omega\|_\infty \leq 1$) maximum amplitude of the performance output $\zeta(t)$ is minimized.

By using the YJBK parameterization of all stabilizing controllers [4], [9], the problem can be cast into the following model matching form

$$\mu_0 = \inf_{K \text{ stabilizing}} \|\Phi(s)\|_A = \inf_{Q \in A} \|T_1(s) + T_2(s)Q(s)\|_A \quad (2)$$

where T_1, T_2 are rational stable transfer functions.

Next, we recall the main result of [4], showing that a solution to the \mathcal{L}^1 optimal control problem can be found by solving a semi-infinite linear programming problem.

Theorem 1 (Dahleh and Pearson [4]): Let $T_2(s)$ have n zeros z_i in the open right-half plane and no zeros on the $j\omega$ axis. Then

$$\begin{aligned} \mu_0 &= \inf_{Q \in A} \|T_1(s) + T_2(s)Q(s)\|_A \\ &= \max_{\alpha_j} \left[\sum_{i=1}^n \alpha_i \operatorname{Re}\{T_1(z_i)\} + \sum_{i=1}^n \alpha_{i+n} \operatorname{Im}\{T_1(z_i)\} \right] \end{aligned} \quad (3)$$

subject to

$$\left| r(t) \right| = \left| \sum_{i=1}^n \alpha_i \operatorname{Re}\{e^{-z_i t}\} + \sum_{i=1}^n \alpha_{i+n} \operatorname{Im}\{e^{-z_i t}\} \right| \leq 1, \quad \forall t \in R_+. \quad (4)$$

Furthermore, the following facts hold: i) the extremal functional $r^*(t)$ equals 1 at only finite points: t_1, \dots, t_m ; ii) an optimal solution $\Phi(s) = T_1(s) + T_2(s)Q(s)$ to the left side problem always exists; and iii) the optimal ϕ has the following form

$$\phi = \sum_{i=1}^m \phi_i \delta(t - t_i), \quad t_i \in R_+, \quad m \text{ finite} \quad (5)$$

and satisfies the following conditions

- a) $\phi_i r^*(t_i) \geq 0$;
- b) $\sum_{i=1}^m |\phi_i| = \mu_0$;
- c) $\sum_{i=1}^m \phi_i e^{-z_k t_i} = T_1(z_k), \quad k = 1, \dots, n.$

Remark 1: It was shown in [4] that we need to satisfy constraints (4) only for all $t \leq t_{\max}$ where t_{\max} is finite and can be determined a priori. Even so, there are still infinite constraints, and therefore the dual problem is a semi-infinite linear programming problem.

C. Rational Approximations to the Optimal \mathcal{L}^1 Controller

From (5) it follows that, unlike in the discrete-time case, the \mathcal{L}^1 optimal controller is irrational even if the plant is rational. Prompted by the difficulty in physically implementing a controller with a nonrational transfer function, two rational approximation methods have been recently developed by Ohta *et al.* [6] and by Blanchini and Sznajder [1]. In the sequel we briefly review these results. For brevity, we refer to the former as the OMK method and to the latter as the EAS method.

Theorem 2 (Ohta *et al.*, [6]): Let

$$T_1(s) = \begin{pmatrix} A_1 & B_1 \\ C_1 & D_1 \end{pmatrix} \quad \text{and} \quad T_2(s) = \begin{pmatrix} A_2 & B_2 \\ C_2 & D_2 \end{pmatrix}$$

be minimal realizations. Define

$$\begin{aligned} L &= B_2 D_2^{-1} \\ \hat{A} &= A_2 - L C_2 \\ M &= L D_1 + R_1 B_1 \end{aligned}$$

where R_1 is the unique solution of the linear matrix equation

$$\hat{A} R_1 - R_1 A_1 = L C_1.$$

Then, there exist finite sets $\{t_1, t_2, \dots, t_m\}$ and $\{\phi_1, \phi_2, \dots, \phi_m\}$ such that

$$M = \sum_{i=1}^m \phi_i \exp(-\hat{A} t_i) L \quad (6)$$

and $\mu_0 = \sum_{i=1}^m |\phi_i|$. For $\tau > 0$, define $N(t_i, \tau) \triangleq$ the smallest integer larger than or equal to t_i/τ , $i = 1, 2, \dots, m$, and $N(\tau) \triangleq N(t_m, \tau)$. Finally, denote by $\phi(\tau)$ the minimizer of $\|\phi(\tau) - \phi\|_2$ subject to

$$M = \sum_{i=1}^m \phi_i(\tau) (I + \tau \hat{A})^{-N(t_i, \tau)} L \quad (7)$$

where $\phi(\tau) = [\phi_1(\tau), \dots, \phi_m(\tau)]$, and $\phi = [\phi_1, \dots, \phi_m]$. Consider the rational system $\Phi(s, \tau)$ with the following state-space realization

$$\Phi(s, \tau) = \begin{pmatrix} A(\tau) & B_4(\tau) \\ C_3(\tau) & D_{34}(\tau) \end{pmatrix}$$

where the matrices A, B_4, C_3, D_{34} are defined as follows

$$A(\tau) = \tau^{-1} \begin{pmatrix} -1 & 1 & 0 & \dots & \dots & 0 \\ 0 & -1 & 1 & 0 & \dots & 0 \\ 0 & 0 & -1 & 1 & \dots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & \dots & \dots & 0 & -1 & 1 \\ 0 & \dots & \dots & 0 & 0 & -1 \end{pmatrix}, \quad N(\tau) \text{ by } N(\tau)$$

$B_4(\tau)$: its k th element $\begin{cases} 0, & \text{if } k \notin N(t_i, \tau), i = 1, 2, \dots, m \\ \phi_i(\tau), & \text{if } k = N(t_i, \tau) \end{cases}$

$$C_3(\tau) = (\tau^{-1} \quad 0 \quad \dots \quad 0), \quad 1 \text{ by } N(\tau)$$

$$D_{34}(\tau) = \begin{cases} 0, & \text{if } N(t_1, \tau) \neq 0 \\ \phi_1(\tau), & \text{if } N(t_1, \tau) = 0. \end{cases}$$

Then, as $\tau \rightarrow 0$, we have that $\Phi(s, \tau) \rightarrow \Phi_{\text{OPT}}(s)$ uniformly in the wide sense in the open half plane $\operatorname{Re}(s) > -\sigma$ for some $\sigma > 0$; and $\|\Phi\|_A$, as well as its upper bound $\gamma = \sum_{i=1}^m |\phi_i(\tau)|$, converge to μ_0 .

Remark 2: As we will show later, (6) and (7) are just another version of the interpolation condition.

Next, we recall the main result of [1] showing that the \mathcal{L}^1 norm of a stable transfer function is bounded above by the l^1 norm of its EAS. Moreover, this bound can be made arbitrarily tight by taking the parameter τ in (1) small enough. This result is the basis for the approximation procedure proposed in [1].

Theorem 3 (Blanchini and Sznajder [1]): Consider a continuous time system with rational Laplace transform $\Phi(s)$ and its EAS, $\Phi^E(z, \tau)$. If $\Phi^E(z, \tau)$ is asymptotically stable, then $\Phi(s)$ is also asymptotically stable and such that

$$\|\Phi(s)\|_1 \leq \|\Phi^E(z, \tau)\|_1.$$

Conversely, if $\Phi(s)$ is asymptotically stable and such that $\|\Phi(s)\|_1 \triangleq \mu_c$, then for all $\mu > \mu_c$ there exists $\tau^* > 0$ such that for all $0 < \tau \leq \tau^*$, $\Phi^E(z, \tau)$ is asymptotically stable and such that $\|\Phi^E(z, \tau)\|_1 \leq \mu$.

Theorem 4 [1]: Consider a strictly decreasing sequence $\tau_i \rightarrow 0$, and define

$$\mu_i \triangleq \inf_{\text{stabilizing } K} \|\Phi_{cl}^E(z, \tau_i)\|_1$$

where $\Phi_{cl}^E(z, \tau_i)$ denotes the closed-loop transfer function. Then the sequence μ_i is nonincreasing and such that $\mu_i \rightarrow \mu_0$, the optimal \mathcal{L}^1 cost.

Corollary: A suboptimal rational solution to the \mathcal{L}^1 optimal control problem for continuous time systems, with cost arbitrarily close to the optimal cost, can be obtained by solving a discrete-time l_1 optimal control problem for the corresponding EAS. Moreover, if $K(z)$ denotes the optimal l_1 compensator for the EAS, the suboptimal \mathcal{L}^1 compensator is given by $K(\tau s + 1)$.

III. ANALYSIS OF THE DIFFERENT RATIONAL APPROXIMATIONS

In this section we analyze the rational approximations generated by the OMK and EAS methods. The main result shows that both approximations belong to a certain subset Ω_τ of the set of rational approximations, and that the EAS method generates the best approximation among the elements of this subset. We begin by showing that the two expressions for matrix M in Theorem 2 are just another version of the interpolation conditions.

A. Characterization of All Rational Approximations

Lemma 1: For a closed-loop system of the form

$$\Phi(s) = \sum_{i=1}^q \phi_i e^{-t_i s}, \quad t_i \in \mathcal{R}_+$$

the following two conditions are equivalent

- $\Phi(z_k) = \sum_{i=1}^q \phi_i e^{-z_k t_i} = T_1(z_k), \quad k = 1, \dots, n.$
- $M = \sum_{i=1}^q \phi_i \exp(-\hat{A} t_i) L.$

Moreover, we have $\|\Phi(s)\|_A = \gamma \triangleq \sum_{i=1}^q |\phi_i|$.

Proof: b) \Rightarrow a) can be proved following the proof procedure of [6, lemma 2] by simply replacing Φ_{OPT} with Φ . Similarly, the fact that b) is necessary for a) to hold can also be concluded from the proof. The expression for $\|\Phi(s)\|_A$ follows from direct calculations.

In the next lemma we give a complete characterization of all rational approximations.

Lemma 2: For any rational closed-loop system

$$\Phi(s) = \sum_{j=1}^{q_j} \sum_{i=1}^{q_i} \phi_{ij} (1 + \lambda_j s)^{-N_{ij}}$$

where $\text{Re}(\lambda_j) > 0$ and N_{ij} integers, the following two conditions are equivalent

- $\Phi(z_k) = \sum_{j=1}^{q_j} \sum_{i=1}^{q_i} \phi_{ij} (1 + \lambda_j z_k)^{-N_{ij}} = T_1(z_k), \quad k = 1, \dots, n.$
- $M = \sum_{j=1}^{q_j} \sum_{i=1}^{q_i} \phi_{ij} (I + \lambda_j \hat{A})^{-N_{ij}} L.$

Moreover, we have $\|\Phi(s)\|_A \leq \gamma \triangleq \sum_{j=1}^{q_j} \sum_{i=1}^{q_i} |\phi_{ij}|$.

Proof: a) \Leftrightarrow b) can be proved using the same idea. The calculations, through straightforward, are tedious, and are omitted here for space reasons. By direct calculation we have

$$\begin{aligned} \|\Phi(s)\|_A &= \int_0^\infty \left| \sum_{j=1}^{q_j} \sum_{i=1}^{q_i} \phi_{ij} \frac{1}{(N_{ij}-1)! \lambda_j^{N_{ij}}} t^{N_{ij}-1} e^{-t/\lambda_j} \right| dt \\ &\leq \sum_{j=1}^{q_j} \sum_{i=1}^{q_i} |\phi_{ij}| \int_0^\infty \frac{1}{(N_{ij}-1)! \lambda_j^{N_{ij}}} t^{N_{ij}-1} e^{-t/\lambda_j} dt \\ &= \gamma \triangleq \sum_{j=1}^{q_j} \sum_{i=1}^{q_i} |\phi_{ij}|. \quad \square \end{aligned}$$

B. Comparison of the OMK and the EAS Rational Approximations

Lemma 2 gives a characterization of all rational admissible closed-loop systems. All these closed-loop systems can be thought as candidate rational approximations of the \mathcal{L}^1 -optimal closed-loop system. In the sequel we concentrate on a specific subset Ω_τ and we show that both the OMK and the EAS methods generate approximations that belong to this subset. For $\tau > 0$, define

$$\begin{aligned} \Omega_\tau &= \left\{ \Phi(s) = \sum_{i=1}^q \phi_i(\tau) (1 + \tau s)^{-N_i} : M \right. \\ &= \left. \sum_{i=1}^q \phi_i(\tau) (I + \tau \hat{A})^{-N_i} L \right\}. \end{aligned} \quad (8)$$

By direct calculation, the closed-loop system obtained by OMK methods is

$$\Phi(s) = \sum_{i=1}^m \phi_i(\tau) (1 + \tau s)^{-N_i(\tau)}.$$

Suppose that the l_1 -optimal closed-loop system for the EAS is given by

$$\Phi^E(z) = \sum_{i=1}^q \phi_i^E(\tau) z^{-N_i^E}$$

then the closed-loop system obtained using the EAS method is

$$\Phi(s) = \sum_{i=1}^q \phi_i^E(\tau) (1 + \tau s)^{-N_i^E}.$$

It follows that the approximations generated by both methods belong to the set Ω_τ , with a specific $\{N_i\}$ determined by each method.

Remark 3: In the OMK method, $\{N_i(t_i, \tau)\}$ depend directly on $\{t_i\}$, and hence on the \mathcal{L}^1 optimal closed-loop system. Hence obtaining a rational approximation requires solving the \mathcal{L}^1 optimal control problem first. However, as pointed out in Remark 1, solving exactly this problem entails solving a semi-infinite linear programming problem. The EAS method requires only solving a discrete l_1 optimal control problem, which is considerably easier, since only finite-dimensional linear programming is involved.

Remark 4 Note that additional OMK-like rational approximations can be chosen among the elements of Ω_τ by simply modifying the rule for selecting $N(t, \tau)$. For instance, N could be selected as the largest integer smaller than or equal to t_i/τ or $t/\tau + 0.5$. Clearly, the convergence property also holds for these approximations.

As it is shown in Theorem 6, the EAS method can be interpreted as approximating the original optimization problem as opposed to directly approximating its irrational solution. This makes it quite unique. Besides the computational advantages, we show in the sequel that the EAS method has two other important merits.

Theorem 5 The rational approximation of the \mathcal{L}^1 optimal controller given by the EAS method is the best one in the set Ω_τ in the sense that it leads to the smallest upper bound γ .

To prove Theorem 5, we need to prove first the following results.

Lemma 3 Consider the following discrete time systems

$$T^I = \left(\begin{array}{c|c} A_{1I} & B_{1I} \\ \hline C_{1I} & D_{1I} \end{array} \right) \triangleq \left(\begin{array}{c|c} I + \tau A_1 & \tau B_1 \\ \hline C_1 & D_1 \end{array} \right)$$

and

$$T^I = \left(\begin{array}{c|c} A_{2I} & B_{2I} \\ \hline C_{2I} & D_{2I} \end{array} \right) \triangleq \left(\begin{array}{c|c} I + \tau A_2 & \tau B_2 \\ \hline C_2 & D_2 \end{array} \right)$$

Define

$$\begin{aligned} I_I &= B_{2I} D_{1I}^{-1} \\ A_I &= A_{2I} - I_I C_{1I} \\ M_I &= I_I D_{1I} + A_I^{-1} R_{1I} B_{1I} \end{aligned}$$

where R_{1I} is the unique solution of the linear matrix equation

$$A_I^{-1} R_{1I} A_I - R_{1I} + I_I C_{1I} = 0$$

Then we have

$$M_I = \tau M$$

where M is defined in Theorem 2.

Proof First we show that A_I is always invertible. Note that

$$(I^I)^{-1} = \left(\begin{array}{c|c} A_I & -I_I \\ \hline D_{1I}^{-1} C_{1I} & D_{1I}^{-1} \end{array} \right)$$

Since it is assumed that $F(s)$ has only unstable zeros, so does $T^I(z)$. This means all the zeros (poles) of $T^I(z)$ ($(T^I)^{-1}$) have magnitudes larger than 1. Invertibility of A_I follows immediately. Recall now that R_1 is the unique solution of the following linear matrix equation

$$A R_1 - R_1 A - I C_1 = 0$$

We can verify that $A_I^{-1} R_{1I}$ also satisfies the above equation

$$\begin{aligned} A_I A_I^{-1} R_{1I} - A_I^{-1} R_{1I} A_I - I_I C_{1I} \\ = -I_I (R_{1I} - A_I^{-1} R_{1I} A_I - I_I C_{1I}) = 0 \end{aligned}$$

Hence $R_I = A_I^{-1} R_{1I}$ and $M_I = \tau M$.

Lemma 4 Consider the discrete time l_1 optimal control problem for the EAS system

$$\mu_I = \inf_{Q \in \mathcal{H}_1} \|T_1^I + T_2^I Q\|_1$$

A closed-loop system $\Phi^I(z) = \sum_{k=1}^n \phi_k z^{-k}$ is admissible i.e. satisfies the interpolation conditions

$$\Phi^I(z_k) = T_1^I(z_k) \quad k = 1, \dots, n \quad (9)$$

where z_k are the zeros of I_2^I and only if

$$M_I = \sum_{k=1}^n \phi_k A_I^{-k} L_I \quad (10)$$

Proof From the definition of EAS (9) is equivalent to

$$\Phi(z_k) = \sum_{i=1}^l \phi_i (1 + \tau z_k)^{-i} = T_1^I(z_k), \quad k = 1, \dots, n.$$

From Lemma 3 (10) is equivalent to

$$\begin{aligned} M &= \sum_{i=1}^l \phi_i (I + \tau A)^{-i} I \Leftrightarrow \\ \tau M &= \sum_{i=1}^l \phi_i (I + \tau A_2 - \tau I C)^{-i} \tau L \\ M_I &= \sum_{i=1}^l \phi_i A_I^{-i} I \end{aligned} \quad (11)$$

Equivalence of (9) and (10) follows now from Lemma 2.

Note that Lemma 4 is true for any discrete time systems since a discrete time systems can always be thought as an EAS of some continuous time systems.

Proof of Theorem 6 Consider a set of admissible closed-loop systems

$$\Omega_I = \left\{ \Phi^I(z) = \sum_{i=1}^l \phi_i z^{-i} \mid M_I = \sum_{i=1}^l \phi_i A_I^{-i} L_I \right\} \quad (12)$$

From Lemma 3 it follows that conditions (8) and (12) are identical. Therefore for every $\Phi^I(z)$ in Ω_I there exists a corresponding $\Phi(z) = \Phi^I(1 + \tau z)$ in Ω_τ and vice versa. Since

$$\sum_{k=1}^l |\phi_k| = \|\Phi^I\|_1$$

it follows that the closed loop system Φ^I obtained by solving the optimal l_1 control problem for the LAS yields the smallest γ among the elements of the set Ω_I . Hence the rational closed-loop system obtained by EAS methods also has the smallest upper bound γ among the set Ω .

C. The EAS Method Revisited

Although the results of [6] and [1] show that the optimal \mathcal{L}^1 controllers can be approximated arbitrarily close with a rational controller, these results did not provide a way of obtaining an approximation with error smaller than a prescribed bound, rather, they required solving a sequence of problems and checking the approximation error until the desired precision was achieved. In this section we indicate how to select the parameter τ for the EAS method in such a way that the error of the resulting approximation is smaller than a prescribed bound. Moreover, we show that this approximation error converges to 0 as fast as τ .

Theorem 6 Given any $\epsilon > 0$, we can find a τ a priori for the EAS method such that

$$\mu_I \leq \mu_0(1 + \epsilon)$$

Moreover, the approximation error converges to zero as $O(\tau)$.

Proof Consider the optimal l_1 control problem for the EAS

$$\mu_I = \inf_{Q \in \mathcal{H}_1} \|T_1^I(z) + T_2^I(z)Q\|_1 \quad (13)$$

and its dual

$$\mu_I = \max_v \left[\sum_{k=1}^n \alpha_k \operatorname{Re}\{T_1^I(z_k^{-1})\} + \sum_{k=1}^n \alpha_{k+n} \operatorname{Im}\{T_1^I(z_k^{-1})\} \right] \quad (14)$$

subject to

$$\begin{aligned} |T^I(z_k^{-1})| &\triangleq \left| \sum_{i=1}^l \alpha_i \operatorname{Re}\{(z_k^{-1})^{-i}\} + \sum_{i=1}^n \alpha_{i+n} \operatorname{Im}\{(z_k^{-1})^{-i}\} \right| \\ &\leq 1, \quad 0 \leq i \leq 2 \end{aligned} \quad (15)$$

where T_1^E and T_2^E are the EAS of T_1 and T_2 , respectively, and where z_k^E denotes the zeros of T_2^E . From the relationship between the EAS and its corresponding continuous system, the above dual problem is equivalent to

$$\mu_E = \max_{\alpha_j} \left[\sum_{i=1}^n \alpha_i \operatorname{Re}\{T_1(z_i)\} + \sum_{i=1}^n \alpha_{i+n} \operatorname{Im}\{T_1(z_i)\} \right] \quad (16)$$

subject to

$$\left| \sum_{i=1}^n \alpha_i \operatorname{Re}\{(1 + \tau z_i)^{-k}\} + \sum_{i=1}^n \alpha_{i+n} \operatorname{Im}\{(1 + \tau z_i)^{-k}\} \right| \leq 1, \quad k = 0, 1, 2, \dots \quad (17)$$

which can further be thought as an approximation of the dual problem of \mathcal{L}^1 -optimal control problem

$$\mu_0 = \max_{\alpha_j} \left[\sum_{i=1}^n \alpha_i \operatorname{Re}\{T_1(z_i)\} + \sum_{i=1}^n \alpha_{i+n} \operatorname{Im}\{T_1(z_i)\} \right] \quad (18)$$

subject to

$$|\tau(t, \alpha)| \triangleq \left| \sum_{i=1}^n \alpha_i \operatorname{Re}\{e^{-z_i t}\} + \sum_{i=1}^n \alpha_{i+n} \operatorname{Im}\{e^{-z_i t}\} \right| \leq 1, \quad \forall t \in R_+ \quad (19)$$

in the sense that the constraints (19) are firstly sampled at the time interval $t_k = k\tau$ and then the irrational terms $e^{-z_i t_k}$ are approximated by rational terms $(1 + \tau z_i)^{-k}$.

For simplicity, in the sequel we will assume that all the zeros z_i are real as in [4], although the proofs can be easily extended to encompass complex zeros as well.

An upper bound on $\|\alpha\|_1$ for all α satisfying the constraints (15) can be derived as follows. Define the following sets

$$\begin{aligned} S_c &= \left\{ \alpha: \left| \sum_{i=1}^n \alpha_i e^{-z_i t} \right| \leq 1 \forall t \geq 0 \right\} \\ S(\tau) &= \left\{ \alpha: \left| \sum_{i=1}^n \alpha_i (1 + \tau z_i)^{-k} \right| \leq 1 \forall k \geq 0 \right\} \\ R(\tau) &= \left\{ \alpha: \left| \sum_{i=1}^n \alpha_i (1 + \tau z_i)^{-k} \right| \leq 1 \quad k = 0, 1, \dots, n-1 \right\}. \end{aligned} \quad (20)$$

From [1] it can be shown that, if $\tau \leq \bar{\tau}$, then $S_c \subseteq S(\tau) \subseteq S(\bar{\tau})$ and $S(\tau) \subseteq R(\tau)$. Hence

$$\begin{aligned} \sup_{\alpha \in S_c} \|\alpha\|_1 &\leq \sup_{\alpha \in S(\tau)} \|\alpha\|_1 \leq \sup_{\alpha \in S(\bar{\tau})} \|\alpha\|_1 \\ &\leq \sup_{\alpha \in R(\bar{\tau})} \|\alpha\|_1 \leq \|F^{-1}(\bar{\tau})\|_{\infty, 1} \end{aligned} \quad (21)$$

where

$$F(\tau) = \begin{pmatrix} 1 & 1 & \dots & 1 \\ (1 + \tau z_1)^{-1} & (1 + \tau z_2)^{-1} & \dots & (1 + \tau z_n)^{-1} \\ \vdots & \vdots & \dots & \vdots \\ (1 + \tau z_1)^{-n+1} & (1 + \tau z_2)^{-n+1} & \dots & (1 + \tau z_n)^{-n+1} \end{pmatrix}.$$

$\|F^{-1}\|_{\infty, 1}$ denotes the induced norm of F^{-1} from l_n^∞ to l_n^1 , and where $\bar{\tau}$ is fixed.

Note also that constraints (19) will be automatically satisfied for all $t > t_{\max}$ where t_{\max} is finite and can be determined a priori [4]. Given any $t \leq t_{\max}$, assume that the constraints (17) are satisfied and consider any $t \leq t_{\max}$. Selecting k such that $t_k \leq t < t_k + \tau$ we have that

$$\begin{aligned} &\left| \sum_{i=1}^n \alpha_i (1 + \tau z_i)^{-1} - \sum_{i=1}^n \alpha_i e^{-z_i t} \right| \\ &\leq \|\alpha\|_1 \max_i \{ |(1 + \tau z_i)^{-1} - e^{-z_i t}| \} \\ &\leq \|\alpha\|_1 \left(\max_i \{ |(1 + \tau z_i)^{-1} - e^{-z_i t_k}| \} \right. \\ &\quad \left. + \max_i \{ |e^{-z_i t_k} - e^{-z_i t}| \} \right) \\ &\leq \|\alpha\|_1 \left(\max_i \{ t_{\max} \tau^{-1} |(1 + \tau z_i)^{-1} - e^{-z_i \tau}| \} \right. \\ &\quad \left. + \max_i \{ 1 - e^{-z_i \tau} \} \right) \triangleq \epsilon(\tau). \end{aligned} \quad (22)$$

The first inequality is immediate. The second one follows from the triangle inequality. The last one can be proved as follows: If $|a| \leq 1$ and $|b| \leq 1$, then

$$|a^k - b^k| = |a - b| |a^{k-1} + a^{k-2}b + \dots + b^{k-1}| \leq k|a - b|$$

so we have

$$\begin{aligned} |(1 + \tau z_i)^{-1} - e^{-z_i t_k}| &\leq k|(1 + \tau z_i)^{-1} - e^{-z_i \tau}| \\ &\leq t_{\max} \tau^{-1} |(1 + \tau z_i)^{-1} - e^{-z_i \tau}|. \end{aligned}$$

Note that both terms in the parenthesis can be made as small as one desires. So given any $\epsilon > 0$, we can choose a τ such that the right-hand side of the inequality is less than or equal to ϵ . For this value of τ we have

$$|r(t, \alpha)| = \left| \sum_{i=1}^n \alpha_i e^{-z_i t} \right| \leq 1 + \epsilon, \quad \forall t \in R_+.$$

In particular the above inequality holds for α^* which solves the dual problem of EAS. Since

$$\langle T_1, r(t, \alpha^*) \rangle = \sum_{i=1}^n \alpha_i^* T_1(z_i) = \mu_E$$

we have that

$$\mu_0 = \max_{r \neq 0} \frac{\langle T_1, r \rangle}{\|r\|_\infty} = \max_{\|r\|_\infty \leq 1} \frac{\langle T_1, r \rangle}{1 + \epsilon} \geq \frac{\mu_E}{1 + \epsilon}.$$

Finally, the fact that $\epsilon(\tau) = O(\tau)$ follows from considering the Taylor expansion of equation (22).

IV. AN EXAMPLE

Consider the example introduced in [4] and further studied in [1] and [6]. The plant is

$$P(s) = \frac{s-1}{s-2}.$$

The control objective is to minimize $\|\Phi\|_1 = \|PC(1 + PC)^{-1}\|_1$. The optimal closed-loop system is [4]

$$\Phi_{\text{OPT}}(s) = 1.7071 - 4.1213e^{-0.8814s}$$

Fig. 2 Upper bound γ versus τ : EAS method—solid line; OMK method—dotted line; and OMK-like method—dashed line.

with an optimal cost $\mu_0 = 5.8284$. For $\tau = 0.45$ the rational closed-loop system obtained using the EAS method is

$$\Phi(s) = 1.8001 - 5.1878(1 + 0.45s)^{-1}$$

with $\gamma = \|\Phi(s)\|_1 = 7.2679$. The OMK method yields

$$\Phi(s) = 2.3947 - 5.0348(1 + 0.45s)^{-1}$$

with $\gamma = \|\Phi(s)\|_1 = 7.4295$. Finally, if we consider the OMK-like approximation obtained by selecting $N(t_i, \tau) \triangleq$ largest integer smaller than or equal to t_i/τ , $i = 1, \dots, m$, we obtain

$$\Phi(s) = 4.222 - 6.122(1 + 0.45s)^{-1}$$

with $\gamma = \|\Phi(s)\|_1 = 10.341$. Fig. 2 shows the upper bounds corresponding to different approximation methods versus τ . For this example the $\| \cdot \|_1$ norm of the closed-loop system coincides with its upper bound in all cases (since there are only 2 interpolation constraints). It is interesting to note that while the bound obtained using the EAS method decreases monotonously with τ (theoretically proved in Theorem 4), those corresponding to the OMK and OMK-like methods do not. An estimated error bound $\epsilon(\tau)$ curves for this example is shown in Fig. 3. It is very close to a straight line if a linear scale is used for the τ axis.

V. CONCLUSIONS

A recent research effort [3]–[5], [7], [8], has led to techniques for designing optimal compensators that minimize the worst case output amplitude with respect to all inputs of bounded amplitude. In the discrete-time SISO case, minimizing the l^1 norm of the closed-loop impulse response yields a rational compensator. Unfortunately, the solution to the continuous-time version of the problem is nonrational. Prompted by the difficulty of physically implementing a system with a nonrational transfer function, rational approximations were recently developed [6], [1].

In this paper we compare these approximations and we show that they are strongly connected. Indeed, both approximations can be considered as elements of the same subset Ω_r of the set of rational approximations.

Fig. 3 An estimated error bound.

In Section III-B we show that the EAS method proposed in [1] yields the best approximation (in the sense of providing the tightest upper bound of the error) among the elements of this set.

Finally, in Section III-C we exploit the structure of the dual problem to provide a procedure that allows for selecting the parameter τ for the EAS method to guarantee that the approximation error is smaller than a prespecified bound ϵ . Moreover, we also show that this approximation error $\rightarrow 0$ as $O(\tau)$.

We believe that these results, combined with the features of the EAS method mentioned in [1], namely, the facts that i) it removes the ill-posedness due to the presence of zeros on the imaginary axis; ii) it leads to computationally simple problems; iii) it furnishes a monotonically nonincreasing bound; and iv) it is easily extendable to the MIMO case, make this method an attractive tool for the design of controllers for continuous time systems.

Supervisory Control of Timed Discrete-Event Systems under Partial Observation

F. Lin and W. M. Wonham

Abstract—This paper extends the authors' previous work on observability of discrete-event systems by taking time into consideration. In a timed discrete-event system, events must occur within their respective lower and upper time bounds. A supervisor can disable, enable, or force some events to achieve a given control objective. We assume that the supervisor does not observe all events, which is often the case in practice. We generalize the concept of observability to timed discrete-event systems and show that it characterizes the existence condition for a supervisor. We also generalize normality, a stronger version of observability, to timed discrete-event systems, which has nice properties that are absent in observability. We then derive conditions under which observability and normality are equivalent. We propose two methods to synthesize a supervisor, a direct approach and an indirect approach. An example is given to illustrate the results.

I. INTRODUCTION

Since the theory of supervisory control was introduced about 10 years ago in [13], many ideas have been developed, notably the concepts of controllability [13], [14], observability [3], [6], [8], and normality [8], [9], [10]. These concepts were, however, defined only for untimed discrete-event systems, in which the occurrence times of events were not modeled. As the theory advances and applications increase, there is a need to generalize these concepts to timed discrete-event systems, in which lower and upper time bounds of events are specified and events must occur within their respective lower and upper time bounds. In [1], controllability is generalized to timed discrete-event systems and supervisory control is discussed under the assumption of full event observation. In practice, however, not all events are observable due to limitations on detection and communication. In such cases, observability becomes relevant, because a supervisor must control the system based on partial observation of events. This paper is devoted to supervisory control under partial observation.

We begin with a brief review of the definitions on timed discrete-event systems and the definition of controllability of [1] in Section II. In Section III, we formalize supervisory control under partial observation and discuss the constraints it must satisfy. We also generalize the definition of observability to take time into consideration. We then prove that a supervisor exists if and only if the language to be synthesized is controllable, observable, and $L_m(G)$ -closed. If the language to be synthesized is not controllable and observable, then the problem of synthesizing an optimal supervisor becomes complicated, partly because, as to be shown in Section IV, the supremal controllable and observable sublanguage of a given maximal legal language need not exist. Two methods will be proposed to solve the synthesis problem. In the first method, a stronger version of observability, called normality, is defined. The supremal controllable and normal sublanguage of a given language exists, and preserves the $L_m(G)$ -closedness of the language, and hence a supervisor can be synthesized

based on it. We also show that this stronger version of observability is actually equivalent to observability itself if all controllable (or prohibitable) events as well as *tick* are observable. In the second method a supervisor is first synthesized assuming full observation and then modified when some events become unobservable. We show that, under some conditions, the second method is better than the first in the sense that the second method yields a supervisor generating a larger language and it can be implemented more efficiently. Finally, an example of two trains is given to illustrate the results of the paper. The development in this paper is parallel to the corresponding development by the authors on untimed discrete-event systems [8].

II. PRELIMINARIES

In this section, we briefly review the relevant results of [1] on timed discrete-event systems. Following the notation and definitions of [1], a timed discrete-event system is modeled by an automaton

$$G = (\Sigma, Q, \delta, q_0, Q_m)$$

where the events are partitioned into 1) prospective events Σ_{pr} that have finite upper time bounds, 2) remote events Σ_{rm} whose upper time bounds are infinite, and 3) tick of the global clock:

$$\Sigma = \Sigma_{\text{pr}} \cup \Sigma_{\text{rm}} \cup \{\text{tick}\}.$$

Remark 1 To exclude the physically unrealistic possibility that events in $\Sigma - \{\text{tick}\}$ occur infinitely often during one unit of time, we require that G be activity loop free [1], that is,

$$(\forall q \in Q)(\forall s \in (\Sigma - \{\text{tick}\})^+) \delta(s, q) \neq q.$$

Remark 2 If G is constructed from the activity transition graph G_{act} and time bounds on events as shown in [1], then the advance of time will never stop. Under the assumption of activity loop freedom, this is equivalent to saying that G is type-1 blocking free [11], that is,

$$(\forall s \in L(G)) \Sigma_{L(G)}(s) \neq \emptyset$$

where $\Sigma_L(s) = \{\sigma \in \Sigma : s\sigma \in L\}$.

Remark 3 Again, if G is constructed from G_{act} and time bounds on events, then the fact that no *tick* is possible after a string implies that some prospective events must be possible after that string, that is,

$$(\forall s \in L(G)) \text{tick} \notin \Sigma_{L(G)}(s) \Rightarrow \Sigma_{\text{pr}} \cap \Sigma_{L(G)}(s) \neq \emptyset.$$

In this paper, we assume that G is constructed from G_{act} and time bounds on events.

Example 1 Consider a single track linking two stations as depicted in Fig. 1. To control the movement of trains, three traffic lights are installed along the track. Also installed are four detectors to observe the movement of trains. The track is divided accordingly into four sections: S_1 , S_2 , S_3 , and S_4 .

Suppose there are two trains T_1 and T_2 scheduled to depart from Station 1 to Station 2. For T_i , $i = 1, 2$ the designated events are as follows:

- σ_{11} : T_1 entering S_1 , σ_{14} : T_1 exiting S_4
- σ_{13} : T_1 entering S_2 , σ_{16} : T_1 exiting S_2
- σ_{12} : T_1 entering S_3 , σ_{18} : T_1 exiting S_3
- σ_{15} : T_1 entering S_4 , σ_{10} : T_1 exiting S_4

Fig. 2 (Numbers denote subscripts of event)

The activity transition graphs G_{act}^i (for T_i) is given in Fig. 2. The lower time bound l_σ and upper time bound u_σ for events σ are

σ	σ_{11}	σ_{13}	σ_{12}	σ_{15}	σ_{14}	σ_{16}	σ_{18}	σ_{10}
l_σ	0	0	0	0	1	1	2	1
u_σ	∞	∞	∞	∞	1	2	3	1

Hence the prospective events are

$$\Sigma_{pro} = \{\sigma_{14}, \sigma_{16}, \sigma_{18}, \sigma_{10}, \sigma_{21}, \sigma_{26}, \sigma_{28}, \sigma_{20}\}$$

and the remote events are

$$\Sigma_{rem} = \{\sigma_{11}, \sigma_{13}, \sigma_{12}, \sigma_{15}, \sigma_{21}, \sigma_{24}, \sigma_{22}, \sigma_{27}\}$$

Simple time bounds are used here for the sole purpose of limiting the number of states. They do, however, illustrate the advantages of the timed model (cf. Section VI). More general time bounds could be used at the expense of more computation.

From G_{act}^1 , G_{act}^2 , and the time bounds, we can construct the timed discrete event system G describing the concurrent movement of T_1 and T_2 , which has 256 states.

To introduce control, let $\Sigma_{hib} \subseteq \Sigma_{rem}$ be the set of prohibitable (or uncontrollable) events, $\Sigma_f \subseteq \Sigma_{rem} \cup \Sigma_{pro}$ be the set of forcible events, and $\Sigma_{uc} = (\Sigma_{rem} \cup \Sigma_{pro}) - \Sigma_{hib}$ be the set of uncontrollable events. The following definition [1] generalizes the definition in [13].

Definition 1 Let $K \subseteq L(G)$. We define K to be controllable (with respect to $L(G)$) if, for all $s \in \bar{K}$

- 1) $\Sigma_K(s) \cap \Sigma_f = \emptyset \Rightarrow \Sigma_{L(G)}(s) \cap (\Sigma \cup \{tick\}) \subseteq \Sigma_K(s)$ and
- 2) $\Sigma_K(s) \cap \Sigma_f \neq \emptyset \Rightarrow \Sigma_{L(G)}(s) \cap \Sigma \subseteq \Sigma_K(s)$

In other words, given history $s \in \bar{K}$, if there are no forcible events available then $tick$ is not controllable; if forcible events are available, then $tick$ can be postponed. In proofs we will often use the following equivalent definition for controllability:

- 1) $(\forall s \in \bar{K}) \Sigma_{L(G)}(s) \cap \Sigma_f \subseteq \Sigma_K(s)$ and
- 2) $(\forall s \in \bar{K}) \Sigma_K(s) \cap \Sigma_f = \emptyset \wedge tick \in \Sigma_{L(G)}(s) \Rightarrow tick \in \Sigma_K(s)$

III. OBSERVABILITY

In practice, a supervisor may not be able to detect the occurrences of all events. When that happens, the existence of a supervisor is no longer guaranteed by controllability alone; we need to introduce the concept of observability. Observability for untimed discrete-event systems was introduced in [3], [8]. In this paper, we generalize this concept to timed discrete event systems.

To this end, we denote the observable events by $\Sigma \subseteq \Sigma$ and the unobservable events by $\Sigma_u = \Sigma - \Sigma$. A projection $P: \Sigma^* \rightarrow \Sigma_u^*$ is defined inductively as follows:

$$P\epsilon = \epsilon, \quad \epsilon \text{ is the empty string}$$

$$P(s\sigma) = \begin{cases} P s, & \text{if } \sigma \in \Sigma \\ (P s)\sigma, & \text{if } \sigma \in \Sigma_u \end{cases}$$

In other words, if a sequence of events s occurred in G , a supervisor can only observe $P s$. Therefore, a supervisor is now described by $\text{map } \gamma: PL(G) \rightarrow 2^\Sigma$. The language generated by γ ($L(G, \gamma)$ called closed behavior), is defined inductively as follows:

- 1) $\epsilon \in L(G, \gamma)$,
- 2) If $s \in L(G, \gamma)$, $\sigma \in \gamma(P s)$, and $s\sigma \in L(G)$, then $s\sigma \in L(G, \gamma)$, and
- 3) No other strings belong to $L(G, \gamma)$.

The language marked by γ (called marked behavior) is defined as

$$L_m(G, \gamma) = L(G, \gamma) \cap L_m(G).$$

The supervisor γ is said to be nonblocking if

$$\overline{L_m(G, \gamma)} = L(G, \gamma)$$

We say a supervisor is admissible if it satisfies the following two requirements. First, no uncontrollable events can be disabled, and second, if $tick$ is physically possible and no forcible events can preempt it, then it cannot be disabled. Formally, for all $s \in L(G, \gamma)$, we require

- 1) $\Sigma_u \subseteq \gamma(P s)$, and
- 2) $\Sigma_{L(G)}(s) \cap \gamma(P s) \cap \Sigma_f = \emptyset \wedge tick \in \Sigma_{L(G)}(s) \Rightarrow tick \in \gamma(P s)$

The system supervised under an admissible supervisor cannot have type 1 blocking as noted in the following proposition.

Proposition 1 ([12]) For all $s \in L(G, \gamma)$

$$\Sigma_{L(G)}(s) \cap \gamma(P s) \neq \emptyset \quad \square$$

We show that for a supervisor to make a correct decision (i.e., to synthesize a language K) based on partial observation, the following observability condition must be satisfied.

Definition 2 Let $K \subseteq L(G)$. We define K to be observable (with respect to $L(G)$) if, for all $s, s' \in \Sigma^*$

$$P s = P s' \Rightarrow \text{consis}(s, s')$$

where $\text{consis}(s, s')$ is true if and only if

- 1) $(\forall \sigma \in \Sigma) s\sigma \in \bar{K} \wedge s' \in \bar{K} \wedge s'\sigma \in L(G) \Rightarrow s'\sigma \in \bar{K}$, and
- 2) $(\forall \sigma \in \Sigma) s'\sigma \in \bar{K} \wedge s \in \bar{K} \wedge s\sigma \in L(G) \Rightarrow s\sigma \in \bar{K}$

In words, two strings s and s' satisfy $\text{consis}(s, s')$ if and only if s and s' are consistent with respect to one-step continuations in K . Observability requires that if two strings look the same to a supervisor, then they must be consistent. This definition is a modification of observability as defined in [8].

This observability condition together with the controllability condition guarantees the existence of a supervisor as shown in the following theorem.

Theorem 1 ([12]) Let $K \subseteq L(G)$ be a nonempty language. There exists a nonblocking supervisor γ such that $L_m(G, \gamma) = K$ if and only if the following three conditions are all satisfied:

- 1) K is controllable with respect to $L(G)$
- 2) K is observable with respect to $L(G)$, and
- 3) K is $L(G)$ -closed.

If we are only interested in the closed behavior, then we have the following corollary.

Corollary 1 Let $K \subseteq L(G)$ be a nonempty language. There exists a supervisor γ such that $L(G, \gamma) = K$ if and only if the following three conditions are all satisfied:

- 1) K is controllable with respect to $L(G)$
- 2) K is observable with respect to $L(G)$, and
- 3) K is closed.

IV. NORMALITY

The language describing a control objective is not very likely to be controllable and observable when a control objective is first specified because the objective is usually laid down independently of the consideration of controllability and observability of events. When this happens, the original control objective is not achievable by a supervisor. So we will try to achieve the largest possible part of the original control objective. This means finding, if possible, the largest sublanguage of the original language that is controllable and

observable. Such a supervisor is "optimal" in the sense that a system generating a larger language can "run" faster when driven by the same stochastic process generating event lifetimes, if a certain "fairness" condition is satisfied. The reader is referred to [7] for this result.

Let $\emptyset \neq E \subseteq L_m(G)$ be the language describing the original control objective, called the maximal legal language. We assume that E is $L_m(G)$ -closed.

The supremal controllable and observable sublanguage of E does not exist in general (see [12, example 2]) because the set of observable languages is not closed under union. To overcome this difficulty, we first modify the definition of normality introduced in [8].

Definition 3: Let $K \subseteq L(G)$. We define K to be normal (with respect to $L(G)$) if, for all $s \in \Sigma^*$,

$$s \in L(G) \wedge Ps \in P\bar{K} \Rightarrow s \in \bar{K}. \quad \square$$

Since $s \in \bar{K} \Rightarrow s \in L(G) \wedge Ps \in P\bar{K}$ is always true, K is normal if and only if $L(G) \cap P^{-1}P\bar{K} = \bar{K}$. Therefore, if K is normal, we can check whether a string $s \in L(G)$ is in \bar{K} by checking whether its projection Ps is in $P\bar{K}$. In other words, information on occurrences of unobservable events is not needed in deciding whether $s \in \bar{K}$. Hence, we expect that normality will be stronger than observability.

Proposition 2 ([12]): If K is normal, the K is observable.

The set of normal languages is algebraically better behaved than that of observable languages, in the sense that it is closed under arbitrary unions.

Theorem 2 ([12]): The set

$$CN(E) = \{K \subseteq E: K \text{ is controllable and normal}\}$$

is nonempty and closed under arbitrary unions. Therefore, the supremal element of $CN(E)$, $\sup CN(E)$, exists and belongs to $CN(E)$.

Assume that all events are observable. Then normality is automatically satisfied. So we have the following corollary.

Corollary 2: The set

$$C(E) = \{K \subseteq E: K \text{ is controllable}\}$$

is nonempty and closed under arbitrary unions. Therefore, the supremal element of $C(E)$, $\sup C(E)$, exists and belongs to $C(E)$.

Similarly, by assuming that all events are controllable, we have the following corollary.

Corollary 3: The set

$$N(E) = \{K \subseteq E: K \text{ is normal}\}$$

is nonempty and closed under arbitrary unions. Therefore, the supremal element of $N(E)$, $\sup N(E)$, exists and belongs to $N(E)$.

From the above results, we propose a direct approach to synthesize a supervisor when E is not controllable and observable. The approach is to synthesize a supervisor for $\sup C'N(E)$. For this to work, however, we need to know that $\sup C'N(E)$ is also $L_m(G)$ -closed.

Proposition 3 ([12]): If E is $L_m(G)$ -closed, then $\sup C'N(E)$ is also $L_m(G)$ -closed.

Proposition 2 shows that normality is stronger than observability. But, how strong is it? The following proposition partially answers this question. It states that if *tick* and all controllable events are observable, then normality is equivalent to observability in the presence of controllability.

Proposition 4 ([12]): Assume $\Sigma_{\text{tick}} \cup \{\text{tick}\} \subseteq \Sigma_o$. If K is controllable and observable, then K is controllable and normal.

V. MODIFICATION FOR PARTIAL OBSERVATION

In the previous section, a direct approach was proposed to synthesize a supervisor if E is not controllable and observable, that is, a supervisor was synthesized for $\sup C'N(E)$. In this section, we

propose a different approach: we will first synthesize a supervisor for $\sup C(E)$ under the assumption of full observation and then modify the supervisor for partial observation. We show that, under certain conditions, this indirect approach leads to a supervisor with a larger closed behavior. Furthermore, as shown in [4], when the resulting supervisor is implemented on-line, the computational complexity for updating control after observing a new event is linear with respect to the number of states in the supervisor for full observation. In other words, in the worst case, the computational complexity of the indirect approach at each step is of the order $O(|X|)$, in comparison with the total complexity of $O(2^{|X|})$ for the direct approach, where $|X|$ is the number of states in the refined generator of K .

We need the following preliminary results.

Proposition 5 ([12]): The set

$$\overline{CN}(\bar{E}) = \{K \subseteq \bar{E}: K \text{ is closed, controllable, and normal}\}$$

is nonempty and closed under arbitrary unions. Therefore, the supremal element of $\overline{CN}(\bar{E})$ exists, belongs to $\overline{CN}(\bar{E})$, and is given by

$$\sup \overline{CN}(\bar{E}) = \sup C'N(\bar{E}). \quad \square$$

By this proposition, we do not need to distinguish $\sup \overline{CN}(\bar{E})$ and $\sup C'N(\bar{E})$.

Corollary 4: The set

$$\bar{C}(\bar{E}) = \{K \subseteq \bar{E}: K \text{ is closed and controllable}\}$$

is nonempty and closed under arbitrary unions. Therefore, the supremal element of $\bar{C}(\bar{E})$ exists, belongs to $\bar{C}(\bar{E})$, and is given by

$$\sup \bar{C}(\bar{E}) = \sup \bar{C}(\bar{E}). \quad \square$$

Corollary 5: The set

$$\bar{N}(\bar{E}) = \{K \subseteq \bar{E}: K \text{ is closed and normal}\}$$

is nonempty and closed under arbitrary unions. Therefore, the supremal element of $\bar{N}(\bar{E})$ exists, belongs to $\bar{N}(\bar{E})$, and is given by

$$\sup \bar{N}(\bar{E}) = \sup \bar{N}(\bar{E}). \quad \square$$

Since $\sup C'(\bar{E}) = \sup \bar{C}(\bar{E})$ is closed and controllable, we can synthesize a supervisor with full observation $\gamma': L(G) \rightarrow 2^X$ such that

$$L(G, \gamma') = \sup C'(\bar{E})$$

where $L(G, \gamma')$ is defined in the same way for $L(G, \gamma)$ except that $Ps = s$.

Under partial observation, we modify γ' to a supervisor $\gamma: PL(G) \rightarrow 2^X$ as follows. Let $[t] = P^{-1}(t) \cap L(G, \gamma')$ be the set of strings in $L(G, \gamma')$ having the projection t and

$$\gamma(t) = \bigcup_{s \in [t]} (\gamma'(s) \cup (\Sigma - \Sigma_{I(t)}(s))).$$

A similar modification was introduced in [4] for untimed discrete event systems. However, for a timed discrete-event system, the issues of forcible events and nonblocking need to be dealt with differently. To this end, we define coherence as follows.

Definition 4: Let $K \subseteq L(G)$. We define K to be coherent (with respect to $L(G)$) if, for all $s \in \bar{K}$,

$$\begin{aligned} \text{tick} \in \Sigma_{L(t)}(s) &\Rightarrow (\forall s', s'' \in P^{-1}Ps \cap \bar{K}) \\ &\quad (\Sigma_K(s') \cap \Sigma_{\text{tick}} = \Sigma_K(s'') \cap \Sigma_{\text{tick}}) \\ &\quad \wedge (\Sigma_{L(t)}(s') \cap \Sigma_{\text{tick}} = \Sigma_{L(t)}(s'') \cap \Sigma_{\text{tick}}). \end{aligned}$$

In words, if K is coherent, then for every string s that can be followed by *tick* in $L(G)$, the set of forcible events that are feasible (or legal) after any string having the same projection as s is the same.

Fig. 3. (Horizontal events in same column, or vertical events in same row are same.)

Proposition 6 ([12]): If γ' is an admissible supervisor and $L(G, \gamma')$ is coherent, then γ is also an admissible supervisor.

This modified supervisor γ may block. To guarantee nonblocking, it is convenient to introduce the additional condition of livelock-freedom [5]. First, let us recall the definition of livelock-freedom given in [5].

Definition 5: Let $K \subseteq \Sigma^*$. We define K to be livelock free if, for all $s \in \bar{K}$

$$(\exists n \in \mathbb{N})(\forall t \in \Sigma^*)|t| \geq n \wedge st \in \bar{K} \Rightarrow (\exists u \in \Sigma^*) (s \leq u \leq st \wedge u \in K)$$

where \mathbb{N} denotes the set of natural numbers and $s \leq u$ denotes that s is a prefix of u .

In words, if K is livelock-free, then every infinite chain of strings in \bar{K} visits the set of marker states infinitely often.

Proposition 7 ([12]): If $L_m(G)$ is livelock-free and γ is admissible, then γ is nonblocking.

The implication of the above proposition is that, under the assumption of livelock-freedom, any admissible supervisor is nonblocking. Finally, we can prove that the modified supervisor generates only legal behavior that contains at least $\sup CN(E)$.

Theorem 3 ([12]): The language marked by the modified supervisor γ is bounded by

$$\sup CN(E) \subseteq L_m(G, \gamma) \subseteq E. \quad \square$$

To conclude this section, we note that $L(G, \gamma)$ obtained this way may not be maximal (see Example 3 in [12]).

VI. EXAMPLE

We continue our discussion of the example in Section II. Our control objective is to prevent two trains from colliding. So the corresponding maximal legal language E can be obtained by deleting states in G corresponding to two trains being in the same section at the same time.

Because of the locations of the traffic lights and detectors, the controllable and observable events are

$$\begin{aligned} \Sigma_{lib} &= \{\sigma_{11}, \sigma_{13}, \sigma_{15}, \sigma_{21}, \sigma_{23}, \sigma_{25}\} \\ \Sigma_o &= \{\sigma_{11}, \sigma_{12}, \sigma_{15}, \sigma_{10}, \sigma_{21}, \sigma_{22}, \sigma_{25}, \sigma_{20}\}. \end{aligned}$$

Fig. 4. (Horizontal events in same column, or vertical events in same row are the same.)

Since the movement of a train can be initiated, we assume the following events are forcible:

$$\Sigma_{for} = \{\sigma_{11}, \sigma_{13}, \sigma_{12}, \sigma_{15}, \sigma_{21}, \sigma_{23}, \sigma_{22}, \sigma_{25}\}.$$

To compare the result with that of untimed model, we use the direct method to synthesize a supervisor. We first calculate $\sup CN(E)$ and then synthesize a supervisor based on $\sup CN(E)$.

In [6], the same example is discussed in the untimed framework. Only events $\Sigma_{unt} = \{\sigma_{11}, \sigma_{13}, \sigma_{12}, \sigma_{15}, \sigma_{10}, \sigma_{21}, \sigma_{23}, \sigma_{22}, \sigma_{25}, \sigma_{20}\}$ are used in the untimed model. Therefore, we project $\sup CN(E)$ onto Σ_{unt} and compare it (Fig. 3) with the controlled behavior of the untimed model (Fig. 4) from [6]. Clearly, the timed model allows more strings to be generated. This is due to the additional information provided by the timed model. For example, in the untimed model, the fact that a train has left S_1 cannot be verified until it enters S_3 (where a detector is located). However, in the timed model, this can be inferred by the passage of one unit of time as a consequence of the time bounds imposed.

VII. CONCLUSION

We have generalized supervisory control under partial observation to timed discrete-event systems. Observability and normality are generalized to express the existence conditions of a supervisor for timed discrete event systems. Two approaches for supervisor synthesis are proposed. Although the detailed derivations of the results are different from those for untimed discrete-event systems, the two developments are parallel. Future research will focus on efficient implementations [2] and decentralized supervision [3], [8], [9].

Apology and Correction to "Process Control and Machine Learning: Rule-Based Incremental Control"

Dominique Luzeaux and Bertrand Zavidovique

APOLOGY AND CORRECTION

It has come to our attention that the name of the second author was omitted from the above paper appearing in the June, 1994, issue of *TRANSACTIONS ON AUTOMATIC CONTROL*, pp. 1166–1171. Due to an apparent error in transcription, a former editorial assistant omitted the name of Bertrand Zavidovique, who was the second author on this paper. Through a regrettable and remarkably coincidental sequence of oversights, the original error was not corrected either in the typesetting of the article or in the proofreading of the galleys by the first author. The *TRANSACTIONS* offers a sincere apology to Prof. Zavidovique for this mistake and hereby provides publication of the title and authors as it should have appeared in June. The paper in question appears in vol. 39, no. 6.

Book Reviews.

In this section, the IEEE Control Systems Society (CSS) publishes reviews of books in the control field and related areas. Readers are invited to send comments on these reviews for possible publication in the Technical Notes and Correspondence section of this TRANSACTIONS. The CSS does not necessarily endorse the opinions of the reviewers.

If you have used an interesting book for a course or as a personal reference, we encourage you to share your insights with our readers by writing a review for possible publication in the TRANSACTIONS. All material published in the TRANSACTIONS is reviewed prior to publication. Submit a completed review or a proposal for a review to:

Mathematical Control Theory: Deterministic Finite-Dimensional Systems—Eduardo D. Sontag (New York: Springer-Verlag, 1990). *Reviewed by Stephen P. Boyd.*

The title of this book gives a very good description of its contents and style, although "Introduction to" could be added to the beginning. The style is mathematical: precise, clear statements (i.e., theorems) are asserted, then carefully proved. The book covers many of the key topics in control theory, except (as the subtitle has warned us) those involving stochastic processes or infinite-dimensional systems. The level is appropriate for a senior undergraduate majoring in mathematics or a graduate student in electrical engineering who has been exposed to the style of mathematics (in a first course on analysis or algebra). This book fills an important niche and can play a key role in increasing the awareness and appreciation of control theory among mathematicians.

The first chapter is a nicely written extended discussion about what control theory is. Sontag introduces some of the key concepts (e.g., system, feedback, state-space, and nonlinearity) with simple examples in an informal style. For an engineering graduate student, it will be a review of some undergraduate courses; for the mathematics student, it provides some cultural background for the rest of the book. This chapter is not in the same style as the remainder of the book so I might have numbered it Chapter 0. There are no theorems or proofs, and Sontag keeps the discussion at the level of informal ideas, for example, (p. 5) "Designs based on linearizations work locally for the original system." Pity the mathematics student who then searches backward for the precise definition of the terms "design" and "work"!

The book proper starts at Chapter 2, which covers the abstract idea of a system. The style jumps from the informality of Chapter 1 to a more in-depth style with a list of long mathematical definitions. Sontag writes that the chapter contains some "abstract nonsense" (p. ix), e.g., very general and abstract definitions of a dynamical system. On this topic he points out a very good analogy from the foundations of mathematics. A student of mathematics first thinks of a function in an informal way, as a "mapping" or "subroutine." The student then encounters the formal definition of a function from A to B as a subset of $A \times B$ which satisfies certain properties. Not long thereafter

the student reverts to the more informal model of a function as a "mapping" or "subroutine." The difference is that now the student really knows what a function is. In a similar way, Chapter 2 introduces the student to the formal definition of a dynamical system. After this introduction, the student can revert to a less formal idea of a dynamical system (e.g., "the state summarizes the effects of the past inputs on the future outputs"). But now, these ideas rest on a firm footing. Sontag punctuates the heavy definitions with nice examples, which makes the medicine of a formal foundation easier to take.

Chapter 3 covers various topics involving reachability and controllability. Sontag examines these topics in some depth for the important special case of linear, time-invariant (LTI) systems. The treatment might be too brief for the student who has had no previous exposure to LTI systems; this is no problem for the engineering graduate student, who will have had one or possibly two courses which use these ideas.

Chapter 4 covers (state) feedback, with a bit on Lyapunov stability. In this chapter, the author gives a precise statement of the linearization principle described informally in Chapter 1. Chapter 5 covers the dual notion of observability as well as an introduction to realization theory and minimality. Although Section 5.8, Abstract Realization Theory,* is marked as skippable, it shows the advantage of the abstract approach: generality. As an example, Sontag constructs a minimal realization of a parity check system.

In Chapter 6 Sontag considers observers and dynamic feedback. He cannot give a detailed discussion of the design of observers (e.g., the trade-off between convergence rate and noise sensitivity) since he assumes no knowledge of stochastic processes, but he does give a deterministic version of the Kalman filter in the next (and final) chapter, which covers optimal control. Two sections in Chapter 6 are too brief for students who have not been introduced to the topics: frequency-domain considerations (Section 6.4) and parameterization of stabilizers (Section 6.5). These sections should have been marked as optional or even not covered (like stochastic processes).

Chapter 7 covers optimal control, taking Bellman's dynamic programming approach. One of the advantages of this approach is that it applies to more abstract systems (e.g., finite state systems) so an example of this type would be useful before launching into the traditional case of a linear system with quadratic cost. This chapter ends with a nice deterministic development of the Kalman filter. Here the goal is to find the initial state that minimizes an integral quadratic measure of the difference between the output observed and the output predicted, given the initial state.

The reviewer is with the Information Systems Laboratory, Department of Electrical Engineering, Stanford University, Stanford, CA 94305 USA.
IEEE Log Number 9407567.

The appendixes cover very useful material, e.g., singular value decomposition. It is a pity that some of these topics are not covered in the traditional mathematics curriculum.

The book contains about 400 references. A list of references does not have great added value today because of computerized literature searches. Sontag, however, ends each chapter with a very useful Notes and Comments section with annotated pointers to the references. The references seem to be concentrated in Western journals (e.g., IEEE TRANSACTIONS ON AUTOMATIC CONTROL, *Systems and Control Letters*); only a handful are from the former Soviet Union, which has a very strong tradition in mathematical control theory tracing back to Pontriagin and Lyapunov. I must admit that this comment applies equally as well to the books I have written.

There are several uses for this book. It would work very well as the text for an undergraduate senior-level mathematics course. This course could replace, or at least complement, the traditional course on 19th century calculus of variations that is often found as a senior-level mathematics elective. The course could also serve graduate students in engineering.

The second use for the book is as a reference or supplementary text for engineering graduate students, particularly Ph.D. students. These students have already been exposed to many of the ideas in Sontag's book in engineering-oriented courses. Often in their first year of Ph.D. study they firm up their mathematics background by taking mathematics courses such as analysis, functional analysis, abstract algebra, and differential geometry. Sontag's book serves as an excellent bridge between the two disciplines: it covers topics traditionally treated in engineering courses, but in a mathematical style.

One similar book is Vidyasagar [3], which is oriented more towards the advanced engineering student and I think more appropriate for an engineering course on advanced control theory. The book by Delchamps [1] could serve as a secondary text with Sontag's book, since it covers more linear systems theory, also in a precise mathematical style. The book by Wonham [4] covers linear system and control theory in the most elegant mathematical style. It could serve as the text for a sequel to the introductory mathematical control theory course based on Sontag's book. The recent text by Zabczyk [5], *Mathematical Control Theory: An Introduction*, is similar to Sontag's book in style, level, and coverage. Zabczyk's choice of more advanced topics differs from Sontag's; Zabczyk includes more on optimal control as well as a fairly complete introduction to infinite-dimensional systems.

Sontag clearly put much thought and effort into this book, and it shows. The book succeeds in conveying the important basic ideas of mathematical control theory, with appropriate level and style, to seniors in mathematics.

Bilinear systems

- bilinear systs, adaptive stabilization, least sq *Xi Sun* + T-AC Jan 94 207-211
 bilinear systs, state space anal orthogonal series approach *Paraskevopoulos P N* + T-AC Apr 94 793-797
 finite-time optimal control of bilinear systs successive approx procedure *Aganovic Z* + T-AC Sep 94 1932-1935
 output feedback problem in lin systs, bilinear formulation *Syrmos V I* + T-AC Feb 94 410-414

Biological control systems

- cat, falling near-optimal nonholonomic motion planning *Fernandes C* + T-AC Mar 94 450-463

Biomechanics

- cat, falling near-optimal nonholonomic motion planning *Fernandes C* + T-AC Mar 94 450-463

Book reviews

- Adaptive Control Systems (Isermann, R, et al 1992) *Kanellakopoulos I* + T-AC Aug 94 1776
 Applications of Lyapunov Methods in Stability (Halanay A and Rasvan V, 1993) *Popov I M* T-AC Dec 94 2526-2527
 Applied Optimal Control and Estimation (Lewis I I 1992) *Kamen E W* T-AC Aug 94 1773-1774
 Controlled and Conditioned Invariants in Linear System Theory (Basile G, and Marro, G, 1992) *Schumacher J M* T-AC Jan 94 250-251
 Feedback Control Theory (Doyle, J et al 1992) *Moore K L* T-AC Jul 94 1532-1534
 Handbook of Intelligent Control Neural Fuzzy and Adaptive Approaches (White D A, and Sofge, D A Eds 1992) *Samad T* T-AC Jul 94 1534-1535
 H_∞ Control Problem A State Space Approach (Stoorvogel A, 1992) *Saberi A* T-AC Jan 94 252-254
 Linear Multivariable Control Algebraic Analysis and Synthesis Methods (Vardulakis, A I G, 1991) *Lewis F L* T-AC Jul 94 1536
 Linear System Theory (Rugh W J 1993) *Khalil H K* T-AC Dec 94 2528-2529
 New Tools for Robustness of Linear Systems (Barmish B R 1994) T-AC Dec 94 2525-2526
 Nonlinear System Analysis, 2nd edn (Vidyasagar M 1993) *Abed E H* T-AC Jul 94 1535-1536
 Nonlinear Systems (Khalil H 1992) *Grizzle J W* T-AC Jan 94 251-252
 Robot Dynamics and Control (Spong, M W and Vidyasagar, M, 1989) *Pota H R* + T-AC Aug 94 1774-1776

Boundary-value problems

- dyn syst simul, fast parallel recursive aggregation *Fu W K* + T-AC Mar 94 534-540
 multipoint boundary value stochastic systs stationarity/reciprocity *Ji Chen* + T-AC May 94 1114-1116

Brushless rotating machines

- brushless DC motors, feedback-lin control charactn *In-Joong Ha* + T-AC Mar 94 673-677

C**Cascade systems**

- cascaded nonlin systs, global robust stabilization *Imura J-I* + T-AC May 94 1084-1089
 lin continuous-time systs, global stabilization, bounded control *Sussmann H J* + T-AC Dec 94 2411-2425
 robust control design, cascade struct approach *Bonivento C* + T-AC Apr 94 846-849

- stabilization of discrete-time nonlin sys^ts, global *Byrnes C J* + *T-AC Jan 94* 83-98
- Chaos**
adaptive control sys^ts, chaotic behavior *Gonzalez G A* + *T-AC Oct 94* 2145-2148
- Circuit noise; cf. Filter noise**
- Circuits; cf. Sample-and-hold circuits**
- Communication channels**
optimal multicopy Aloha *Wong E W M* + *T-AC Jun 94* 1233-1236
- Communication network routing**
data network path formulated optimal routing time complexity *Antonio J K* + *T-AC Feb 94* 385-391
deterministic/stochastic queuing networks anal *Cheng-Shang Chang T-AC May 94* 913-931
distributed asynchronous routing, convergence rate *Zhi-Quan Luo* + *T-AC May 94* 1123-1129
queuing networks anal, projection techs *Mooi Choo Chuah T-AC Aug 94* 1588-1599

Geometry

- output feedback problem in lin. systs., bilinear formulation. *Syrmos, V.L.*, +, T-AC Feb 94 410-414
- uncertain nonlin. systs., struct. invariance. *Castro-Linares, R.*, +, T-AC Oct 94 2154-2158

Geometry; cf. Computational geometry; Differential geometry

Gradient methods

- path formulated optimal routing algm., time complexity. *Antonio, J.K.*, +, T-AC Sep 94 1839-1844

Graph theory

- complex discrete-time control systs., simul. automation. *Ellis, R.D.*, +, T-AC Sep 94 1795-1801
- continuous coprime factors. *Treil, S.*, T-AC Jun 94 1262-1263
- data network path formulated optimal routing, time complexity. *Antonio, J.K.*, +, T-AC Feb 94 385-391
- LP, timed marked graphs eval. *Yamada, T.*, +, T-AC Mar 94 696-698
- packet switching, flow control, rate-based, monotonicity/concavity. *Budka, K.C.*, T-AC Mar 94 544-548
- path formulated optimal routing algm., time complexity. *Antonio, J.K.*, +, T-AC Sep 94 1839-1844
- stochastic dyn. job shops/prod. planning. *Sethi, S.*, +, T-AC Oct 94 2061-2076
- stochastic timed-event graphs, superposn. props./perform. bounds. *Xiao-Lan Xie*, T-AC Jul 94 1376-1386

Graph theory; cf. Trees, graphs

H

Hermitian matrices

- polynomial J-spectral factorization. *Kwakernaak, H.*, +, T-AC Feb 94 315-328
- spectral rad. bounds in terms of Hermitian parts. *Rachid, A.*, T-AC Jan 94 196-198

Hilbert spaces

- constrained optim. in Hilbert space. *Shimizu, K.*, +, T-AC May 94 982-986
- finite-dimens. controllers designed for infinite-dimens. systs., state space. *Morris, K.A.*, T-AC Oct 94 2100-2104

 H^∞ optimization

- $2\frac{1}{2}$ -d.o.f. LQG control, rel., H^2 control. *Grimble, M.J.*, T-AC Jan 94 122-127
- book review; H_∞ Control Problem: A State Space Approach (Stoorvogel, A.; 1992). *Saberi, A.*, T-AC Jan 94 252-254
- discrete-time Riccati eqn., H_∞ control appl. *Stoorvogel, A.A.*, +, T-AC Mar 94 686-691
- discrete-time systs., mixed H_2/H_∞ control, exact convex optim. based soln. *Sznaier, M.*, T-AC Dec 94 2511-2517
- dissipative H_2/H_∞ controller synthesis. *Haddad, W.M.*, +, T-AC Apr 94 827-831
- dual-rate control syst., sampled-data, stabil. robustness. *Tongwen Chen*, T-AC Jan 94 164-167
- floating platform, modeling and control. *Damen, A.A.H.*, +, T-AC May 94 1075-1078
- H_∞ compensator design, min. order observers. *Hsu, C.S.*, +, T-AC Aug 94 1679-1681
- H_∞ control of discrete-time uncertain systs. *Geromel, J.C.*, +, T-AC May 94 1072-1075
- H_∞ control, state availability rel., pole/zero cancellations. *Miyamoto, S.*, +, T-AC Feb 94 379-381

- H_∞ multiobjective robust control, infinite-horizon. *Theodor, Y.*, +, T-AC Oct 94 2130-2134
- H_∞ -norm approx. of systs. by const. matrices. *Kavranoglu, D.*, T-AC May 94 1006-1009
- H_∞ -optim., reduced order observer based controller. *Stoorvogel, A.A.*, +, T-AC Feb 94 355-360
- H_∞ optim., time-domain constraints. *Rotstein, H.*, +, T-AC Apr 94 762-779
- H^∞ -optimal control for sing. perturbed systs., imperfect state meas. *Zigang Pan*, +, T-AC Feb 94 280-299
- LTI syst. pos. real control. *Weiglan Sun*, +, T-AC Oct 94 2034-2046
- mixed H_2/H_∞ control, Nash game approach. *Limebeer, D.J.N.*, +, T-AC Jan 94 69-82
- mixed H_2/H_∞ perform. objectives. *Kemin Zhou*, +, T-AC Aug 94 1564-1574
- mixed H_2/H_∞ perform. objectives, optimal control. *Doyle, J.*, +, T-AC Aug 94 1575-1587
- nonlin. syst. H_∞ control, output-feedback based. *Lu, W.-M.*, +, T-AC Dec 94 2517-2524
- rational transfer fn., optimal L_∞ approx. *Kavranoglu, D.*, +, T-AC Sep 94 1899-1904
- risk-averse decentralized discrete-time LEQG games. *Srikant, R.*, T-AC Apr 94 861-864
- sampled data control systs., H_∞ type problem. *Hayakawa, Y.*, +, T-AC Nov 94 2278-2284
- SISO-distributed plants, optimal mixed sensitivity. *Flamm, D.S.*, +, T-AC Jun 94 1150-1165
- state delayed systs., memoryless H^∞ controllers. *Joon Hwa Lee*, +, T-AC Jan 94 159-162
- worst case ident., H^∞ model validation. *Guoxiang Gu*, T-AC Aug 94 1657-1661
- Hurwitz stability; cf. Routh methods**
- Hysteresis nonlinearities**
- nonminimum phase first-order continuous-time systs., adaptive stabilization. *Lozano, R.*, +, T-AC Aug 94 1748-1751
- uncertain SISO min phase lin. syst., nonlin. universal servomechanism. *Ryan, E.P.*, T-AC Apr 94 753-761

I

Identification

- discrete time Hammerstein syst. ident. *Lang Zi-Qiang*, T-AC Mar 94 569-573
- signed output error adaptive ident., convergence. *Garnett, J.*, +, T-AC Jul 94 1387-1399

Identification; cf. Parameter identification, System identification

Image processing

- multiscale recursive estim., data fusion/regularization. *Chou, K.C.*, +, T-AC Mar 94 464-478

Information theory

- dyn. shock-error models, online estim. *Krishnamurthy, V.*, T-AC May 94 1129-1135

Innovations methods (stochastic processes)

- lin. discrete-time systs., optimum lin. recursive estim. *Carazo, A.H.*, +, T-AC Aug 94 1636-1638

Input-output stability

- interval plants, closed-loop hyperstability. *Foo, Y.K.*, +, T-AC Jan 94 151-154
- nonlin. discrete-time systs., input-to-state stabil. condition and global stabilization. *Kazakos, D.*, +, T-AC Oct 94 2111-2113
- robust direct adaptive controllers, normalization tech. *Gang Feng*, +, T-AC Nov 94 2330-2334
- semi-cancellable fraction transfer fns. in syst. theory. *Bourles, H.*, T-AC Oct 94 2148-2153

Integer programming

- vector discrete-event syst. controller synthesis. *Yong Li*, +, T-AC Mar 94 512-531

Integration (math.)

- delta-operator formulated discrete-time approx. *Premaratne, K.*, +, T-AC Mar 94 581-585

Integration (math.); cf. Numerical integration

Intelligent control

- book review; Handbook of Intelligent Control: Neural, Fuzzy and Adaptive Approaches (White, D.A., and Sofge, D.A., Eds., 1992). *Samad, T.*, T-AC Jul 94 1534-1535
- continuous-time nonlin. systs. adaptive control by neural nets. *Fu-Chun Chen*, +, T-AC Jun 94 1306-1310
- rule-based incremental control, machine learning. *Luzeaux, D.*, T-AC Jan 94 1166-1171

Interconnected systems

- discrete-time systs., stabil. robustness anal. *Karan, M.*, +, T-AC May 94 991-995

- interconnected systs, decentralized adaptive regulation *Changyun Wen* *T-AC Oct 94* 2163-2166
- large scale interconnected systs with delays, decentralized stabilization *Zhongzhi Hu* *T-AC Jan 94* 180-182
- nonlin discrete-time systs, input-to-state stabil condition and global stabilization *Kazakos, D., +*, *T-AC Oct 94* 2111-2113
- uncertain nonlin interconnected systs, time-varying state delay, stabilizing control *Mahmoud MS* *T-AC Dec 94* 2484-2488
- interconnected systems; cf. Cascade systems, Large-scale systems
- interference; cf. Noise
- interpolation
- four-block problem, recursive Schur-based soln *Constantinescu T +* *T-AC Jul 94* 1476-1481
- polynomial J-spectral factorization *Kwakernaak H +* *T-AC Feb 94* 315-328
- SISO systs, robust stabilization *Olbrot A W +* *T-AC Mar 94* 652-657
- time-variant displacement struct and interpolation problems *Sayed A H +* *T-AC May 94* 960-976
- Interpolation; cf. Spline functions
- Inverse problems
- discrete-time q-Markov cover generation inverse Lyapunov method *Sreeram V +* *T-AC Feb 94* 381-385
- lin discrete syst pole assignment *Benzaouia A* *T-AC Oct 94* 2091-2095
- Inverse problems, linear; cf. Matrix inversion
- Irreducible realizations, cf. Minimal realizations
- Iterative methods
- data network path formulated optimal routing, time complexity *Antonio J K +* *T-AC Feb 94* 385-391
- dyn syst simul, fast parallel recursive aggregation *Tsai W K +* *T-AC Mar 94* 534-540
- fault detect filters eigenstructure assignment *Jaehong Park +* *T-AC Jul 94* 1521-1524
- interval lin control syst robust parametric design *Keel I II +* *T-AC Jul 94* 1524-1530
- least absol values estim, computational aspects *Fiodorov E D* *T-AC Mar 94* 626-630
- matrix sign ln calc iterated fraction expansion *Koc C K +* *T-AC Aug 94* 1644-1647
- path formulated optimal routing algm time complexity *Antonio J K +* *T-AC Sep 94* 1839-1844
- pole placement by output feedback *Iee T H +* *T-AC Mar 94* 565-568
- queuing networks anal projection techs *Mooi Choo Chuah* *T-AC Aug 94* 1588-1599
- Riccati eqn discrete alg iter matrix bounds *Komaroff N* *T-AC Aug 94* 1676-1678
- state-constrained optimal control generalised dual quasi-Newton algm *Shimizu K +* *T-AC May 94* 982-986
- textured iter algm for tridiagonal lin eqns *Tian-Shen Tang* *T-AC Mar 94* 592-596

J

Jump parameter systems

- discrete-time Markovian jump lin systs, lin min MSF estim *Costa O I V* *T-AC Aug 94* 1685-1689
- jump lin systs coupled Riccati eqns *Abou Kandil H +* *T-AC Aug 94* 1631-1636
- jump-Markov systs stabilizing control law *Dufour F +* *T-AC Nov 94* 2354-2357

K

Kalman filtering

- autonomous vision-based mobile robot *Baumgartner E T +* *T-AC Mar 94* 493-502
- lyn shock-error models, online estim *Krishnamurthy V* *T-AC May 94* 1129-1135
- uaranteed estim problem, Kalman-Bucy filter appl *Golovan A +* *T-AC Jun 94* 1282-1286
- uaranteed param estim problem with uncertain stats, Kalman-Bucy filter accuracy *Matasov A I* *T-AC Mar 94* 635-639
- in sing perturbed systs, Kalman filtering *Gajic Z +* *T-AC Sep 94* 1952-1955
- IMO stochastic discrete syst state estim *Liu Danyang +* *T-AC Oct 94* 2087-2091
- modified EKF *Ahmed N U +* *T-AC Jun 94* 1322-1326
- ultiscale recursive estim, data fusion/regularization *Chou K C +* *T-AC Mar 94* 464-478
- ultiscale systs, Kalman filters, Riccati eqns *Chou K C +*, *T-AC Mar 94* 479-492

- optimal cost control/filtering, uncertain lin systs *Petersen, I R., +* *T-AC Sep 94* 1971-1977
- three-block generalized/std Riccati eqns comparison *Darouach, M., +*, *T-AC Aug 94* 1755-1758
- uncertain discrete time systs appl *Lihua Xie, +* *T-AC Jun 94* 1310-1314
- Kalman filtering; cf. Adaptive Kalman filtering
- Knowledge-based systems
- rule-based incremental control, machine learning *Luzeaux D, T-AC Jun 94* 1166-1171

L

Laguerre processes

- lin syst approx, time-scaling factor, Laguerre models *Wang I +* *T-AC Jul 94* 1463-1467

Land navigation

- autonomous vision-based mobile robot *Baumgartner E T +* *T-AC Mar 94* 493-502

Laplace transforms

- transfer fn param ident in freq domain *Pintelon R +* *T-AC Nov 94* 2245-2260

Large-scale integration; cf. Very-large-scale integration

Large-scale systems

- complex discrete-time control systs, simul automation *Ellis R D +* *T-AC Sep 94* 1795-1801
- H[∞]-optimal control for sing perturbed systs, imperfect state meas *Zigang Pan +* *T-AC Feb 94* 280-299
- large scale interconnected systs with delays, decentralized stabilization *Zhongzhi Hu* *T-AC Jan 94* 180-182
- sing perturbed control systs and nonlin differential-alg eqns *Krishnan H +* *T-AC May 94* 1079-1084

Large-scale systems; cf. Interconnected systems, Reduced-order systems

Learning control systems

- P-type learning control *Saab S S* *T-AC Nov 94* 2298-2302
- rule-based incremental control, machine learning *Luzeaux D* *T-AC Jun 94* 1166-1171

Learning systems

- autonomous vision-based mobile robot *Baumgartner E T +* *T-AC Mar 94* 493-502
- continuous-time nonlin systs adaptive control by neural nets *Fu-Chuang Chen +* *T-AC Jun 94* 1306-1310
- I/O map inverse pass learning update-spline-smoothing *Heiss M* *T-AC Feb 94* 259-268
- robotic arms, repositioning control by learning *Lucibello P* *T-AC Aug 94* 1690-1694
- rule-based incremental control, machine learning *Luzeaux D* *T-AC Jun 94* 1166-1171

Least-mean-square methods

- H_∞ control syst ident least sq methods comment *Livstone M M +* *T-AC Jul 94* 1531

Least-squares methods

- adaptive pole placement without excitation probing sigs *Lozano R +* *T-AC Jan 94* 47-58
- bilinear systs, adaptive stabilization, least sq *Xi Sun +* *T-AC Jan 94* 207-211
- convergence of least sq estim in white noise *Nassiri-Toussi K +* *T-AC Feb 94* 364-368
- discrete-time adaptive nonlin syst least sq estimator *Kanellakopoulos I* *T-AC Nov 94* 2362-2365
- efficient algm for least sq estim *Rafajlowicz E +* *T-AC Jun 94* 1241-1243

- freq. response aros, stable polynomial, convexity. *Keqin Gu*, *T-AC Nov 94* 2262-2265

Realization theory; cf. Minimal realizations**Real-time systems**

constrained nonlin. syst. receding horizon control. *Shin-Yeu Lin*, *T-AC Sep 94* 1893-1899

Recursive digital filters

1-D and 2-D digital recursive filters, stabil., Schur polynomials. *Barret, M.*, +, *T-AC Nov 94* 2335-2339
optimal filtering, stochastic discrete-time systs., unknown inputs. *Borisov, A.V.*, +, *T-AC Dec 94* 2461-2464

Recursive estimation

lin. discrete-time systs., optimum lin. recursive estim. *Carazo, A.H.*, +, *T-AC Aug 94* 1636-1638
multiscale recursive estim., data fusion/regularization. *Chou, K.C.*, +, *T-AC Mar 94* 464-478
recursive prediction error algm. log likelihood fn. derivatives. *Hooker, M.A.*, *T-AC Mar 94* 662-664
stochastic lin. discrete systs., state estim. algm. *Ahmed, M.S.*, *T-AC Aug 94* 1652-1656
time-varying params., bounded error ident. *Bittanti, S.*, +, *T-AC May 94* 1106-1110

Reduced-order systems

discrete-time q-Markov cover models. *Sreeram, V.*, +, *T-AC May 94* 1102-1105
discrete-time systs., generalized q-Markov cover models. *Sreeram, V.*, *T-AC Dec 94* 2502-2505
distributed delay lin. systs., feedback stabilisation. *Feng Zheng*, +, *T-AC Aug 94* 1714-1718
full-order/low-order observers, LTI plant, unified singular syst. based theory. *Cobb, J.D.*, *T-AC Dec 94* 2497-2502
 H_∞ compensator design, min. order observers. *Hsu, C.S.*, +, *T-AC Aug 94* 1679-1681
 H_2 -optim., reduced order observer based controller. *Stoorvogel, A.A.*, +, *T-AC Feb 94* 355-360
interval systs. order reduction, Routh-Pade approx. *Bandyopadhyay, B.*, +, *T-AC Dec 94* 2454-2456
 L^2 optimal model order reduction problem, input normal form homotopy. *Ge, Y.*, +, *T-AC Jun 94* 1302-1305
model reduction, LF approx. balancing, props. *Prakash, R.*, *T-AC May 94* 1135-1141
structural wave control, reduced-order model. *Quan Wang*, +, *T-AC Aug 94* 1711-1713
unstable plants, sampled-data observers, generalized holds. *Haddad, W.M.*, +, *T-AC Jan 94* 229-234
vibr. systs. control. *Karl, W.C.*, +, *T-AC Jan 94* 222-226

Regenerative stochastic processes

DEDS, steady state fn., nondifferentiability. *Shapiro, A.*, +, *T-AC Aug 94* 1707-1711
regenerative syst. optim., infinitesimal perturb. anal. *Chong, E.K.P.*, +, *T-AC Jul 94* 1400-1410

Regulators

discrete-time H_∞ control problem, strictly proper meas. feedback. *Stoorvogel, A.A.*, +, *T-AC Sep 94* 1936-1939
finite-dimens. controllers designed for infinite-dimens. systs., state space. *Morris, K.A.*, *T-AC Oct 94* 2100-2104
mfg. scheduling syst., regulator stabilization tech. *Humes, C., Jr.*, *T-AC Jan 94* 191-196
nonlin. regulator, num. design. *Kreisselmeier, G.*, +, *T-AC Jan 94* 33-46

Relaxation methods

noncooperative equilibria computation, relax. algms. *Uryas'ev, S.*, +, *T-AC Jun 94* 1263-1267

Reliability

failure-prone mfg. systs., structural props. of optimal prod. controllers. *Jian-Qiang Liu*, +, *T-AC Mar 94* 640-643

Reliability; cf. Failure analysis; Fault tolerance**Reliability theory**

mfg. syst. with unreliable machines, stabil. anal. *Han-Fu Chen*, +, *T-AC Mar 94* 681-686

Resource management

machine capacity allocation. *Nain, P.*, +, *T-AC Sep 94* 1853-1855
single-machine scheduling, resource optimal control. *Cheng, T.C.E.*, +, *T-AC Jun 94* 1243-1246

Reviews; cf. Book reviews**Riccati equations**

four-block problem, recursive Schur-based soln. *Constantinescu, T.*, +, *T-AC Jul 94* 1476-1481
jump lin. systs., coupled Riccati eqns. *Abou-Kandil, H.*, +, *T-AC Aug 94* 1631-1636
mixed H_2/H_∞ control, Nash game approach. *Limebeer, D.J.N.*, +, *T-AC Jan 94* 69-82
model-following systs., time/freq. domain design equivalence. *Yen-Ting Hsu*, +, *T-AC Aug 94* 1722-1726

perturbed lin. systs., upper covariance bounds. *Bolzern, P.*, +, *T-AC Mar 94* 623-626

Riccati equations, algebraic

comments on "Stability margin evaluation for uncertain linear systems" (by C. Gong and S. Thompson, Jun 94 548-550). *Su, J.-H.*, *T-AC Dec 94* 2523-2524

constrained Riccati eqn. factorizations. *Weiss, M.*, *T-AC Mar 94* 677-681
continuous alg. Riccati eqn. eigenvalues. *Komaroff, N.*, *T-AC Mar 94* 532-534

discrete-time Riccati eqn., H_∞ control appl. *Stoorvogel, A.A.*, +, *T-AC Mar 94* 686-691

lin. sing. perturbed systs., Kalman filtering. *Gajic, Z.*, +, *T-AC Sep 94* 1952-1955

LTI syst. pos. real control. *Wei-qian Sun*, +, *T-AC Oct 94* 2034-2046

min. lin. plants parameterization. *Davis, L.D.*, +, *T-AC Apr 94* 849-852

multiscale systs., Kalman filters, Riccati eqns. *Chou, K.C.*, +, *T-AC Mar 94* 479-492

polynomial J-spectral factorization. *Kwakernaak, H.*, +, *T-AC Feb 94* 315-328

quadratic stabilization of continuous time systs. *Mahmoud, M.S.*, +, *T-AC Oct 94* 2135-2139

Riccati eqn., discrete alg., iter. matrix bounds. *Komaroff, N.*, *T-AC Aug 94* 1676-1678

Riccati eqn., discrete-time alg., closed loop eigenvalues. *Lin-Zhang Lu*, +, *T-AC Aug 94* 1682-1685

sampled-data robust control, exponential hold, optimal algm. *Yung-Chun Wu*, +, *T-AC Jan 94* 112-117

sing. perturbed syst. block-diagonalization, Taylor expansion. *Derbel, N.*, +, *T-AC Jul 94* 1429-1431

state delayed systs., memoryless H^∞ controllers. *Joon Hwa Lee*, +, *T-AC Jan 94* 159-162

three-block generalized/std. Riccati eqns. comparison. *Darouach, M.*, +, *T-AC Aug 94* 1755-1758

uncertain lin. systs., multivariable, stabil. margin eval. *Gong, C.*, +, *T-AC Mar 94* 548-550

Riccati equations, differential

exponential lin. quadratic optimal control, discounting. *Hopkins, W.E., Jr.*, *T-AC Jan 94* 175-178

Riccati equations, discrete-time

H_∞ control appl. *Stoorvogel, A.A.*, +, *T-AC Mar 94* 686-691

periodic discrete-time Riccati eqn., num. soln. *Hench, J.J.*, +, *T-AC Jun 94* 1197-1210

Riccati eqn., discrete alg., iter. matrix bounds. *Komaroff, N.*, *T-AC Aug 94* 1676-1678

Riccati eqn., discrete-time alg., closed loop eigenvalues. *Lin-Zhang Lu*, +, *T-AC Aug 94* 1682-1685

sampled-data robust control, exponential hold, optimal algm. *Yung-Chun Wu*, +, *T-AC Jan 94* 112-117

uncertain systs., sampled-data controller design. *Dolphus, R.M.*, *T-AC May 94* 1036-1042

Robots

adaptive control based passivity. *Yu Tang*, +, *T-AC Sep 94* 1871-1875

adaptive controller, Lyapunov stabil. *Egeland, O.*, +, *T-AC Aug 94* 1671-1673

arms, repositioning control, robust finite dimens. learning algms. *Lucibello, P.*, *T-AC Aug 94* 1690-1694

flexible joint robots, global regulation, approx. diff. *Kelly, R.*, +, *T-AC Jun 94* 1222-1224

manipulators with parametric uncertainty, robust control. *Keun-Mo Koo*, +, *T-AC Jun 94* 1230-1233

robust control, lin. estim. state feedback. *Berghuis, H.*, +, *T-AC Oct 94* 2159-2162

variable struct. control schemes. *Bin Yao*, +, *T-AC Feb 94* 371-376

Robots; cf. Manipulators...; Mobile robots...**Robots, sensing systems; cf. Robots, vision systems****Robots, vision systems**

autonomous vision-based mobile robot. *Baumgartner, E.T.*, +, *T-AC Mar 94* 493-502

Robustness

adaptive control algms., robust approach. *Gang Feng*, *T-AC Aug 94* 1738-1742

adaptive control systs. robustness. *Bodson, M.*, *T-AC Apr 94* 864-870

adaptive predictive controller, robustness anal. *Clarke, D.W.*, +, *T-AC May 94* 1052-1056

book review: New Tools for Robustness of Linear Systems (Barmish, B.R.; 1994). *T-AC Dec 94* 2525-2526

cascaded nonlin. systs., global robust stabilization. *Imura, J.-I.*, +, *T-AC May 94* 1084-1089

continuous direct adaptive control, saturation input constraint. *Cishen Zhang*, +, *T-AC Aug 94* 1718-1722

- corrections to "Robust stability and performance via fixed-order dynamic compensation: The discrete-time case" (May 93 776-782). *Haddad, W.M.*, +, *T-AC Aug 94* 1772

Scanning the Issue*

Adjoint and Hamiltonian Input-Output Differential Equations, *Crouch, Lamnabhi-Lagarigue, and van der Schaft*.

In 1887, Helmholtz established conditions under which a set of second-order nonlinear differential equations are, or can be transformed into, Lagrangian (or Hamiltonian) form. This paper generalizes the classical Helmholtz conditions to nonlinear input-output differential systems, i.e., to nonlinear control systems. The adjoint variational system and the meaning of self-adjointness for a general input-output system are defined in the course of the analysis. The results employ recent developments in the theory of variational and Hamiltonian control systems. A main advantage of the results of this paper over previous related results is their verifiability directly in terms of the given input-output model. Several examples are given illustrating the results and associated computations.

Language Convergence in Controlled Discrete-Event Systems, *Willner and Heymann*.

This paper addresses the issue of how to supervise a discrete-event system modeled by a finite automaton so that after a bounded, but unknown, number of transitions, the behavior of the controlled system will conform to some specified behavior. Several issues within this problem area are addressed. Necessary and sufficient conditions for finite convergence are provided, and algorithms for implementing these tests are developed. These are then applied to achieving language convergence through control. This is discussed within the context of finite string behavior as well as asymptotic behavior. The main contribution is a detailed analysis of existence and computation of supervisors to achieve eventually correct supervisory control.

Concurrent Vector Discrete-Event Systems, *Li and Wonham*.

In earlier papers published in these transactions, the authors have addressed the control of vector discrete-event systems (VDES). VDES are a class of discrete-event models where the state is represented by a vector of integers and state transitions are manifested through integer vector addition. This paper extends VDES control theory by incorporating simultaneity of events into the model and by considering nondeterminism of controllers. The extended VDES model with simultaneous (or concurrent) events is termed concurrent VDES (CVDES). The main part of the paper deals with nondeterministic control of CVDES. The nondeterminism comes from the fact that the control action issued by the controller at each step is "randomly" (i.e., according to some hidden mechanism) chosen among a set of possible control actions. The authors show how to exploit the power of nondeterministic control in the presence of concurrency.

Structure of Model Uncertainty for a Weakly Corrupted Plant, *Zhou and Kimura*.

Robust control paradigms are typically based on a plant model set described by a nominal model and a bound on the distance, in a certain metric, between this nominal model and all other models in the set. For paradigms to be usable, a procedure must be available to determine an appropriate model set from available plant information. Several philosophies have been put forth that assign different meanings to "appropriateness." Consistent with the control motivation, the philosophy embraced in the present paper is that of

"worst case deterministic" modeling, by which the model set is to be the smallest set of plants which includes all those which could have produced the available plant information, under given assumptions on the noise, and which satisfy given *a priori* conditions. Specifically, the first task undertaken by the authors is to characterize the set of all linear, time-invariant, stable transfer function matrices, with the H_∞ norm below a prescribed threshold, which are consistent with given experimental data known to be weakly affected by noise. The key result here is a parameterization of this set as the linear fractional transformation of a fixed transfer function matrix and a structured, norm bounded, free transfer function matrix. Next, with the robust control problem in mind, the authors consider determining the smallest superset of the set just characterized that consists of a "nominal" transfer function matrix of prescribed order, and of an H_∞ "ball" around it. They show that this problem can be expressed as a mixed- m synthesis problem.

Explicit Formulas for Optimally Robust Controllers for Delay Systems, *Dym, Georgiou, and Smith*.

H_∞ control for distributed parameter systems, initiated in the mid 1980's, focused first on developing formulas to provide further insight into limitations on performance due to infinite dimensional elements (such as time-delays) and second, on developing a direct approach to design which does not rely on first finding a finite dimensional approximation of the plant. Such an approach has the potential to shed light on the structure of ideal compensators for distributed parameter systems.

In this paper, the authors consider single-input/single-output systems whose transfer functions consist of a strictly proper rational function times a delay. They present a closed-form expression for the controller which is optimally robust with respect to perturbations of the nominal plant measured in the gap metric. The derivations involve a synthesis of state-space techniques and the use of a certain algebra of "pseudo-derivation" operators, which amounts to a specific class of distributed delays. The controller transfer function has a simple expression involving state-space matrices computed from the rational part of the plant together with a distributed delay element. The expression makes it quite straightforward to carry out directly the H_∞ loop-shaping procedure of Glover-McFarlane for the class of plants considered and rational weights. An example design is worked out to illustrate the technique and a comparison is made with a Smith predictor.

Stochastic System Identification with Noisy Input-Output Measurements Using Polyspectra, *Tugnait and Ye*.

In this paper, parameter estimation in linear SISO systems (with prescribed orders) is considered. Here inputs and outputs are assumed to be contaminated by noise, and identifiability is obtained by additional assumptions on the probability distributions of the signal and noise processes, respectively. Based on a simple relation between the true transfer function and some (population) bispectra or integrated polyspectra, first estimators of the transfer function are derived from the corresponding sample counterpoints. From these, two classes of estimators for the transfer function, one called linear (which, strictly speaking is also nonlinear) and one called nonlinear, are derived. Consistency is analyzed, and bias and variance of the estimators are compared (also with other, already existing, estimators) by means of a Monte-Carlo simulation.

Minimum Bias Priors for Estimating Parameters of Additive Terms in State-Space Models, *Hochwald and Nehorai*.

We treat the problem of estimating parameters of additive terms, sometimes called bias terms, in state-space models. We consider

models that depend linearly on the state but possibly nonlinearly on the parameters, where both the state and observation are corrupted by additive noise. A prior density for the parameters is introduced that, when combined with the likelihood function to form a posterior density, minimizes the bias of the posterior mean.

Adjoint and Hamiltonian Input–Output Differential Equations

Peter E. Crouch, *Senior Member, IEEE*, Francoise Lamnabhi-Lagarrigue, and Arjan J. van der Schaft

Abstract—Based on recent developments in the theory of variational and Hamiltonian control systems by Crouch and van der Schaft, this paper answers two questions: given an input–output differential equation description of a nonlinear system, what is the adjoint variational system in input–output differential form and what are the conditions for the system to be Hamiltonian, i.e., such that the variational and the adjoint variational systems coincide? This resulting set of conditions is then used to generalize classical conditions such as the well-known Helmholtz conditions for the inverse problem in classical mechanics.

I. INTRODUCTION

THE work we are describing in this paper has its roots in a very old problem in classical mechanics, where one asks which Newtonian systems correspond to Lagrangian, or variational systems; the so-called inverse problem. There are many variants of this problem, see Santilli [14], but the simplest one can be stated as follows.

If $q \in \mathbb{R}^n$ is a configuration variable, which satisfies the Newtonian system

$$F(q, \dot{q}, \ddot{q}) = 0 \quad (1)$$

for a smooth \mathbb{R}^n valued mapping F , such that $\partial F / \partial \ddot{q}$ is a nonsingular matrix in a suitable open domain, then under what conditions does there exist a function L of q, \dot{q} , so that for some ordering of the variables of q

$$F(q, \dot{q}, \ddot{q}) = \frac{d}{dt} \frac{\partial L^T}{\partial \dot{q}}(q, \dot{q}) - \frac{\partial L^T}{\partial q}(q, \dot{q}). \quad (2)$$

The conditions under which this property holds are known as the classical Helmholtz conditions, see Santilli [14] where generalizations to functions F depending on arbitrary finite jets of q are also considered.

The condition on the rank of $\partial F / \partial \ddot{q}$ in the system (1) above enables those systems satisfying (2) to be written also as a

Hamiltonian set of equations

$$\begin{aligned} \dot{q} &= \frac{\partial H^T}{\partial p}(q, p) \\ \dot{p} &= -\frac{\partial H^T}{\partial q}(q, p) \end{aligned} \quad (3)$$

where $H(p, q)$ is the Hamiltonian function of the system, and (p, q) are coordinates on the symplectic phase space \mathbb{R}^{2n} . A result of Brockett and Rahimi [1] is also of interest in this context and concerns the linear system Σ

$$\begin{aligned} \dot{x} &= Ax + Bu; \quad x(0) = 0 \\ y &= Cx \end{aligned} \quad (4)$$

in which $x \in \mathbb{R}^n$, $u, y \in \mathbb{R}^m$, and the so-called adjoint system Σ^a (see also [12])

$$\begin{aligned} \dot{p} &= -A^T p - C^T u_a; \quad p(0) = 0 \\ y_a &= B^T p. \end{aligned} \quad (5)$$

It was shown with the minimality of both systems, together with the “self-adjointness” condition that the input–output maps of Σ and Σ^a coincide, that this is equivalent to the fact that the system Σ has another internal representation as a linear “Hamiltonian Control” system

$$\begin{aligned} \dot{p} &= -\frac{\partial H^T}{\partial q}(p, q, u) \\ \dot{q} &= \frac{\partial H^T}{\partial p}(p, q, u) \\ y &= \frac{\partial H^T}{\partial u}(p, q, u) \end{aligned} \quad (6)$$

where for a linear Hamiltonian system

$$H(p, q, u) = \frac{1}{2}(p^T, q^T)F \begin{bmatrix} p \\ q \end{bmatrix} + (p^T, q^T)Gu$$

for some matrices F and G .

The term “self-adjointness” is also used to describe the conditions which ensure that a Newtonian system does correspond to a Lagrangian, or Hamiltonian, system. This is explained by performing integration by parts to give an expression

$$\begin{aligned} &\int_0^T \xi^T \left[\frac{\partial F}{\partial q} q_v + \frac{\partial F}{\partial \dot{q}} \dot{q}_v + \frac{\partial F}{\partial \ddot{q}} \ddot{q}_v \right] dt \\ &= \int_0^T q_v^T F^*(\xi, \dot{\xi}, \ddot{\xi}) dt \\ &\quad + Q(q, \dot{q}, \ddot{q}, q_v, \dot{q}_v, \ddot{q}_v, \xi, \dot{\xi}, \ddot{\xi}) \Big|_0^T \end{aligned} \quad (7)$$

Manuscript received November 26, 1991; revised January 3, 1994 and August 9, 1994. Paper recommended by Past Associate Editor, E. H. Abed. The work of P. E. Crouch was supported in part by the National Science Foundation under Grants INT 8914643 and DMS 9101964. The work of F. Lamnabhi-Lagarrigue was supported in part by the National Science Foundation under Grant 0693 and by EEC Science RTD SCI0433CA.

IEEE Log Number 9408274.

for some functions F^* and Q . The adjoint variational system to the variational system $\ddot{q}_v + \frac{\partial F}{\partial q} \dot{q}_v + \frac{\partial F}{\partial \dot{q}} \ddot{q}_v = 0$ corresponding to (1) is then

$$F^*(\xi, \dot{\xi}, \ddot{\xi}) = 0.$$

Self-adjointness of F is simply the statement that

$$F^*(\xi, \dot{\xi}, \ddot{\xi}) = \frac{\partial F}{\partial q} \xi + \frac{\partial F}{\partial \dot{q}} \dot{\xi} + \frac{\partial F}{\partial \ddot{q}} \ddot{\xi}.$$

Work by Crouch and van der Schaft [5], [6], made an extensive investigation and generalization of the result by Brockett and Rahimi [1] to nonlinear control systems, based on earlier work by van der Schaft [15]. In particular, a state space form of the variational and adjoint variational systems was introduced, generalizing the relationship between Σ and Σ^a to nonlinear systems. The concept of self-adjointness was correspondingly generalized, and under suitable hypotheses it was shown that self-adjointness is necessary and sufficient for Hamiltonian realizations of input-output maps. Moreover, the self-adjointness condition was successfully interpreted in terms of the Volterra series and Fliess series. See also Jakubczyk [12] for a generalization to control systems with control entering in a nonaffine manner.

This work, although implicitly generalizing the classical Helmholtz condition, fails to give conditions in terms of the differential equation representation of the input-output map, generalizing the system representation given by (1), and here represented by an equation of the form

$$F(y, y^{(1)}, \dots, y^{(N)}, u, u^{(1)}, \dots, u^{(N-1)}) \equiv 0 \quad (8)$$

where F is a smooth vector valued function of its arguments. Furthermore, the self-adjointness conditions of [5] and [6] are difficult to check in practice, since in principle one needs to compute the state trajectories of the nonlinear system under consideration. The present paper gives the full generalization of the classical Helmholtz conditions to control systems described by (8). The resulting conditions are completely in terms of the mapping F and its partial derivatives. They are worked out in detail for control systems

$$F(y, y^{(1)}, y^{(2)}, u, u^{(1)}) = 0 \quad (9)$$

so that they have a Hamiltonian representation by a system of the form (6). To the knowledge of the authors, the only previous results in this direction are those given by two of the current authors [4], when dealing with the scalar input-scalar output version of the system (9). It is interesting to note that many problems associated with the preceding analysis coincide with those met in the study of time-varying linear systems; see, e.g., [2], [9], [10], [11], and [13].

II. THE ADJOINT VARIATIONAL SYSTEM

We consider analytic (i.e., C^ω), complete, state-space systems which may be written in the form

$$\Sigma_s \quad \dot{x} = f(x, u), \quad y = h(x), \quad u \in \mathbb{R}^m, \quad y \in \mathbb{R}^p \quad (10)$$

where $x = (x_1, \dots, x_n)$ denote local coordinates for some state space manifold M and corresponding analytic input-output differential representations

$$\Sigma_{i/o} \quad F(y, \dot{y}, \dots, y^{(N)}, u, \dot{u}, \dots, u^{(N-1)}) = 0 \in \mathbb{R}^p. \quad (11)$$

If system (10) is minimal in the sense of Crouch and van der Schaft [5, ch. 3 for the input-affine case and ch. 6 for the general case], the corresponding representation (11) will also be called a minimal representation. Note that we do not insist here on the relationship between state-space representations (10) and input-output differential representations (11); we assume that all conditions are met for obtaining one representation from the other representation.

A variational system Σ_s^v about a given trajectory $(x(t), u(t), y(t))$ of Σ_s is defined in the usual way (see [5]) as

$$\begin{aligned} \dot{v}(t) &= F(t)v(t) + G(t)u_v(t), & u_v &\in \mathbb{R}^m, \quad v \in \mathbb{R}^n \\ y_v(t) &= H(t)v(t), & y_v &\in \mathbb{R}^p \end{aligned} \quad (12)$$

with $F(t) := \frac{\partial f}{\partial x}(x(t), u(t))$, $G(t) := \frac{\partial f}{\partial u}(x(t), u(t))$, $H(t) = \frac{\partial h}{\partial x}(x(t))$, and v , u_v , y_v denoting, respectively, the variational state, variational input, and variational output. Note that (12) results from differentiation of a one-parameter family of solutions to (10), cf. [5]. The adjoint variational system Σ_s^a , along the same trajectory $(x(t), u(t), y(t))$, is defined as (see [5])

$$\begin{aligned} \dot{p}(t) &= -F^T(t)p(t) - H^T(t)u_a(t), & u_a &\in \mathbb{R}^p, \quad p \in \mathbb{R}^n \\ y_a(t) &= G^T(t)p(t), & y_a &\in \mathbb{R}^m \end{aligned} \quad (13)$$

with p , u_a , y_a denoting the adjoint variational state, input, and output, respectively. The fundamental connection between variational and adjoint variational systems (along the same trajectory of Σ_s) is [5, Lemma 2.1]

$$y_a^T(t)u_v(t) - u_a^T(t)y_v(t) = \frac{d}{dt}p^T(t)v(t). \quad (14)$$

Now let us translate this to input-output differential representations $\Sigma_{i/o}$ given by (11). Clearly, the variational systems $\Sigma_{i/o}^v$ (along solutions $u(t), y(t)$ of $\Sigma_{i/o}$) are defined by the system of equations

$$\begin{aligned} \frac{\partial F}{\partial y} y_v(t) + \frac{\partial F}{\partial \dot{y}} \dot{y}_v(t) + \dots + \frac{\partial F}{\partial y^{(N)}} y_v^{(N)}(t) + \frac{\partial F}{\partial u} u_v(t) \\ + \frac{\partial F}{\partial \dot{u}} \dot{u}_v(t) + \dots + \frac{\partial F}{\partial u^{(N-1)}} u_v^{(N-1)}(t) = 0 \end{aligned} \quad (15)$$

where the solution $u(t), y(t)$ is substituted in $\frac{\partial F}{\partial y}$, $\frac{\partial F}{\partial \dot{y}}$, \dots , $\frac{\partial F}{\partial u}$, $\frac{\partial F}{\partial \dot{u}}$, \dots . Again, (15) results from differentiation of a one-parameter family of solutions $(u(t, c), y(t, c))$ to (11). Comparing $\Sigma_{i/o}^v$ to Σ_s^v there is a potential problem since (see [20]) the set of solutions u_v, y_v to (15) may be strictly larger than the set of solutions u_v, y_v generated by (12). This has to do with the form of the input-output differential representation (11) (note that this representation is far from unique); we will later on make an assumption on (11) which will eliminate this potential problem.

The next logical question is how to define the adjoint variational system $\Sigma_{i/o}^a$. This is not immediate from the

definition of Σ_s^a . Relation (14) should provide the clue to a proper definition, although the right-hand side of (14) is expressed in the variational and adjoint variational state. Direct calculation based on Σ_s^v and Σ_s^a provides the following alternative to (14)

$$\begin{aligned} y_a^T(t)u_v(t) - u_a^T(t)y_v(t) \\ = \frac{d}{dt} \left[- \int_{-\infty}^t \int_{-\infty}^s u_a^T(\tau) H(\tau) \Phi(\tau, s) G(s) u_v(s) ds d\tau \right] \end{aligned} \quad (16)$$

with $\Phi(\tau, s)$ being the transition matrix of $F(t)$ (and the variational and adjoint variational states initialized at 0 at time $-\infty$). Although the right-hand side of (16) is an integral expression in u_a, u_v , this partly motivates the following definition (another motivation is provided by the classical definition of adjoint variational systems for sets of differential equations, cf. [14]).

Definition 1 (see also [5]): Consider the variational system (15) along a solution $(u(t), y(t))$ of $\Sigma_{i/o}$. The adjoint variational system $\Sigma_{i/o}^a$ consists of the following set of input-output pairs $(u_a(\cdot), y_a(\cdot))$: there exists a function $Q(y, \dot{y}, \dots, u, \dot{u}, \dots, y_v, \dot{y}_v, \dots, u_v, \dot{u}_v, \dots, y_a, \dot{y}_a, \dots, u_a, \dot{u}_a, \dots)$ such that for all $t \in R$

$$y_a^T(t)u_v(t) - u_a^T(t)y_v(t) = \frac{d}{dt} Q \quad (17)$$

for all input-output pairs $(u_v(\cdot), y_v(\cdot))$ which are solutions of $\Sigma_{i/o}^v$.

To justify this definition we first have to prove that Definition 1 uniquely characterizes the adjoint variational system.

Proposition 1: Suppose that there exists a function

$$\begin{aligned} \hat{Q}(y, \dot{y}, \dots, u, \dot{u}, \dots, y_v, \dot{y}_v, \dots, u_v, \dot{u}_v, \dots, \\ \tilde{y}_a, \dot{\tilde{y}}_a, \dots, u_a, \dot{u}_a, \dots) \end{aligned}$$

such that for all solutions $(u_v(t), y_v(t))$ to $\Sigma_{i/o}^v$ and all $u_a(t)$

$$\tilde{y}_a^T(t)u_v(t) - u_a^T(t)y_v(t) = \frac{d}{dt} \hat{Q} \quad (18)$$

for all $t \in R$, then $\tilde{y}_a(t) = y_a(t)$, $t \in R$, and $\hat{Q} = Q$ modulo a constant.

Proof. Subtracting (17) from (18) yields

$$(\tilde{y}_a - y_a)^T u_v = \frac{d}{dt} (\hat{Q} - Q)$$

for all u_v . Hence

$$\int_{t_1}^t [\tilde{y}_a(t) - y_a(t)]^T u_v(t) dt = [\hat{Q} - Q]_{t_1}^t. \quad (19)$$

Now take a fixed function u_a on $[t_1, t_2]$ and corresponding fixed functions y_a, \tilde{y}_a on $[t_1, t_2]$ and arbitrary u_v . It follows that the left-hand side of (19) only depends on $u_v(t_1)$ and $u_v(t_2)$ (since the right-hand side does), thus implying that both sides of (19) are zero, and $\tilde{y}_a = y_a$ and $\hat{Q} = Q$ modulo a constant. ■

The next thing we have to do is to show that Definition 1 is consistent with the definition of the adjoint variational system Σ_s^a . Comparing (17) to (14) we see that this

means that $p^T v$ has to be expressible as a function Q of $y_v, \dot{y}_v, \dots, u_v, \dot{u}_v, \dots, y_a, \dot{y}_a, \dots, u_a, \dot{u}_a, \dots$ (and of course $y, \dot{y}, \dots, u, \dot{u}, \dots$). To do so we make fundamental use of some results obtained by Ilchmann *et al.* [10] on time-varying linear systems and Coron [3] and Sontag [17] on the relation between nonlinear state space systems Σ_s and the variational systems Σ_s^v ; see also [3], [18], and [7]. Indeed, in [3], [17] the following is shown. Consider the minimal state space system Σ_s . Let I be an open interval of R , and denote by $C^\infty(I; R^m)$ the set of smooth input functions $u: I \rightarrow R^m$, equipped with the Whitney topology. Then the set of all u in $C^\infty(I; R^m)$ such that all corresponding solutions $(x(t), u(t))$ of Σ_s defined on I have the property that the variational systems (12) along $(x(t), u(t))$ satisfy

$$\dim \text{span} \left\{ \left(\frac{d}{dt} - F(t) \right)^i G(t) w; \quad w \in R^m, i \geq 0 \right\} = n \quad (20)$$

for all $t \in I$, is a dense subset of $C^\infty(I; R^m)$; see [3, Corollary 1.8]. (Note that the definition of the strong accessibility algebra used in [3] is the usual definition in the case of input-affine systems Σ_s , while for general systems $\dot{x} = f(x, u)$ it corresponds exactly to the definition given in [5, ch. 6].)

Furthermore, see [3, Corollary 1.15], the set of all u in $C^\infty(I; R^m)$ such that all corresponding solutions $(x(t), u(t))$ of Σ_s defined on I have the property that the variational systems (12) along $(x(t), u(t))$ satisfy

$$\dim \text{span} \left\{ \left(\frac{d}{dt} + F^T(t) \right)^i H^T(t) w; \quad w \in R^p, i \geq 0 \right\} = n \quad (21)$$

for all $t \in I$, is also a dense subset of $C^\infty(I; R^m)$. Properties (20) and (21) express well-known controllability, respectively, observability, properties of the time-varying linear systems given by the variational systems Σ_s^v , and thus the above statements imply, loosely speaking, that in case Σ_s is minimal then its variational systems are controllable and observable for a dense subset of input functions.

To use now the fundamental results obtained in Ilchmann *et al.* [10] and Ilchmann [11] we will now restrict to analytic (C^ω) input functions on the time-interval I . Since (10) is assumed to be analytic this will mean that the variational and adjoint variational systems (12), respectively (13), are analytic, i.e., the entries of $F(t)$, $G(t)$, and $H(t)$ are analytic functions on I . Let \mathcal{M} denote the meromorphic functions on I , and denote by $\mathcal{M}[D]$ the set of polynomials

$$\sum_{i=0}^n f_i D^i$$

in D with coefficients from \mathcal{M} (D will represent the differentiation operator $\frac{d}{dt} \in \text{End}(\mathcal{M})$, the algebra of R -linear maps from \mathcal{M} to \mathcal{M}). Considering also the multiplication in $\text{End}(\mathcal{M})$, we arrive at the skew-polynomial ring $\mathcal{M}[D]$ (see [10], [11]) with multiplication rule

$$\begin{aligned} D(fg) &= fD(g) + D(f)g = (fD + D(f))g, \\ f, g &\in \text{End}(\mathcal{M}). \end{aligned} \quad (22)$$

The set of $m \times n$ matrices over $\mathcal{M}[D]$ will be denoted by $\mathcal{M}[D]^{m \times n}$. A useful property (see [10]) is that a left inverse of a square matrix in $\mathcal{M}[D]^{n \times n}$ is also a right inverse, and vice versa.

Let us now denote the variational and adjoint variational system in shorthand notation by

$$\begin{aligned} \left(I \frac{d}{dt} - F\right)v - Gu_v &= 0 \\ y_v - Hv &= 0 \end{aligned} \quad (23)$$

$$\begin{aligned} \left(I \frac{d}{dt} + F^T\right)p + H^T u_a &= 0 \\ y_a - G^T p &= 0. \end{aligned} \quad (24)$$

Throughout we will restrict to the dense subset of analytic input functions for which (23) satisfies the controllability and observability properties (20) and (21). Then by [10, Lemma 3.3 and Theorem 6.4] there exists an invertible matrix

$$\begin{bmatrix} \tilde{U}(\frac{d}{dt}) & \tilde{W}(\frac{d}{dt}) \\ \tilde{V}(\frac{d}{dt}) & \tilde{Z}(\frac{d}{dt}) \end{bmatrix} \in \mathcal{M}[D]^{(n+m) \times (n+m)}$$

such that

$$\left[I \frac{d}{dt} - F, -G\right] \begin{bmatrix} \tilde{U}(\frac{d}{dt}) & \tilde{W}(\frac{d}{dt}) \\ \tilde{V}(\frac{d}{dt}) & \tilde{Z}(\frac{d}{dt}) \end{bmatrix} = [I_n, 0] \quad (25)$$

and an invertible matrix

$$\begin{bmatrix} \tilde{P}(\frac{d}{dt}) & \tilde{Q}(\frac{d}{dt}) \\ \tilde{S}(\frac{d}{dt}) & \tilde{R}(\frac{d}{dt}) \end{bmatrix} \in \mathcal{M}[D]^{(n+p) \times (n+p)}$$

such that

$$\left[I \frac{d}{dt} + F^T, H^T\right] \begin{bmatrix} \tilde{P}(\frac{d}{dt}) & \tilde{Q}(\frac{d}{dt}) \\ \tilde{S}(\frac{d}{dt}) & \tilde{R}(\frac{d}{dt}) \end{bmatrix} = [I_n, 0]. \quad (26)$$

We will now apply the following "integration by parts" procedure to (25), (26). This will be a key tool in all of our subsequent developments.

Consider two matrices $M(\frac{d}{dt})$, $N(\frac{d}{dt})$ over $\mathcal{M}[D]$, of appropriate dimensions such that

$$M\left(\frac{d}{dt}\right)N\left(\frac{d}{dt}\right) = C \quad (27)$$

with C some constant matrix, say of dimension $k \times l$. (Note that $M(\frac{d}{dt})$ acts also on the entries of $N(\frac{d}{dt})$, cf. (22); the same of course applies to the expressions (25) and (26).)

Let now $\xi(t)$ be an l -vector of analytic functions, and consider the k -vector of analytic functions

$$M\left(\frac{d}{dt}\right)N\left(\frac{d}{dt}\right)\xi(t). \quad (28)$$

Now premultiply (28) by a k -row vector of analytic functions $\eta^T(t)$, i.e.,

$$\eta^T(t)M\left(\frac{d}{dt}\right)N\left(\frac{d}{dt}\right)\xi(t) \quad (29)$$

and apply integration by parts to the integral

$$\int_{t_1}^{t_2} \eta^T(t)M\left(\frac{d}{dt}\right)N\left(\frac{d}{dt}\right)\xi(t) dt$$

(with $[t_1, t_2] \subset I$) in order to shift the differentiations on $\xi(t)$ to differentiations on $\eta(t)$. It follows that

$$\begin{aligned} \int_{t_1}^{t_2} \eta^T(t)M\left(\frac{d}{dt}\right)N\left(\frac{d}{dt}\right)\xi(t) dt \\ = \int_{t_1}^{t_2} \xi^T(t)\hat{N}\left(\frac{d}{dt}\right)\tilde{M}\left(\frac{d}{dt}\right)\eta(t) dt + \text{remainders} \end{aligned} \quad (30)$$

for certain matrices $\hat{N}(\frac{d}{dt})$, $\tilde{M}(\frac{d}{dt})$ over $\mathcal{M}[D]$ (in fact, \hat{N} and \tilde{M} are dimensioned as M^T , respectively N^T). Furthermore, from (27) and (30) it follows that the differential operator $\hat{N}(\frac{d}{dt})\tilde{M}(\frac{d}{dt})$ equals the constant linear mapping C^T on all functions $\eta(t)$ of support within (t_1, t_2) . However, this means that $\hat{N}(\frac{d}{dt})\tilde{M}(\frac{d}{dt})$ equals C^T , and thus the remainders in (30) are necessarily zero.

Applying this procedure to (25) and (26) yields

$$\begin{bmatrix} U(\frac{d}{dt}) & V(\frac{d}{dt}) \\ W(\frac{d}{dt}) & Z(\frac{d}{dt}) \end{bmatrix} \begin{bmatrix} -I \frac{d}{dt} - F^T \\ -G^T \end{bmatrix} = \begin{bmatrix} I_n \\ 0 \end{bmatrix} \quad (31)$$

$$\begin{bmatrix} P(\frac{d}{dt}) & S(\frac{d}{dt}) \\ Q(\frac{d}{dt}) & R(\frac{d}{dt}) \end{bmatrix} \begin{bmatrix} -I \frac{d}{dt} + F \\ H \end{bmatrix} = \begin{bmatrix} I_n \\ 0 \end{bmatrix} \quad (32)$$

respectively, for invertible matrices $\begin{bmatrix} U & V \\ W & Z \end{bmatrix}$, $\begin{bmatrix} P & S \\ Q & R \end{bmatrix}$ obtained from $\begin{bmatrix} \tilde{U} & \tilde{W} \\ \tilde{V} & \tilde{Z} \end{bmatrix}$, $\begin{bmatrix} \tilde{P} & \tilde{Q} \\ \tilde{S} & \tilde{R} \end{bmatrix}$ by partial integration.

The action of the differential operator $\begin{bmatrix} P & S \\ Q & R \end{bmatrix}$ on (23) thus results in the equivalent system of equations

$$\begin{aligned} -PGu_v + Sy_v &= v \\ -QG u_v + Ry_v &= 0 \end{aligned} \quad (33)$$

and, similarly, a combination of (31) and (24) yields

$$\begin{aligned} UH^T u_a - Vy_a &= p \\ WH^T u_a - Zy_a &= 0 \end{aligned} \quad (34)$$

It thus follows that $v(t) = -P(\frac{d}{dt})G(t)u_v(t) + S(\frac{d}{dt})y_v(t)$ and $p(t) = U(\frac{d}{dt})H^T(t)u_a(t) - V(\frac{d}{dt})y_a(t)$, implying that $\frac{d}{dt}p^T(t)v(t)$ appearing in the right-hand side of (14) can be expressed as a function Q in y_v , u_v , u_a , y_a and their time-derivatives (and implicitly of y , y , \dots , u , u , \dots). This shows that Definition 1 is consistent with the definition of the adjoint variational system Σ_a^* . Furthermore, as additional information we obtain from (33), (34) that input-output differential representations of Σ_a^v and Σ_a^* are given by

$$-Q\left(\frac{d}{dt}\right)G(t)u_v(t) + R\left(\frac{d}{dt}\right)y_v(t) = 0 \quad (35)$$

respectively

$$W\left(\frac{d}{dt}\right)H^T(t)u_a(t) - Z\left(\frac{d}{dt}\right)y_a(t) = 0. \quad (36)$$

Now compare (35) to (15), and write (15) in a more convenient notation as

$$\Sigma_{i/o}^v: D\left(\frac{d}{dt}\right)y_v(t) - N\left(\frac{d}{dt}\right)u_v(t) = 0. \quad (37)$$

The requirement, as alluded to before, that the set of solutions u_v , y_v generated by Σ_a^v equals the solution set of $\Sigma_{i/o}^v$ can thus be rephrased as the following.

Assumption 1: There exists an invertible matrix $E(\frac{d}{dt}) \in \mathcal{M}[D]^{p \times p}$ such that

$$\begin{aligned} E\left(\frac{d}{dt}\right)N\left(\frac{d}{dt}\right) &= Q\left(\frac{d}{dt}\right)G(t), \\ E\left(\frac{d}{dt}\right)D\left(\frac{d}{dt}\right) &= R\left(\frac{d}{dt}\right). \end{aligned} \quad (38)$$

From now on we will suppose throughout that Assumption 1 holds.

Our next objective is to give a procedure to compute an input-output differential representation of the adjoint variational system directly in terms of the input-output differential representation $\Sigma_{i/o}^v$ of the variational system (without going through the state space representation). Thus, let us consider $\Sigma_{i/o}^v$ as given by (15), denoted in shorthand notation by (37). Premultiply (37) by a p -dimensional row-vector $\xi^T(t)$ and again apply partial integration to

$$0 = \int_{t_1}^{t_2} \xi^T(t) \left[D\left(\frac{d}{dt}\right)y_v(t) - N\left(\frac{d}{dt}\right)u_v(t) \right] dt \quad (39)$$

to shift all differentiations in $y_v(t)$, $u_v(t)$ to differentiation in $\xi(t)$. This results in

$$\begin{aligned} 0 = \int_{t_1}^{t_2} y_v^T(t) \left[\tilde{D}\left(\frac{d}{dt}\right)\xi(t) \right] - u_v^T(t) \left[\tilde{N}\left(\frac{d}{dt}\right)\xi(t) \right] dt \\ + R(y, \dot{y}, \dots, u, \dot{u}, \dots, y_v, \dot{y}_v, \dots, u_v, \dot{u}_v, \dots, \xi, \dot{\xi}, \dots) \Big|_{t_1}^{t_2} \end{aligned} \quad (40)$$

for certain matrices \tilde{D} , \tilde{N} in $\mathcal{M}[D]$, and remainders R .

Comparing this to (17) (with Q playing the role of the remainders R) motivates the following definition of the adjoint variational system by $(\Sigma_{i/o}^a)$

$$\begin{aligned} u_a(t) &= D\left(\frac{d}{dt}\right)\xi(t) \\ y_a(t) &= N\left(\frac{d}{dt}\right)\xi(t). \end{aligned} \quad (41)$$

Note that (41) is an image representation, in contrast with the kernel representation (37). (For a linear time-invariant system (41) corresponds to a right factorization, while (37) corresponds to a left factorization of the transfer matrix.) Indeed, the (analytic) input-output behavior of (41) consists of all analytic time-functions $y_a(t)$, $u_a(t)$ satisfying (41) for some analytic function $\xi(t)$.

Theorem 1: The equations (41) are an image representation of the adjoint variational system defined in Definition 1.

Proof: We only have to show that R in (40) can also be expressed as a function of $y, \dot{y}, \dots, u, \dot{u}, \dots, y_v, \dot{y}_v, \dots, u_v, \dot{u}_v, \dots, y_a, \dot{y}_a, \dots, u_a, \dot{u}_a, \dots$.

From (25) we obtain

$$\begin{bmatrix} I \frac{d}{dt} - F & -G & 0 \\ -H & 0 & I_p \end{bmatrix} \begin{bmatrix} \tilde{U} & 0 \\ \tilde{V} & 0 \\ 0 & I_p \end{bmatrix} \begin{bmatrix} K & I_p \end{bmatrix} \quad (42)$$

for some K in $\mathcal{M}[D]$. Hence, from (32) and (42) we obtain

$$\begin{aligned} \begin{bmatrix} P & S \\ Q & R \end{bmatrix} \begin{bmatrix} I \frac{d}{dt} - F & -G & 0 \\ -H & 0 & I_p \end{bmatrix} \begin{bmatrix} \tilde{U} & 0 \\ \tilde{V} & 0 \\ 0 & I_p \end{bmatrix} \\ = \begin{bmatrix} -I_n & -PG & S \\ 0 & -QG & R \end{bmatrix} \begin{bmatrix} \tilde{U} & 0 \\ \tilde{V} & 0 \\ 0 & I_p \end{bmatrix} \\ = \begin{bmatrix} P & S \\ Q & R \end{bmatrix} \begin{bmatrix} I_n & 0 \\ -K & I_p \end{bmatrix}. \end{aligned} \quad (43)$$

Clearly the right-hand side of (43) is an invertible matrix, and thus "postmultiplication" of (43) by this inverse yields

$$-Q\left(\frac{d}{dt}\right)G(t)\bar{B}\left(\frac{d}{dt}\right) + R\left(\frac{d}{dt}\right)\bar{A}\left(\frac{d}{dt}\right) = I_p \quad (44)$$

for some matrices $\bar{A}(\frac{d}{dt})$, $\bar{B}(\frac{d}{dt})$ in $\mathcal{M}[D]$. Now recall that an input-output differential representation of Σ_s^v is given by (35), while also (38) holds. Thus there also exist matrices $A(\frac{d}{dt})$, $B(\frac{d}{dt})$ in $\mathcal{M}[D]$ such that

$$D\left(\frac{d}{dt}\right)A\left(\frac{d}{dt}\right) - N\left(\frac{d}{dt}\right)B\left(\frac{d}{dt}\right) = I_p. \quad (45)$$

Applying the partial integration procedure [sec (27)–(30)] to (45) yields

$$\tilde{A}\left(\frac{d}{dt}\right)D\left(\frac{d}{dt}\right) - \tilde{B}\left(\frac{d}{dt}\right)\tilde{N}\left(\frac{d}{dt}\right) = I_p \quad (46)$$

for certain matrices \tilde{A} , \tilde{B} in $\mathcal{M}[D]$, and with \tilde{D} , \tilde{N} as given by (41). Thus, by (41)

$$\begin{aligned} \xi(t) &= \tilde{A}\left(\frac{d}{dt}\right)\tilde{D}\left(\frac{d}{dt}\right)\xi(t) - \tilde{B}\left(\frac{d}{dt}\right)\tilde{N}\left(\frac{d}{dt}\right)\xi(t) \\ &= A\left(\frac{d}{dt}\right)u_a(t) - B\left(\frac{d}{dt}\right)y_a(t) \end{aligned}$$

showing that ξ can be expressed into y_a , u_a and their time-derivatives. ■

Remark 1 The above notions seem to be also useful for analyzing the controllability properties of an input-output differential system (11). Consider the variational and adjoint variational systems of (11) given by (37), respectively (41), where the entries of the matrix differential operators D , N , and \tilde{D} , \tilde{N} are seen as functions of $y, \dot{y}, \dots, u, \dot{u}, \dots$. Then one may construct matrix differential operators D_a , N_a (with entries depending on $y, \dot{y}, \dots, u, \dot{u}, \dots$) of maximal rank such that $D_a\tilde{N} - N_a\tilde{D} = 0$, implying that

$$D_a\left(\frac{d}{dt}\right)y_a(t) - N_a\left(\frac{d}{dt}\right)u_a(t) = 0 \quad (47)$$

for all trajectories u_a , y_a generated by (41). Integration by parts applied to the kernel representation (47) yields the "adjoint of the adjoint system," given in image representation

$$\begin{aligned} u_v(t) &= \tilde{D}_a\left(\frac{d}{dt}\right)\eta(t) \\ y_v(t) &= \tilde{N}_a\left(\frac{d}{dt}\right)\eta(t) \end{aligned} \quad (48)$$

where we have suggestively denoted the inputs and outputs by u_v and y_v , since we want to compare (48) to the variational system (37). Indeed, it is easily checked that all trajectories u_v, y_v generated by (48) satisfy (37), while equality of the behavior of (48) and (37) seems to correspond to some form of controllability of the original nonlinear system (11) [(48) defines the "controllable" part of the system]. This is an area for future research.

In the next section we will use the representation of the adjoint variational system $\Sigma_{i/o}^a$ as given by (41) in order to give a convenient characterization of Hamiltonian systems.

III. CHARACTERIZATION OF HAMILTONIAN SYSTEMS FROM THE INPUT-OUTPUT DIFFERENTIAL REPRESENTATION

We will derive in this section a complete characterization of Hamiltonian systems using the representation of the adjoint variational systems as in (41). In Section IV we will use an alternative approach based on the adjoint variational system Σ_s^a found in [5]. Note that for systems described as

$$\Sigma_{i/o} \quad F(y, \dot{y}, y, u, \dot{u}) = 0 \in \mathbb{R}, \quad u \in \mathbb{R}, y \in \mathbb{R} \quad (49)$$

the conditions under which (49) represents a Hamiltonian system have been found already in an earlier paper by Crouch and Lamnabhi [4], i.e.,

$$\begin{aligned} \text{i)} \quad & \frac{\partial F}{\partial u} = 0 \\ \text{ii)} \quad & \frac{\partial F}{\partial u} \left(\frac{d}{dt} \frac{\partial F}{\partial y} - \frac{\partial F}{\partial y} \right) = \frac{\partial F}{\partial y} \frac{d}{dt} \frac{\partial F}{\partial u} \end{aligned} \quad (50)$$

for every solution $(y, \dot{y}, y, u, \dot{u})$ satisfying (49).

Using the characterization of the adjoint variational system given in Section II we now obtain similar conditions for a general input-output differential representation (11).

Theorem 2 Consider a minimal input-output differential representation $\Sigma_{i/o}$ given by (11) with $p = m$, and its variational systems $\Sigma_{i/o}^v$ given by (37) satisfying Assumption 1. Compute the adjoint variational system $\Sigma_{i/o}^a$ given by (41). Then $\Sigma_{i/o}$ is an input-output representation of a Hamiltonian system if and only if

$$D \left(\frac{d}{dt} \right) \tilde{N} \left(\frac{d}{dt} \right) - N \left(\frac{d}{dt} \right) \tilde{D} \left(\frac{d}{dt} \right) = 0 \quad (51)$$

along every analytic solution $(y(t), u(t))$ of $\Sigma_{i/o}$.

Proof. Observe that (51) is equivalent to $\Sigma_{i/o}^v = \Sigma_{i/o}^a$, i.e., the input-output behavior defined by (37) is the same as the input-output behavior defined by (41). In the terminology of [5], [6] this means that every variational system Σ_s^v along an analytic solution of $\Sigma_{i/o}$ is self-adjoint. In [5, ch. 4] it is shown that Σ_s is Hamiltonian if and only if every variational system along trajectories resulting from piecewise constant inputs are self-adjoint. We finally note that by the Approximation Lemma [19, Lemma 1] the approximation of piecewise constant input functions by analytic input functions will result in state trajectories converging to the state trajectories corresponding to the piecewise constant input functions. ■

We will now work out in detail the self-adjointness condition (51) in case $N = 2$, i.e., we consider

$$\Sigma_{i/o}: \quad F(y, \dot{y}, \ddot{y}, u, \dot{u}) = 0 \in \mathbb{R}^m, \quad u, y \in \mathbb{R}^m \quad (52)$$

and

$$\Sigma_{i/o}^v: \quad Ay_v + B\dot{y}_v + C\ddot{y}_v + Du_v + E\dot{u}_v = 0, \quad u_v, y_v \in \mathbb{R}^m \quad (53)$$

where the (i, k) th elements of the $m \times m$ matrices A, B, C, D, E are given by

$$\begin{aligned} A_{ik} &= \frac{\partial F_i}{\partial y^k}, & B_{ik} &= \frac{\partial F_i}{\partial \dot{y}^k}, & C_{ik} &= \frac{\partial F_i}{\partial \ddot{y}^k}, \\ D_{ik} &= \frac{\partial F_i}{\partial u^k}, & E_{ik} &= \frac{\partial F_i}{\partial \dot{u}^k}. \end{aligned} \quad (54)$$

To compute the adjoint variational system $\Sigma_{i/o}^a$ two consecutive partial integrations yield (we are using summation convention)

$$\begin{aligned} 0 &= \int_{t_1}^{t_2} \xi^i [A_{ik} y_v^k + B_{ik} \dot{y}_v^k + C_{ik} \ddot{y}_v^k + D_{ik} u_v^k + E_{ik} \dot{u}_v^k] dt \\ &= \int_{t_1}^{t_2} [\xi^i A_{ik} y_v^k - (\xi^i B_{ik})^{(1)} y_v^k + (\xi^i C_{ik})^{(2)} y_v^k \\ &\quad + \xi^i D_{ik} u_v^k - (\xi^i E_{ik})^{(1)} u_v^k] dt \\ &\quad + [\xi^i B_{ik} y_v^k + \xi^i C_{ik} \dot{y}_v^k + \xi^i E_{ik} u_v^k - (\xi^i C_{ik})^{(1)} y_v^k]_{t_1}^{t_2} \end{aligned} \quad (55)$$

Thus the adjoint variational system is

$$\Sigma_{i/o}^a: \quad \begin{cases} \dot{u}_v^k = \xi^i A_{ik} - (\xi^i B_{ik})^{(1)} + (\xi^i C_{ik})^{(2)} \\ \dot{y}_v^k = -\xi^i D_{ik} + (\xi^i E_{ik})^{(1)} \end{cases} \quad k = 1, \dots, m \quad (56)$$

while Q is given by the terms between the brackets | | The self-adjointness condition (51) now becomes

$$\begin{aligned} \sum_{k=1}^m & -A_{jk} D_{ik} \xi^i + A_{jk} (E_{ik} \xi^i)^{(1)} - B_{jk} (D_{ik} \xi^i)^{(1)} \\ & + B_{jk} (E_{ik} \xi^i)^{(2)} - C_{jk} (D_{ik} \xi^i)^{(2)} + C_{jk} (E_{ik} \xi^i)^{(3)} \\ & + D_{jk} A_{ik} \xi^i - D_{jk} (B_{ik} \xi^i)^{(1)} + D_{jk} (C_{ik} \xi^i)^{(2)} \\ & + E_{jk} (A_{ik} \xi^i)^{(1)} - E_{jk} (B_{ik} \xi^i)^{(2)} + E_{jk} (C_{ik} \xi^i)^{(3)} = 0 \end{aligned} \quad (57)$$

along every solution $(u(t), y(t))$ of $\Sigma_{i/o}$. This gives the following conditions.

Terms with $(\xi^i)^{(3)}$.

$$\sum_{k=1}^m [C_{jk} E_{ik} + E_{jk} C_{ik}] = 0$$

Terms with $(\xi^i)^{(2)}$.

$$\begin{aligned} \sum_{k=1}^m & [B_{jk} E_{ik} - C_{jk} D_{ik} + 3C_{jk} E_{ik} + D_{jk} C_{ik} \\ & - E_{jk} B_{ik} + 3E_{jk} C_{ik}] = 0. \end{aligned}$$

Terms with $(\xi^i)^{(1)}$.

$$\begin{aligned} \sum_{k=1}^m & [A_{jk} E_{ik} - B_{jk} D_{ik} + 2B_{jk} \dot{C}_{ik} - 2C_{jk} \dot{D}_{ik} \\ & + 3C_{jk} \ddot{E}_{ik} - D_{jk} B_{ik} + 2D_{jk} \dot{C}_{ik} + E_{jk} A_{ik} \\ & - 2E_{jk} \dot{B}_{ik} + 3E_{jk} \ddot{C}_{ik}] = 0. \end{aligned}$$

Terms with ξ^1 :

$$\sum_{k=1}^m [-A_{jk} D_{ik} + A_{jk} \dot{E}_{ik} - j_k \dot{D}_{ik} + B_{jk} \ddot{E}_{ik} - C_{jk} \ddot{D}_{ik} + C_{jk} E_{ik}^{(3)} + D_{jk} A_{ik} - D_{jk} \dot{B}_{ik} + D_{jk} \ddot{C}_{ik} + E_{jk} \dot{A}_{ik} - E_{jk} \ddot{B}_{ik} + E_{jk} C_{ik}^{(3)}] = 0.$$

$i, j = 1, \dots, m$.

Hence, we have the following theorem.

Theorem 3: Consider a minimal system (52). Then it is Hamiltonian if and only if the following conditions

$$\begin{aligned} \mathcal{L}_1) & CE^T + EC^T = 0, \\ \mathcal{L}_2) & BE^T - CD^T + 3C\dot{E}^T + DC^T - EB^T + 3E\dot{C}^T = 0, \\ \mathcal{L}_3) & AE^T - BD^T + 2B\dot{E}^T - 2C\dot{D}^T + 3C\ddot{E}^T \\ & - DB^T + 2D\dot{S}^T + EA^T - 2E\dot{B}^T + 3E\ddot{C}^T = 0, \\ \mathcal{L}_4) & -AD^T + A\dot{E}^T - B\dot{D}^T + B\ddot{E}^T - CD^T \\ & + CE^{(3)T} + DA^T - D\dot{B}^T + D\ddot{C}^T \\ & + E\dot{A}^T - E\dot{B}^T + EC^{(3)T} = 0 \end{aligned} \quad (58)$$

hold along every solution $(u(t), y(t))$ of (52).

Elaboration of the Conditions \mathcal{L}_1 , \mathcal{L}_2 , \mathcal{L}_3 , and \mathcal{L}_4 in Special Cases

Case 1: Let us first consider the case $m = 1$, i.e., (47). If we assume $C' = \frac{\partial F}{\partial y} \neq 0$, then \mathcal{L}_1 yields

$$E = \frac{\partial F}{\partial \dot{u}} = 0$$

which is the condition (50)-i). Then \mathcal{L}_2 reduces to

$$-\frac{\partial F}{\partial y} \frac{\partial F}{\partial u} + \frac{\partial F}{\partial u} \frac{\partial F}{\partial y} = 0$$

which is automatically satisfied. Furthermore \mathcal{L}_3 amounts to

$$-\frac{\partial F}{\partial \ddot{y}} \frac{\partial F}{\partial u} - \frac{\partial F}{\partial u} \frac{\partial F}{\partial \ddot{y}} - 2 \frac{\partial F}{\partial y} \left(\frac{\partial F}{\partial u} \right)^{(1)} + 2 \frac{\partial F}{\partial u} \left(\frac{\partial F}{\partial \ddot{y}} \right)^{(1)} = 0$$

or

$$-\frac{\partial F}{\partial \ddot{y}} \frac{\partial F}{\partial u} - \frac{\partial F}{\partial \ddot{y}} \left(\frac{\partial F}{\partial u} \right)^{(1)} + \frac{\partial F}{\partial u} \left(\frac{\partial F}{\partial \ddot{y}} \right)^{(1)} = 0$$

which is the condition (50)-ii), and it is easily checked that \mathcal{L}_4 is precisely the time-derivative of (50)-ii).

Let us now derive a more explicit expression for the remainder Q in this particular case. Since $E = 0$, from (55)

$$Q = \xi B y_u + \xi C \dot{y}_u - (\xi C)^{(1)} y_u$$

and from (56)

$$\xi = -D^{-1} y_a.$$

If the conditions (50) hold we readily obtain

$$Q = [y_a, \dot{y}_a]^T \begin{bmatrix} 0 & C/D \\ -C/D & 0 \end{bmatrix} \begin{bmatrix} y_u \\ \dot{y}_u \end{bmatrix}. \quad (59)$$

Now let us take a closer look at (50). Writing out

$$\left(\frac{\partial F}{\partial \ddot{y}} \right)^{(1)} \frac{\partial^2 F}{\partial \ddot{y}^2} y^{(3)} + \frac{\partial^2 F}{\partial \ddot{y} \partial \ddot{y}} \ddot{y} + \frac{\partial^2 F}{\partial y \partial \ddot{y}} \dot{y} + \frac{\partial^2 F}{\partial u \partial \ddot{y}} \dot{u}$$

and

$$\left(\frac{\partial F}{\partial u} \right)^{(1)} = \frac{\partial^2 F}{\partial u \partial \ddot{y}} y^{(3)} + \frac{\partial^2 F}{\partial \ddot{y} \partial u} \ddot{y} + \frac{\partial^2 F}{\partial y \partial u} \dot{y} + \frac{\partial^2 F}{\partial u^2} \dot{u}$$

and collecting terms first with $y^{(3)}$ and then \dot{u} we obtain

$$\begin{cases} \frac{\partial F}{\partial u} \frac{\partial^2 F}{\partial \ddot{y}^2} - \frac{\partial^2 F}{\partial u \partial \ddot{y}} \frac{\partial F}{\partial \ddot{y}} = 0 \\ \frac{\partial F}{\partial u} \frac{\partial^2 F}{\partial u \partial \ddot{y}} - \frac{\partial^2 F}{\partial u^2} \frac{\partial F}{\partial \ddot{y}} = 0 \end{cases} \quad (60)$$

which means that the elements of the matrix given in (59) only depend on y, \dot{y} (the state of the system), and thus (59) defines a symplectic form ω on the state space $\{(y, \dot{y}) | y \in \mathbb{R}, \dot{y} \in \mathbb{R}\}$ with coordinate expression

$$\omega = \begin{pmatrix} 0 & \frac{\partial F}{\partial y} / \frac{\partial F}{\partial u} \\ -\frac{\partial F}{\partial y} / \frac{\partial F}{\partial u} & 0 \end{pmatrix}.$$

Case 2: Let us assume that the input-output representation $F_i, i = 1, \dots, m$, have the following particular form

$$F_i(y, \dot{y}, y, u, \dot{u}) = S_i(y, \dot{y}, y) - u_i. \quad (61)$$

This is the classical case (see [14]). Conditions $\mathcal{L}_1, \mathcal{L}_2, \mathcal{L}_3$, and \mathcal{L}_4 reduce to

$$\begin{aligned} \mathcal{L}_1) & \text{ void} \\ \mathcal{L}_2) & \frac{\partial S}{\partial y} - \left(\frac{\partial S}{\partial \dot{y}} \right)^T = 0 \\ \mathcal{L}_3) & \frac{\partial S}{\partial y} + \left(\frac{\partial S}{\partial \dot{y}} \right)^T - 2 \frac{d}{dt} \left(\frac{\partial S}{\partial \dot{y}} \right)^T = 0 \\ \mathcal{L}_4) & \frac{\partial S}{\partial y} - \left(\frac{\partial S}{\partial \dot{y}} \right)^T + \frac{d}{dt} \left(\frac{\partial S}{\partial \dot{y}} \right)^T - \frac{d^2}{dt^2} \left(\frac{\partial S}{\partial \dot{y}} \right)^T = 0 \end{aligned}$$

at every point (y, \dot{y}, y) .

These conditions are precisely the conditions (2.1.17) in [14]. It follows that (61) represents the input-output behavior of a Hamiltonian system if and only if

$$S_i = R_{i,k}(y, \dot{y}) \ddot{y}^k + T_i(y, \dot{y}), \quad i = 1, \dots, m$$

where $R_{i,k}$ and T_i satisfy (2.2.9) in [14].

Case 3:

$$F_i(y, \dot{y}, \ddot{y}, u, \dot{u}) = S_i(y, \dot{y}) - u_i, \quad i = 1, \dots, m.$$

From the result of Santilli, it follows that

$$S_i = X_{i,k}(y) \dot{y}^k + Y_i(y), \quad i = 1, \dots, m$$

where $X_{i,k}$ and Y_i satisfy

$$\begin{aligned} X_{i,k} + X_{k,i} &= 0 \\ \frac{\partial X_{i,k}}{\partial y^k} + \frac{\partial X_{k,i}}{\partial y^i} + \frac{\partial X_{i,i}}{\partial y^k} &= 0 \\ \frac{\partial Y_i}{\partial y^k} - \frac{\partial Y_k}{\partial y^i} &= 0. \end{aligned}$$

Thus $X = (X_{i,j})$ defines the symplectic form ω . This also follows from (18), since $y_a^k = \xi^k$ and $Q = y_a^i X_{i,k} y_u^k$.

Example 1: As an example we consider the system given by the equations

$$\begin{aligned}\dot{q} &= u \\ \dot{p} &= \sin q + \alpha p \\ y &= p.\end{aligned}$$

The corresponding input-output differential equation is given by

$$F(y, \dot{y}, \ddot{y}, u, \dot{u}) = (\ddot{y} - \alpha \dot{y})^2 + (\dot{y} - \alpha y)^2 u^2 - u^2 \equiv 0. \quad (62)$$

Clearly, by inspecting the state representation of the system, we see that the system is Hamiltonian with the Hamiltonian function $H = \cos q + up$, if and only if $\alpha = 0$. This is not so evident, however, from the form of the input-output differential equation above. We shall employ condition (50) of Crouch and Lamnabhi [4] to show this. Condition i), $\partial F / \partial \dot{u} \equiv 0$, is trivially satisfied. We calculate the quantity

$$Z = \frac{\partial F}{\partial u} \left[\frac{d}{dt} \frac{\partial F}{\partial y} - \frac{\partial F}{\partial \dot{y}} \right] - \frac{\partial F}{\partial \ddot{y}} \frac{d}{dt} \frac{\partial F}{\partial u}$$

directly from F to obtain

$$\begin{aligned}Z &= (-4u)(1 - (\dot{y} - \alpha y)^2)[(y^{(3)} - \alpha \ddot{y}) \\ &\quad + \alpha(\ddot{y} - \alpha \dot{y}) - u^2(\dot{y} - \alpha y)] \\ &\quad - 4(\dot{y} - \alpha y)[2u(\dot{y} - \alpha y)(\dot{y} - \alpha \dot{y}) \\ &\quad - \dot{u}(1 - (\dot{y} - \alpha y)^2)].\end{aligned}$$

From $F(y, \dot{y}, \ddot{y}, u, \dot{u}) \equiv 0$ we obtain

$$(y^{(3)} - \alpha \ddot{y}) = \frac{u \dot{u}}{(\dot{y} - \alpha y)} - (\dot{y} - \alpha y)u^2 - \frac{u \dot{u}(\dot{y} - \alpha y)^2}{(\dot{y} - \alpha y)}$$

Substituting this expression into the expression for Z and again using the definition of F , we see that $Z \equiv 0$ if and only if

$$\alpha u(1 - (\dot{y} - \alpha y)^2)(y - \alpha \dot{y}) \equiv 0.$$

This equation can be satisfied for all $y(0)$, $\dot{y}(0)$, $u(0)$ only if $\alpha = 0$, so we conclude that the system (62) is Hamiltonian if and only if $\alpha = 0$, as we previously concluded.

It is also interesting to compare the adjoint system with equation (62). The variational system is given by

$$\begin{aligned}u_v((\dot{y} - \alpha y)^2 u - u) + y_v(-\alpha u^2(\dot{y} - \alpha y)) \\ + \dot{y}_v(u^2(\dot{y} - \alpha y) - \alpha(\dot{y} - \alpha \dot{y})) + \ddot{y}_v(y - \alpha(\dot{y})) = 0.\end{aligned} \quad (63)$$

Using the method of integration by parts introduced in (56), we see that the adjoint system is given by the equation

$$y_a = \xi((\dot{y} - \alpha y)^2 u - u)$$

$$u_a = \xi \alpha u^2(\dot{y} - \alpha y) + \xi(u^2(\dot{y} - \alpha y) - \alpha(\dot{y} - \alpha \dot{y})) - \xi(\dot{y} - \alpha \dot{y}).$$

Thus $\xi = y_a / ((\dot{y} - \alpha y)^2 u - u)$. An explicit expression for the adjoint variational system in input-output differential representation (34) is obtained by eliminating ξ from the equation above. Our theory guarantees that the resulting equation coincides with equation (63) if and only if $\alpha = 0$.

Example 2. In the case of a linear time-invariant system

$$Ay + B\dot{y} + C\ddot{y} + Du + E\dot{u} = 0, \quad u, y \in \mathbf{R}^m$$

with A, B, C, D, E constant $m \times m$ matrices, the conditions $\mathcal{L}_1, \mathcal{L}_2, \mathcal{L}_3, \mathcal{L}_4$ reduce to

$$CE^T + EC^T = 0$$

$$BE^T - CD^T + DC^T - EB^T = 0$$

$$AE^T - BD^T - DB^T + EA^T = 0$$

$$-AD^T + DA^T = 0,$$

which is equivalently to the equality

$$\begin{aligned}(D + Es)(A^T - B^T s + C^T s^2) \\ = (A + Bs + Cs^2)(D^T - E^T s)\end{aligned}$$

for all $s \in \mathbf{C}$. This last equality in turn is equivalent to the transfer matrix $G(s) = (A + Bs + Cs^2)^{-1}(D + Es)$ of the system to satisfy the condition (cf. [1], [15]) $G(s) = G^T(-s)$.

Example 3 It can be straightforwardly checked that the Euler-Lagrange equations with external forces u

$$\frac{d}{dt} \left(\frac{\partial L}{\partial \dot{y}} \right) - \frac{\partial L}{\partial y} = u, \quad u, y \in \mathbf{R}^m$$

for any Lagrangian function $L(y, \dot{y})$ satisfy (56) (see also Santilli [14]).

Consider now an Euler-Lagrange system

$$\frac{d}{dt} \left(\frac{\partial L}{\partial \dot{q}_1} \right) - \frac{\partial L}{\partial q_1} = v_1, \quad v_1, q_1 \in \mathbf{R}$$

in interconnection with a static nonlinearity N (see van der Schaft [15] for details of interconnections), and assume for simplicity that $L(y, \dot{y}_1) = \frac{1}{2} m \dot{y}_1^2 - V(y_1)$, while the nonlinearity N is described by a differentiable function $y_2 = h(v_2)$. The interconnected system with outputs y_1, y_2 and inputs u_1, u_2 is given as (after elimination of v_1 and v_2)

$$\begin{aligned}m \ddot{y}_1 + \frac{\partial V}{\partial y_1}(y_1) - y_2 - u_1 &= 0 \\ h(y_1 + u_2) - y_2 &= 0.\end{aligned}$$

Computing the matrices A, B, C, D, E as in (51) yields

$$\begin{aligned}A &= \begin{bmatrix} \frac{\partial^2 V}{\partial y_1^2}(y_1) & -1 \\ \frac{\partial h}{\partial v_2}(y_1 + u_2) & -1 \end{bmatrix}, \\ C &= \begin{bmatrix} m & 0 \\ 0 & 0 \end{bmatrix}, \\ D &= \begin{bmatrix} -1 & 0 \\ 0 & \frac{\partial h}{\partial v_2}(y_1 + u_2) \end{bmatrix}\end{aligned}$$

while both B and E are zero. It is readily checked that conditions $\mathcal{L}_1, \mathcal{L}_2, \mathcal{L}_3, \mathcal{L}_4$ are satisfied, and thus the interconnected system is a Hamiltonian system for every scalar differentiable nonlinearity $y_2 = h(v_2)$.

In the multivariable case with $y_1, y_2, u_1, u_2, v_1, v_2 \in \mathbf{R}^m$ and $L(y_1, \dot{y}_1) = \frac{1}{2} \dot{y}_1^T M \dot{y}_1 - V(y_1)$, with $M = M^T > 0$,

it is straightforwardly checked that the interconnected system satisfies $\mathcal{L}_1, \mathcal{L}_2, \mathcal{L}_3, \mathcal{L}_4$ if and only if the nonlinearity $y_2 = h(v_2)$ satisfies the integrability condition $\frac{\partial h}{\partial v_2} = \left(\frac{\partial h}{\partial v_2}\right)^T$, and thus there exists (locally) a potential function $P(v_2)$ such that $y_2 = \frac{\partial P}{\partial v_2}(v_2)$.

IV. CHARACTERIZATION OF HAMILTONIAN SYSTEMS FROM THE STATE SPACE REPRESENTATION

In this section we derive another formulation of the criteria for self adjointness of the variational system (12) corresponding to an input-output differential representation (11). In this derivation, however, we work directly with the state space representations of the variational system (12) rather than the input-output differential representation (15) (which we did in the previous section). To do this we obtain a direct correspondence between the representations (12) and (15).

We first observe that the input-output map of the variational system Σ_v^u in equation (12) may be expressed in the form

$$y_v(t) = \int_0^t W_v(t, \sigma, u, x_0) u_v(\sigma) d\sigma \quad (64)$$

where we assume that $v(0) = 0$, and x_0 is the initial condition of the corresponding state space system (10). We also note that the input-output map of the adjoint variational system Σ_v^u in (13) is expressed in the form

$$y_u(t) = - \int_0^t W_v^T(t, \sigma, u, x_0) u_u(\sigma) d\sigma \quad (65)$$

where we assume that $p(0) = 0$. Thus (as formulated in [5], [6]) self-adjointness of the variational systems may be simply expressed as the statement

$$W_v(t, \sigma, u, x_0) = -W_v^T(\sigma, t, u, x_0) \quad (66)$$

for all $t \geq \sigma \geq 0$, all piecewise constant controls u , and one initial state x_0 . As we argued above, it is sufficient to check this identity for analytic controls u . Using the notation of (12), we may express the kernel W_v in the form

$$W_v(t, \sigma, x_0) = H(t)\Phi(t, \sigma)G(\sigma) (= W_v(t, \sigma))$$

where $\Phi(t, \sigma)$ is the transition matrix of $F(t)$. For analytic controls u , H , Φ , and G are all analytic in their arguments. Thus the self-adjointness criteria (66) may be expressed in the form

$$H(t)\Phi(t, \sigma)G(\sigma) = -G(t)^T \Phi(\sigma, t)^T H(t)^T \quad t \geq \sigma \geq 0. \quad (67)$$

Our first task is to give an equivalent formulation of the conditions (67) in terms of standard (time varying) linear system objects. We define the sequence of time varying $p \times n$ matrices $\Gamma_k(t)$ by setting

$$\begin{aligned} \Gamma_k^T(t) &= \left(I \frac{d}{dt} + F^T(t) \right)^k H^T(t); \\ \Gamma_0(t) &= H(t), \quad k \geq 0 \end{aligned} \quad (68)$$

and we define the sequence of time varying $n \times m$ matrices $\Sigma_k(t)$ by setting

$$\begin{aligned} \Sigma_k(t) &= (-1)^k \left(I \frac{d}{dt} - F(t) \right)^k G(t); \\ \Sigma_0(t) &= G(t), \quad k \geq 0. \end{aligned} \quad (69)$$

Noting that

$$\begin{aligned} \frac{\partial}{\partial t} \Phi(t, \sigma) &= F(t) \Phi(t, \sigma); \\ \frac{\partial}{\partial \sigma} \Phi(t, \sigma) &= -\Phi(t, \sigma) F(\sigma) \end{aligned}$$

we easily obtain

$$\frac{\partial^k}{\partial t^k} H(t) \Phi(t, \sigma) = \Gamma_k(t) \Phi(t, \sigma); \quad k \geq 0 \quad (70)$$

$$\frac{\partial^k}{\partial \sigma^k} \Phi(t, \sigma) G(\sigma) = (-1)^k \Phi(t, \sigma) \Sigma_k(\sigma); \quad k \geq 0. \quad (71)$$

Lemma 1. In the case of analytic data the identity (67) is equivalent to the sequence of identities

$$(-1)^{k+l+1} \Gamma_k(t) \Sigma_l(t) = \Sigma_k(t)^T \Gamma_l(t)^T; \quad k, l \geq 0. \quad (72)$$

Proof: By applying (70) and (71) to (67) we obtain

$$(-1)^l \Gamma_k(t) \Phi(t, \sigma) \Sigma_l(\sigma) = -(-1)^k \Sigma_k(t)^T \Phi(\sigma, t)^T \Gamma_l(\sigma)^T.$$

By setting $t = \sigma$ we obtain (72). Conversely, from (72) and analyticity we recover the identity

$$(-1)^{k+l+1} \Gamma_k(t) \Phi(t, \sigma) G(\sigma) = \Sigma_k(t)^T \Phi(\sigma, t)^T H(\sigma)^T.$$

For $k = 0$, this is the desired identity (67). ■

Our main interest is to show that we may replace the infinite set of conditions represented by (72), with a suitable finite subset. We require the following results.

Lemma 2. Consider a time varying state space system

$$\begin{aligned} \dot{x} &= F(t)x + G(t)u, \quad x(0) = 0, \quad x \in \mathbf{R}^l \\ y &= H(t)x. \end{aligned} \quad (73)$$

Then

$$\begin{aligned} \frac{d^p}{dt^p} y(t) &= \sum_{k=0}^{p-1} \frac{d^k}{dt^k} (\Gamma_{p-1-k} \Sigma_0 u)(t) \\ &\quad + \int_0^t \Gamma_p(t) \Phi(t, \sigma) G(\sigma) u(\sigma) d\sigma. \end{aligned} \quad (74)$$

Proof: Since $\Gamma_0 = H(t)$, the statement (74) is true for $p = 0$. Assume by induction that (74) is true. Then

$$\begin{aligned} \frac{d^{p+1}}{dt^{p+1}} y(t) &= \sum_{k=0}^{p-1} \frac{d^{k+1}}{dt^{k+1}} (\Gamma_{p-1-k} \Sigma_0 u)(t) + \Gamma_p(t) G(t) u(t) \\ &\quad + \int_0^t \Gamma_{p+1}(t) \Phi(t, \sigma) G(\sigma) u(\sigma) d\sigma \\ &= \sum_{k=1}^p \frac{d^k}{dt^k} (\Gamma_{p-k} \Sigma_0 u)(t) + \Gamma_p(t) \Sigma_0(t) u(t) \\ &\quad + \int_0^t \Gamma_{p+1}(t) \Phi(t, \sigma) G(\sigma) u(\sigma) d\sigma. \end{aligned}$$

This is, then, the identity (74) with p replaced by $p + 1$. ■

Lemma 3: The input-output map of the controllable time varying linear system (73) satisfies the system

$$\sum_{k=0}^N A_k(t) y^{(k)}(t) = \sum_{k=0}^{N-1} B_k(t) u^{(k)}(t) \quad (75)$$

if and only if

$$\sum_{k=0}^N A_k(t) \Gamma_k(t) = 0 \quad (76)$$

$$B_k(t) = + \sum_{q=k}^{N-1} A_{q+1}(t) \sum_{p=k}^q (\Gamma_{p-k}(t) \Sigma_0(t))^{(p-k)} \binom{p}{k}. \quad (77)$$

Proof: The input-output map of system (73) is given by

$$y(t) = \int_0^t H(t) \Phi(t, \sigma) G(\sigma) u(\sigma) d\sigma.$$

If this satisfies (75), we obtain the following expression using lemma (2)

$$\begin{aligned} & \sum_{p=1}^N A_p(t) \sum_{k=0}^{p-1} (\Gamma_{p-1-k} \Sigma_0 u)^{(k)}(t) \\ & + \sum_{p=0}^N A_p(t) \Gamma_p(t) \int_0^t \Phi(t, \sigma) G(\sigma) u(\sigma) d\sigma \\ & - \sum_{k=0}^{N-1} B_k(t) u^{(k)}(t) = 0. \end{aligned} \quad (78)$$

Thus

$$\begin{aligned} & \sum_{p=0}^N A_p(t) \Gamma_p(t) \int_0^t \Phi(t, \sigma) G(\sigma) u(\sigma) d\sigma = 0 \\ & \sum_{p=1}^N A_p(t) \sum_{k=0}^{p-1} \sum_{r=0}^k (\Gamma_{p-1-k} \Sigma_0)^{(k-r)}(t) u^{(r)}(t) \binom{k}{r} \\ & - \sum_{k=0}^{N-1} B_k(t) u^{(k)}(t) = 0. \end{aligned}$$

Controllability of system (73) and reordering summations now yields the desired identities (76) and (77). Conversely, the identities (76) and (77) yield (78) which by Lemma 2 ensures that the input-output map of (73) satisfies (75) as desired. ■

We wish to employ Lemma 3 in the context of the variational system Σ_s^v in (12) and the corresponding input-output representation $\Sigma_{i/o}^v$ in (15). However, (76) is not written in terms of purely input-output quantities which we require for our purposes. We therefore make the following observation.

If the system (73) is controllable, in the sense that

$$\text{rank} [\Sigma_0(t) | \Sigma_1(t) | \cdots | \Sigma_{N-1}(t)] = l \quad (79)$$

for all times t and all controls u , then the condition (76) may be replaced by the equivalent condition

$$\sum_{k=0}^N A_k(t) \Gamma_k(t) [\Sigma_0(t) | \Sigma_1(t) | \cdots | \Sigma_{N-1}(t)] = 0. \quad (80)$$

We may now state and prove our main result in this section.

Theorem 4: Consider a minimal input-output differential representation $\Sigma_{i/o}$, given by (11) with $p = m$, associated minimal state space representation Σ_s given by (11), and the associated variational system Σ_s^v . Then under the assumption (1) and the assumption that $\frac{\partial F}{\partial y(N)}$ is invertible for all analytic solutions (u, y) of (11), $\Sigma_{i/o}$ is an input-output representation of a Hamiltonian system Σ_s if and only if

$$(-1)^{k+l+1} \Gamma_k(t) \Sigma_l(t) = \Sigma_k(t)^T \Gamma_l(t)^T; \quad 0 \leq k, l \leq N \quad (81)$$

for all t and all analytic controls u .

Proof: As in [5] and [6], we know that Σ_s is Hamiltonian if and only if (66) holds for all analytic controls u . We have shown that these conditions are equivalent to the conditions (72), (Lemma 1). These conditions imply those of (81), hence establishing the necessity of the conditions (81). To prove necessity we argue as follows. We first compute the quantities Σ_k and Γ_k for the adjoint variational system Σ_s^a in (13). We make the substitutions

$$F \rightarrow -F^T; \quad G \rightarrow -H^T; \quad H \rightarrow G^T$$

in definitions (68) and (69). We obtain

$$\begin{aligned} \Sigma_k^a(t) &= (-1)^k \left(I \frac{d}{dt} + F(t)^T \right)^k (-H(t)^T) \\ &= (-1)^{k+1} \Gamma_k^v(t)^T = (-1)^{k+1} \Gamma_k(t)^T \end{aligned}$$

$$\begin{aligned} \Gamma_k^a(t) &= \left(I \frac{d}{dt} - F(t) \right)^k G(t) \\ &= (-1)^k \Sigma_k^v(t) = (-1)^k \Sigma_k(t). \end{aligned}$$

Thus

$$\Sigma_k^a(t) = (-1)^{k+1} \Gamma_k(t)^T; \quad \Gamma_k^a(t) = (-1)^k \Sigma_k(t)^T \quad (82)$$

We wish to generate conditions under which the input-output map (65) of Σ_s^a coincides with that of the input-output map (64) of Σ_s^v . By Assumption 1, the set of solutions (y_v, u_v) generated by Σ_s^v equals the set of solutions of $\Sigma_{i/o}^v$ represented by (15) or

$$\sum_{k=0}^N A_k(t) y_v^{(k)}(t) = \sum_{k=0}^{N-1} B_k(t) u_v^{(k)}(t). \quad (83)$$

(We also have that the set of solutions (y_v, u_v) of Σ_s^v corresponding to zero initial conditions $v(0) = 0$, is equal to the subspace through the origin of the set of solutions of $\Sigma_{i/o}^v$.) Hence, we may check self-adjointness of Σ_s^v , simply by checking that the input-output map (65) of Σ_s^a satisfies (83). By Lemma 3, however, the input-output map (65) satisfies (83) if and only if the (76) and (77) hold with Γ_k and Σ_k replaced by Γ_k^a and Σ_k^a , given in (82). Note that the controllability assumption required in Lemma 3 is translated into controllability of Σ_s^a , which is simply observability of Σ_s^v . Moreover, we may substitute the condition (76) by (80) as long as the condition (79) holds for Σ_s^a . Thus we obtain the

following conditions by substituting (82) into (80) and (77)

$$\sum_{k=0}^N A_k(t) \Sigma_k(t)^T (-1)^k [-\Gamma_0(t)^T | \Gamma_1(t)^T | \dots | \Gamma_{N-1}(t)^T] - \Gamma_2(t)^T \dots | (-1)^N \Gamma_{N-1}(t)^T] = 0$$

$$B_k(t) = \sum_{q=k}^{N-1} A_{q+1}(t) \sum_{p=k}^{N-1} (-1)^{p-k+1} (\Sigma_{p-k}^T(t) \Gamma_0(t)^T)^{(p-k)} \binom{p}{k}. \quad (84)$$

We now note that conditions (81) are indeed sufficient to ensure that (84) may be simply rewritten as (77) and (80). These are satisfied by virtue of the fact that by assumption the solutions (y_v, u_v) of Σ_s^v are solutions of $\Sigma_{i/o}^v$. It follows that we have shown sufficiency of the conditions (81), under the apparent further assumption that (79) holds for Σ_s^v .

To evaluate the further assumption it is useful to make an explicit construction, which is required later on. It is easily seen that we may rewrite the system $\Sigma_{i/o}^v$ given in (83) in the form

$$\sum_{k=0}^N (\hat{A}_k(t) y_v(t))^{(k)} = \sum_{k=0}^{N-1} (\hat{B}_k(t) u_v(t))^{(k)}$$

where $\hat{A}_N(t) = A_N(t) = \frac{\partial F}{\partial y^{(N)}}$. (Clearly the matrices \hat{A}_k and \hat{B}_k are related to the operators \hat{D} and \hat{N} defining the adjoint variational system in (41).) Under the assumption that $\frac{\partial F}{\partial y^{(N)}}$ is invertible we may rewrite (85) in the form

$$y_v^{(N)}(t) + \sum_{k=0}^{N-1} (\bar{A}_k(t) y_v(t))^{(k)} = \sum_{k=0}^{N-1} (\bar{B}_k(t) u_v(t))^{(k)}. \quad (85)$$

In this form we may write down the observable canonical form for the system (85), which will be a particular realization of Σ_s^v

$$\begin{pmatrix} -\bar{A}_{N-1}(t) & I & 0 & 0 \\ -\bar{A}_{N-2}(t) & 0 & I & 0 \\ \vdots & \vdots & \vdots & \vdots \\ -\bar{A}_0(t) & 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_N \end{pmatrix} + \begin{pmatrix} \bar{B}_{N-1}(t) \\ \bar{B}_{N-2}(t) \\ \vdots \\ \bar{B}_0(t) \end{pmatrix} u_v(t) = y_v^{(N)}(t)$$

$$y(t) = (I, 0, \dots, 0)(x_1, x_2, \dots, x_N)^T. \quad (86)$$

Clearly this time varying system satisfies the condition

$$\text{Rank} [\Gamma_0(t)^T | \Gamma_1(t)^T | \dots | \Gamma_{N-1}(t)^T] = Np \quad (87)$$

for all t and all analytic controls u . Thus the corresponding adjoint system does satisfy the controllability condition (79). Note that the conditions (81) are independent of the particular realization of Σ_s^v which is chosen, and in particular there is no necessity for the chosen realization to be minimal (as a time varying system). ■

Finally in this section we point out the relationship between the conditions (81) and the conditions (49) derived in the previous section. Although the conditions (81) are apparently expressed in terms of the system Σ_s^v , or any other realization, we may interpret them directly in terms of $\Sigma_{i/o}^v$. In particular we may apply the conditions (81) to the realization (85) constructed above. The presentation of the resulting conditions on the matrices $A_k(t)$, $B_k(t)$ defining $\Sigma_{i/o}^v$, as in (83) turns out to be different, but equivalent, to the conditions obtained by applying Theorem 2 in the previous section. We demonstrate the conditions obtained in this section on the system (52). We write the corresponding variational system in the form of (53) but assume $C = I_m$, the identity matrix for ease of explanation. (The general conditions may be obtained by replacing A , B , D , and E by $C^{-1}A$, $C^{-1}B$, $C^{-1}D$, and $C^{-1}E$, respectively.) Now if the variational system is written as

$$A(t)y_v + B(t)\dot{y}_v + \ddot{y}_v = -E(t)\dot{u}_v - D(t)u_v$$

this may be rewritten in the form of (85) as follows

$$\ddot{y}_v + B(t)y_v + (A(t) - B(t))\dot{y}_v = (-E(t)u_v) + (-D(t) + \dot{E}(t))u_v.$$

Thus the corresponding observable canonical form (86) becomes

$$\frac{d}{dt} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} -B(t) & I \\ \dot{B}(t) - A(t) & 0 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} + \begin{pmatrix} -E(t) \\ \dot{E}(t) - D(t) \end{pmatrix} u_v$$

$$y(t) = (I, 0)(x, x_2)^T. \quad (88)$$

The first condition in (81) is simply

$$-\Gamma_0(t)\Sigma_0(t) = \Sigma_0(t)^T\Gamma_0(t)^T$$

or simply

$$-H(t)G(t) = G(t)^T H(t)^T.$$

Substituting from (88) we obtain

$$E(t) = -E(t)^T.$$

Replacing E by $C^{-1}E$ we obtain

$$E(t)C(t)^T + C(t)E(t)^T = 0. \quad (89)$$

But this is simply \mathcal{L}_1 , in Theorem 3.

The next condition in (81) is simply

$$\Gamma_1(t)\Sigma_0(t) = \Sigma_1(t)^T\Gamma_0(t)^T$$

or simply $(\dot{H}(t) + H(t)F(t))G(t) = -(\dot{G}(t)^T - G(t)^T F(t)^T)H^T(t)$ or since $\dot{H}(t) \equiv 0$

$$H(t)F(t)G(t) = G(t)^T F(t)^T H(t)^T - \dot{G}(t)^T H(t)^T.$$

Substituting from (88) we obtain

$$\begin{aligned} [J, 0] \begin{bmatrix} -B & I \\ \dot{B} - A & 0 \end{bmatrix} \begin{bmatrix} -E \\ \dot{E} - D \end{bmatrix} \\ = [-E^T, \dot{E}^T - D^T] \begin{bmatrix} -B^T & \dot{B}^T - A^T \\ I & 0 \end{bmatrix} \begin{bmatrix} I \\ 0 \end{bmatrix} \\ - [-\dot{E}^T, \ddot{E}^T - \dot{D}^T] \begin{bmatrix} I \\ 0 \end{bmatrix} \end{aligned}$$

which simply reduces to the condition

$$B(t)E(t) - E(t)^T B(t)^T + D(t)^T - D(t) + E(t) - 2E(t)^T = 0$$

Replacing E , B , and D by $C^{-1}E$, $C^{-1}B$, and $C^{-1}D$, we obtain

$$C^{-1}BC^{-1}E - E^T C^{-T} B^T C^{-T} + D^T C^{-T} - C^{-1}D + \overline{(C^{-1}E)} - 2\overline{(C^{-1}E)^T} = 0$$

However, from (89) we have

$$C^{-1}E = -E^T C^{-T}$$

By expanding the above expression and using this identity we obtain

$$\begin{aligned} & -C^{-1}BE^T C^{-T} + C^{-1}EB^T C^{-T} + D^T C^{-T} \\ & - C^{-1}D + C^{-1}C^T E^T C^{-T} + C^{-1}E \\ & - 2C^{-1}EC^T C^{-T} - 2E^T C^{-T} = 0 \end{aligned}$$

which may be reexpressed, using the invertibility of C , as

$$\begin{aligned} & -BE^T + EB^T + CD^T - DC^T + CE^T + EC^T \\ & - 2EC^T - 2CE^T = 0 \end{aligned}$$

By differentiating (89), however, we obtain

$$CE^T + EC^T = -EC^I - CE^I$$

We therefore obtain the expression

$$-BE^I + EB^T + CD^T - DC^T - 3EC^I - 3CE^I = 0$$

Now it is easily seen that this is just condition \mathcal{L}_2 in Theorem 3. Clearly, the remaining conditions \mathcal{L}_3 and \mathcal{L}_4 will be contained in the conditions (81) for $N = 2$.

We make two final comments on (81). Clearly, by inspecting (77) and (80), the number of conditions in (81) may be reduced to $N \geq k \geq 0$, $N - 1 \geq l \geq 0$, $k \geq l$. For $N = 2$ this results in five conditions, but we already know from Theorem 3 that in the case $N = 2$, there are only four independent conditions. Thus we expect even the reduced set of conditions (81) to include many redundancies. Furthermore, Theorem 4 requires the assumption that $\frac{\partial F}{\partial y^{(N)}}$ is invertible, which Theorem 2 does not.

Conditions (81) do provide a satisfying generalization of the Brockett and Rahami result, discussed in the introduction. In particular, the condition that system (4) is Hamiltonian is simply given by the self-adjointness condition

$$C^T e^{A(t-\sigma)} B = -B^T e^{-A^T(t-\sigma)} C^T$$

By setting $\Gamma_k = C^T A^k$, $\Sigma_k = A^k B$, it is clear that self-adjointness is indeed equivalent to condition (81) for $N = n - 1$.

Dr Lamnabhi-Lagarrigue is an Associate Editor for *Systems and Control Letters* and *International Journal of Control*.

Arjan J. van der Schaft was born in Vlaardingen, The Netherlands, in February 1955. He received the University degree and Doctorate in mathematics from the University of Groningen in 1979 and 1983, respectively.

In 1982 he joined the Department of Applied Mathematics of the University of Twente, where he is presently an Associate Professor. He is (co-) author of the following books: *System Theoretic Descriptions of Physical Systems* (Amsterdam: CWI, 1984); *Variational and Hamiltonian Control Systems*

(with P. F. Crouch, Berlin: Springer, 1987); and *Nonlinear Dynamical Control Systems* (with H. Nijmeijer, New York: Springer, 1990). His research interests include the analysis and control of nonlinear and mechanical systems, and the mathematical modeling of physical systems.

Dr. Van der Schaft is Past Associate Editor of *Systems and Control Letters* and the *Journal of Nonlinear Science*, and presently serves as Associate Editor for the IFEL TRANSACTIONS ON AUTOMATIC CONTROL.

Language Convergence in Controlled Discrete-Event Systems

Yosef M. Willner and Michael Heymann

Abstract—Discrete-event systems modeled as state machines in the framework of Ramadge and Wonham are considered. In this paper, convergence of the language generated or marked by the system to a specified legal language is investigated. The convergence property is studied both with respect to open-loop (uncontrolled) systems and with respect to controlled systems. In the latter case, both questions of existence and synthesis of supervisors that force convergence are examined. Algorithms for verification of convergence and for synthesis of stabilizing supervisors are provided. Finally, the concept of asymptotic behavior of systems is defined, and questions related to this concept are investigated.

I. INTRODUCTION

IN the main paradigm of supervisory control of discrete-event systems (DES) [1]–[3], the system is modeled as a finite automaton that executes state transitions in response to a stream of events that occur nondeterministically and asynchronously. The supervisory control problem consists of synthesizing a supervisor whose task is to disable events in an orderly fashion, from a specified subset of controlled events, so as to confine the behavior of the supervised system to within a specified legal language. It is generally further required that the synthesized supervisor be minimally restrictive in the sense that, to achieve legal behavior, the smallest number of events is disabled.

There are situations, however, when legal supervision is either impossible or impractical. For example, when a system failure occurs, it may be driven to a state at which it is impossible to prevent the occurrence of illegal event sequences. Furthermore, even when the behavior of the system can be confined to within legal bounds, such a constraint may lead to the design of a supervisor that is overly restrictive. In such situations the question of convergence of the system to the legal behavior is of great interest. Intuitively, we say that the system converges to the legal behavior, if, after a finite and bounded number of transitions, it begins to behave legally. The supervisory control task is then to force such convergence to take place.

In [4] and [5] the problem of stabilization of discrete-event systems has been introduced, and the stabilization, or convergence, concept was presented in terms of legal

and illegal states of the system. In [4] legal behavior was specified by a set T of legal states. A system was then defined to be stable if, for any arbitrary initial state, it reaches a state in T after a finite and bounded number of state transitions and thereafter remains in T indefinitely. A system was called stabilizable if there exists a supervisor under which the supervised system is stable. Algorithms for synthesis of stabilizing supervisors were also presented. Optimal stabilizing supervisors were presented in [8].

It is quite clear that the legal behavior of a DES cannot always be specified by a set of (legal) states, which constitutes a static specification, but rather by a legal language which constitutes a dynamic specification. In the latter case the system is said to converge to legal behavior if, after a bounded number of illegal state transitions, the system produces only legal behavior, that is, strings of the specification language.

The concept of language convergence was first introduced by Kumar *et al.* (who called it language-stability) in [9], more recently in [16] and [18], and independently by Willner and Heymann in [15]. A similar concept was also studied in a somewhat different setting by Ozveren and Willsky in [19]. In [15] the convergence concept was formulated in terms of w -languages (i.e., languages that consist of infinite strings). In the present paper we formulate the problem in terms of languages over Σ^* and extend the discussion far beyond that of [15]. We provide algorithms for determining the convergence of a regular language to another regular language and for synthesizing supervisors that guarantee that convergence takes place whenever such supervisors exist.

We show that for suffix-closed legal languages, i.e., languages in which every suffix of a string is also a string of the language, the convergence problem can be resolved with algorithms of polynomial complexity. In fact, for suffix-closed languages the complexity is essentially of the same order as the static stabilization problem of [4]. When the specification language E is not suffix closed, the convergence problem is resolved by an algorithm of complexity that is polynomial in the size of the recognizer of the system language but exponential in the size of the recognizer of the specification language.

A further concept introduced in the present paper is the asymptotic behavior of a DES. The asymptotic behavior is the language that the system executes after performing an arbitrarily large number of state transitions. We discuss the problem of synthesizing a supervisor that guarantees the confinement of the asymptotic behavior of the supervised system within a given legal language. In the case of a

suffix-closed specification, the inclusion of the asymptotic behavior in the specification language is equivalent to the convergence of the supervised system to the legal language. In the general case, inclusion of the asymptotic behavior in the specification language ensures the convergence of the behavior of the supervised system to the legal language. The inverse property, that language convergence implies confinement of the asymptotic behavior, is not in general true.

The paper is organized as follows. In Section II, a brief review of the basic elements of the framework of [1] is given, and the concept of language convergence is introduced. Algorithms for verifying language convergence for regular languages are presented in Section III. In Section IV we discuss the controlled convergence problem, i.e., the problem of existence and synthesis of supervisors that guarantee convergence. Problems associated with asymptotic behavior are considered in Section V. At various points of the paper our results are compared with the results obtained in [9] and [18].

II. PRELIMINARIES

We adopt the Ramadge-Wonham (RW) [1] discrete-event control formalism, that is, the DES under consideration is modeled as a deterministic automaton

$$P = (Q, \Sigma, \delta, q_0, Q_m) \quad (2.1)$$

where Q is a finite set of states, Σ is a finite set of event symbols, partitioned into two disjoint subsets Σ_c of controlled events and Σ_u of uncontrolled events. The map $\delta : \Sigma \times Q \rightarrow Q$ is a partial function called the state transition function, q_0 is the initial state, and $Q_m \subset Q$ is a subset of final (or marked) states.

Let Σ^* denote the set of all finite strings over Σ including the empty string ϵ . A subset $L \subset \Sigma^*$ is called a language over Σ .

Letting δ be extended in the standard way (see, e.g., [6]) to a function $\Sigma^* \times Q \rightarrow Q$, the language generated by P is defined as

$$\mathcal{L}(P) := \{t \in \Sigma^* \mid \delta(t, q_0)!\} \quad (2.2)$$

where the notation "!" means "is defined." The language marked by P is defined as

$$\mathcal{L}_m(P) := \{t \in \mathcal{L}(P) \mid \delta(t, q_0) \in Q_m\}. \quad (2.3)$$

A sequence of states $q_1, \dots, q_n \in R \subset Q$ is called a path of P contained in R (starting at q_1 and ending at q_n) if there exists a sequence of event symbols $\sigma_1, \dots, \sigma_{n-1}$ such that $q_{i+1} = \delta(\sigma_i, q_i)$ for each $i = 1, \dots, n-1$. When $q_n = q_1$ we call the path a cycle (in R). A subset $R \subset Q$ is called acyclic if P has no cycles in R . If P has no cycles in Q we also say that P is acyclic. We shall say that a state q' is accessible from a state q if there is a path of P starting at q and ending at q' . We shall denote by $\mathcal{A}(P, q)$ the set of all states of P that are accessible from q .

For a subset $\hat{Q} \subset Q$, we shall denote by $P_{\hat{Q}}$ the automaton obtained from P by replacing the initial state by the set \hat{Q} , that is

$$P_{\hat{Q}} := (Q, \Sigma, \delta, \hat{Q}, Q_m). \quad (2.4)$$

The language generated by $P_{\hat{Q}}$ is then defined as

$$\mathcal{L}(P_{\hat{Q}}) := \{t \in \Sigma^* \mid \delta(t, \hat{q})! \text{ for some } \hat{q} \in \hat{Q}\}. \quad (2.5)$$

The language marked by $P_{\hat{Q}}$ is then given by (2.3) upon replacing P by $P_{\hat{Q}}$. When \hat{Q} is a singleton $\{q\}$, we shall write P_q instead of $P_{\{q\}}$ and $P_{q_0} = P$.

If $P_1 = (Q_1, \Sigma, \delta_1, q_{10}, Q_{1m})$ and $P_2 = (Q_2, \Sigma, \delta_2, q_{20}, Q_{2m})$ are two automata over the event set Σ , we say that P_2 is a subautomaton of P_1 , denoted $P_2 \subset P_1$, if

$$a) \quad Q_2 \subset Q_1, \quad Q_{2m} \subset Q_{1m}, \quad q_{10} = q_{20}$$

$$b) \quad \delta_2(\sigma, q) = \delta_1(\sigma, q) \quad \forall \sigma \in \Sigma, q \in Q_2 \text{ s.t. } \delta_2(\sigma, q)!$$

Thus, a subautomaton is obtained from a given automaton by deleting from it transitions and/or states along with all the transitions incident on the deleted states. For a subset $\hat{Q} \subset Q$ we define the restriction of P to $Q - \hat{Q}$, denoted $P|_{\hat{Q}}$, as the subautomaton of P obtained by deleting from it all the states of \hat{Q} and the transitions incident on these states.

For given deterministic automata $P = (Q, \Sigma, \delta, q_0, Q_m)$ and $A = (X, \Sigma, \xi, x_0, X_m)$, the strict synchronous composition $P||A$ of P and A is defined as

$$P||A = (Q \times X, \Sigma, \alpha, (q_0, x_0), Q_m \times X_m)$$

where $\alpha : \Sigma \times Q \times X \rightarrow Q \times X$ is defined by

$$\alpha(\sigma, (q, x)) := \begin{cases} (\delta(\sigma, q), \xi(\sigma, x)) & \text{if } \delta(\sigma, q)! \text{ and } \xi(\sigma, x)! \\ \text{undefined} & \text{otherwise.} \end{cases}$$

It is well known that $\mathcal{L}(P||A) = \mathcal{L}(P) \cap \mathcal{L}(A)$ and $\mathcal{L}_m(P||A) = \mathcal{L}_m(P) \cap \mathcal{L}_m(A)$.

A supervisor for a DES P is a map $S : \mathcal{L}(P) \rightarrow 2^{\Sigma_c}$ such that for each $t \in \mathcal{L}(P)$, $S(t) \subset \Sigma_c$ is the set of controlled events that must be disabled next. The concurrent operation of the system P and the supervisor S , denoted by S/P , is called the closed-loop system. That is, a transition in S/P can take place whenever it can take place in P and is not disabled by S . The language $\mathcal{L}(S/P)$ generated by the closed-loop system is thus given recursively by

$$\begin{aligned} \epsilon &\in \mathcal{L}(S/P) \\ (\forall s \in \mathcal{L}(S/P)) s\sigma &\in \mathcal{L}(S/P) \Leftrightarrow s\sigma \in \mathcal{L}(P) \wedge \sigma \notin S(s). \end{aligned}$$

The language marked by S/P will be defined by

$$\mathcal{L}_m(S/P) = \mathcal{L}(S/P) \cap \mathcal{L}_m(P) \quad (2.6)$$

and consists of all the strings marked by P that are not disabled by S .

We shall assume that the system P under consideration is trim, i.e., every state $q \in Q$ is accessible from q_0 and $\mathcal{L}(P) = \mathcal{L}_m(P)$. A supervisor S is then called nonblocking if $\mathcal{L}(S/P) = \mathcal{L}_m(S/P)$.

For strings $s, t \in \Sigma^*$ we let $s \cdot t$ denote their concatenation. A string s is a prefix of t , denoted $s \leq t$, if $t = sw$ for some $w \in \Sigma^*$. If $w \neq \epsilon$, s is said to be a proper prefix of t , denoted $s < t$. The prefix closure \bar{L} of a language $L \subset \Sigma^*$ is the set of all prefixes of strings in L and L is prefix closed if $\bar{L} = L$. The length of a string t is denoted $|t|$ and the prefix of t of length i is denoted $pr_i(t)$ ($pr_0(t) = \epsilon$).

For a string $t \in \Sigma^*$ we denote by $\text{suf}_i(t)$ the string obtained by deleting from t its first i symbols ($\text{suf}_0(t) = t$ and $\text{suf}_{|t|}(t) = \epsilon$). For a language $L \subset \Sigma^*$, the suffix closure of L is the subset of all suffixes of strings in L , that is

$$\text{suf}(L) = \{\text{suf}_i(t) \mid \forall t \in L, \forall i \leq |t|\}. \quad (2.7)$$

A language L is suffix closed if $\text{suf}(L) = L$. The following properties of the suffix operator are readily verified:

- The suffix operator is monotone, i.e.,

$$L_1 \subset L_2 \Rightarrow \text{suf}(L_1) \subset \text{suf}(L_2). \quad (2.8)$$

- For a family of languages $\{L_\alpha \subset \Sigma^*\}$

$$\text{suf}\left(\bigcup L_\alpha\right) = \bigcup \text{suf}(L_\alpha), \quad (2.9)$$

$$\text{suf}\left(\bigcup L_\alpha\right) \subset \bigcup \text{suf}(L_\alpha) \quad (2.10)$$

with equality in (2.10) if for each α , L_α is suffix closed.

Let $L \subset \Sigma^*$ be a regular language and let $P = (Q, \Sigma, \delta, q_0, Q_m)$ be a (trim) recognizer for L , i.e., $\mathcal{L}_m(P) = L$ and $\mathcal{L}(P) = \overline{\mathcal{L}_m(P)}$. A recognizer for $\text{suf}(L)$ is then given by $P_Q = (Q, \Sigma, \delta, Q, Q_m)$, that is, $\mathcal{L}_m(P_Q) = \text{suf}(L)$ (with $\mathcal{L}_m(P_Q)$ as defined following (2.5)). From (2.7), $L \subset \text{suf}(L)$, so that L is suffix closed if and only if $\mathcal{L}_m(P_Q) \subset \mathcal{L}_m(P)$. This inclusion is equivalent to the condition that $\mathcal{L}_m(P_Q) \cap (\Sigma^* - \mathcal{L}_m(P)) = \emptyset$, which can be verified by an algorithm with complexity of $O(|Q|^2)$ (see e.g., [10, Proposition 2.3]).

We conclude this section with the definition of language convergence that will be needed in the sequel. Let $L, M \subset \Sigma^*$ be two languages such that $M \neq \emptyset$.

Definition 2.1: The language L is said to converge asymptotically to M , denoted $M \leftarrow L$, if for each $t \in L$ there exists an integer $i \geq 0$ such that $\text{suf}_i(t) \in M$.

Remark 2.1: It is worth noting that the asymptotic convergence $M \leftarrow L$ is equivalent to $L \subset \Sigma^* \cdot M$ (where $\Sigma^* \cdot M$ denotes the language concatenation, i.e., $s \in \Sigma^* \cdot M$ if and only if $s = r \cdot t$ where $r \in \Sigma^*$ and $t \in M$). Thus, the asymptotic convergence problem can be investigated as a special case of the language confinement problem that was investigated in detail by RW in [1].

Definition 2.2: The language L is said to converge finitely (or, simply, to converge) to M , denoted $M \Leftarrow L$, if there exists a finite integer $k \geq 0$ such that for each $t \in L$ there exists $i, i \leq k$, for which $\text{suf}_i(t) \in M$. In that case the least k for which the above holds is called the convergence time of L to M and is denoted $e_M(L)$.

While finite convergence obviously implies asymptotic convergence, the converse is not generally true as illustrated by the simple example where $L = \alpha^* \beta$ and $M = \{\beta\}$.

It is easily verified that the class of languages that converge asymptotically to a given language is closed under arbitrary intersections and arbitrary unions while the class of languages that converge finitely to a given language is closed under arbitrary intersections but only under finite unions. Finally,

if $L_1, L_2, M \subset \Sigma^*$ are languages such that $L_1 \subset L_2$ and $M \neq \emptyset$, then

$$(M \leftarrow L_2) \Rightarrow (M \leftarrow L_1) \quad (2.11)$$

and

$$(M \Leftarrow L_2) \Rightarrow (M \Leftarrow L_1). \quad (2.12)$$

III. FINITE LANGUAGE CONVERGENCE

In the present section we shall develop necessary and sufficient conditions for finite language convergence. Furthermore, we develop algorithms for testing whether $M \Leftarrow L$ for regular languages $L, M \subset \Sigma^*, M \neq \emptyset$. For a variety of interesting special cases, algorithms of polynomial time complexity are constructed. In the most general case, however, our algorithm is of polynomial complexity in the size of the recognizer for L but exponential in the size of the recognizer for M .

Let $L, M \subset \Sigma^*, M \neq \emptyset$ be two regular languages, let $P = (Q, \Sigma, \delta, q_0, Q_m)$ and $A = (X, \Sigma, \xi, x_0, X_m)$ be deterministic trim recognizers for L and M , respectively, so that $\mathcal{L}_m(P) = L$, $\mathcal{L}_m(A) = M$, $\overline{\mathcal{L}_m(P)} = \mathcal{L}(P)$ and $\overline{\mathcal{L}_m(A)} = \mathcal{L}(A)$. Let T_q be the subset of states in Q given by

$$T_q = \{q \in Q \mid \mathcal{L}_m(P_q) \subset \text{suf}(M)\} \quad (3.1)$$

(where, as defined earlier, P_q is the automaton P initialized at q).

The following is a necessary condition for (finite-) convergence of L to M .

Proposition 3.1 Let $L, M \subset \Sigma^*$ be the languages recognized by the automata P and A , respectively. Then $M \Leftarrow L$ only if the set $Q - T_q$ is acyclic (in P).

Proof: Suppose that P has a cycle C in $Q - T_q$. Since P is trim, every state of P is accessible from q_0 and there is a sequence of strings $\{t_i\}$, $t_i \in \mathcal{L}(P) = \overline{L}$, $t_1 < t_2 < t_3 \dots$ such that for each i , $\delta(t_i, q_0) \in C$. Assume that $M \Leftarrow L$ with convergence time $k (= e_M(L))$. Let t_j be a string of the above sequence such that $n := |t_j| > k$. Then $q = \delta(t_j, q_0) \in C$ and there exists $s \in \mathcal{L}_m(P_q)$ such that $s \notin \text{suf}(M)$ (since the states of C do not belong to T_q). But $t_j \cdot s \in \mathcal{L}_m(P) = L$ and by the convergence of L to M , there exists $l \leq k$ such that $\text{suf}_l(t_j \cdot s) \in M$. Since $n > l$, it follows that $s = \text{suf}_n(t_j \cdot s) = \text{suf}_{n-l}(\text{suf}_l(t_j \cdot s)) \in \text{suf}(M)$. This is a contradiction, and the proof is complete. \square

Next, we present a sufficient condition for convergence of L to M . Let T be the set of all states in Q defined by

$$T := \{q \in Q \mid \mathcal{L}_m(P_q) \subset M\} \quad (3.2)$$

and assume that $q_0 \notin T$, for otherwise $L \subset M$ and convergence is trivial. Next, let R be defined as the set of all states of $Q - T$ that are accessible from q_0 through a path that does not intersect T , that is

$$R := \{q \in Q \mid \exists t \in \overline{L}, \delta(t, q_0) = q \text{ and } (\forall i \leq |t|) \delta(pr_i(t), q_0) \in Q - T\}. \quad (3.3)$$

The set R can conveniently be computed as follows. Consider the automaton $P|T$ (obtained from P by deleting from it all the states of T and the transitions incident on these states).

Then R is the set of all states accessible in $P|T$ from the initial state q_0 , that is

$$R = \mathcal{A}(P|T, q_0) \quad (3.4)$$

(of course, if $q_0 \in T$ then $L \subset M$ and $R = \phi$).

Proposition 3.2: If R is acyclic and $R \cap Q_m = \phi$, then $M \Leftarrow L$.

Proof: Assume first that $T = \phi$. Then (since P is trim) $R = Q$ so that $R \cap Q_m = Q_m$. If $R \cap Q_m = \phi$, then $Q_m = \phi$ and hence $L = \mathcal{L}_m(P) = \phi$ and $M \Leftarrow L$ holds trivially. Assume now that $T \neq \phi$. If $R \cap Q_m = \phi$, then for each $t \in L = \mathcal{L}_m(P)$ there must exist $i, i \leq |t|$, such that $q = \delta(pr_i(t), q_0) \in T$. Now the acyclicity of R implies that this i must satisfy the condition that $i \leq |R|$. Hence we conclude that for each $t \in L$ there exists $i \leq |R|$ such that $q = \delta(pr_i(t), q_0) \in T$, implying that $\text{suf}_i(t) \in \mathcal{L}_m(P_q) \subset M$. It follows that $M \Leftarrow L$ and $c_M(L) \leq |R|$. \square

Proposition 3.2 suggests the following algorithm for determining the convergence of L to M .

Algorithm 3.1:

- 1) Compute the set T of states defined by (3.2). If $q_0 \in T$ then $L \subset M$. Convergence holds trivially. Halt.
- 2) Compute the set R as defined by (3.4).
- 3) Check (e.g., by the algorithm of [7, p. 64]) whether P has cycles in R . If the answer is yes, the algorithm is inconclusive. Halt.
- 4) If $R \cap Q_m = \phi$, then $M \Leftarrow L$. Halt.

The computation of R (which is a standard accessibility computation) and the algorithm for testing acyclicity of R as given in [7] are both of complexity¹ $O(|Q|)$. As regards the computation of T we proceed as follows.

A state $q \in Q$ is in T if and only if $\mathcal{L}_m(P_q) \subset \mathcal{L}_m(A)$ where $A = (X, \Sigma, \xi, x_0, X_m)$ is a deterministic recognizer for M ($\mathcal{L}_m(A) = M$). Equivalently, $q \in T$ if and only if $\mathcal{L}_m(P_q) \cap \mathcal{L}_m(A) = \phi$. A deterministic recognizer for $\Sigma^* - \mathcal{L}_m(A)$ is given by the automaton $\hat{A} = (\hat{X}, \Sigma, \hat{\xi}, x_0, \hat{X}_m)$, where $\hat{X} = X \cup \{d\}$, d being an additional "dump" state, $\hat{X}_m = \{d\} \cup (X - X_m)$, and $\hat{\xi} : \Sigma \times \hat{X} \rightarrow \hat{X}$ is given by

$$\hat{\xi}(\sigma, \hat{x}) = \begin{cases} \xi(\sigma, \hat{x}) & \text{if } \hat{x} \neq d \text{ and } \xi(\sigma, x)! \\ d & \text{otherwise.} \end{cases}$$

The construction of the automaton \hat{A} is of complexity $O(|X|)$.

For a state $q \in Q$, a recognizer for $\mathcal{L}_m(P_q) \cap (\Sigma^* - \mathcal{L}_m(A))$ is given by the automaton $P_q||\hat{A}$ (see Section II) and we have that $\mathcal{L}_m(P_q) \subset \mathcal{L}_m(A)$, or equivalently $q \in T$, if and only if $\mathcal{L}_m(P_q||\hat{A}) = \phi$. Thus, to compute T , we construct the automaton

$$P_Q||\hat{A} = (Q \times \hat{X}, \Sigma, \alpha, \{q, x_0\} | q \in Q, Q_m \times \hat{X}_m)$$

where $\alpha(\sigma, (q, \hat{x})) = (\delta(\sigma, q), \hat{\xi}(\sigma, \hat{x}))$ is defined if and only if $\delta(\sigma, q)!$ and $\hat{\xi}(\sigma, \hat{x})!$. Next, we let $C(Q_m \times \hat{X}_m)$ be the set

of all states $(q, \hat{x}) \in Q \times \hat{X}$ from which the set $Q_m \times \hat{X}_m$ is accessible in $P_Q||\hat{A}$, that is

$$C(Q_m \times \hat{X}_m) := \{(q, \hat{x}) \in Q \times \hat{X} | \exists t \in \Sigma^*, \alpha(t, (q, \hat{x})) \in Q_m \times \hat{X}_m\}.$$

A state q is thus in T if and only if $(q, x_0) \notin C(Q_m \times \hat{X}_m)$, whence T is given by

$$T = Q - \{q \in Q | (q, x_0) \in C(Q_m \times \hat{X}_m)\}.$$

The computation of $C(Q_m \times \hat{X}_m)$ is of complexity $O(|Q||X|)$ and hence the overall complexity of Algorithm 3.1 is $O(|Q||X|)$.

An interesting case of the convergence problem is when the language M includes the empty string ϵ . This implies that all deadlocking behavior of L is regarded as convergent. Specifically, since for each string $t \in L$, $\text{suf}_{|t|}(t) = \epsilon \in M$, it follows that if all strings of L are of bounded length, then L converges to any language M satisfying $\epsilon \in M$. A further observation is the following. When $\epsilon \in M$, then the acyclicity of R (as defined in (3.3) or (3.4)) implies convergence of L to M . Indeed, for $t \in L$ such that $|t| \leq |R|$, $\text{suf}_{|t|}(t) = \epsilon \in M$, and for $t \in L$ such that $|t| > |R|$, the acyclicity of R implies that there exists $i \leq |R|$ such that $\text{suf}_i(t) \in M$. Thus we have the following.

Proposition 3.3: Let $L, M \subset \Sigma^*$ be regular languages recognized by automata P and A , respectively, and let R be the set defined by (3.4). If $\epsilon \in M$ and R is acyclic, then $M \Leftarrow L$.

A special case of languages M that include the empty string are suffix-closed languages. Such language specifications correspond to cases when one is interested in the eventual correctness of the logical behavior of the process P but does not insist on specific initialization. Thus, one is satisfied with the fact that the behavior of P "merges" with that of a given specification language rather than performing complete strings of the specification and one wishes to find conditions for $\text{suf}(M) \Leftarrow \mathcal{L}_m(P) = L$.

Let M be suffix closed. Then $\epsilon \in M$, and it can be further noted that the sets T_s as defined in (3.1) and T as defined in (3.2) coincide. Proposition 3.1 then states that if $M \Leftarrow L$ then $Q - T$ is acyclic, and since $R \subset Q - T$, so is also R . Combining this fact with Proposition 3.3 gives the following interesting theorem.

Theorem 3.1: Let $L, M \subset \Sigma^*$ be (regular) languages recognized by automata P and A , respectively. Assume that M is suffix closed. Then $M \Leftarrow L$ if and only if $Q - T$ is acyclic.

Theorem 3.1 provides the theoretical foundation for the following algorithm that determines the convergence of L to M in case L and M are regular languages and M is suffix closed.

Algorithm 3.2:

- 1) Compute the set T of states defined by (3.2). If $q_0 \in T$ then $L \subset M$. Convergence holds trivially. Halt.
- 2) Check (e.g., by the algorithm of [7, p. 64]) whether P has cycles in $Q - T$.
- 3) L converges to M if and only if the answer to 2) is negative. Halt.

¹In the present paper we shall assume $|\Sigma| = O(1)$ and we give the complexity bounds only in terms of the number of states.

Fig 1

Fig 2

The complexity of Algorithm 3.2 is $O(|Q||\Sigma|)$ (see the analysis of complexity of Algorithm 3.1 for details).

We turn next to the problem of language convergence in the case when M is a general (not necessarily suffix-closed) regular language. The conditions of Proposition 3.2, and in the case when $\epsilon \in M$ of Proposition 3.3, are sufficient for convergence and, in view of their relative efficiency, should be tested first. When the corresponding algorithms (Algorithms 3.1 and 3.2, respectively) are inconclusive, one must resort to a more elaborate examination. As we shall see later, the algorithms in the general case are no longer of polynomial complexity.

Let us first examine two examples that will prove helpful in obtaining some intuitive insight. The first example shows that while the acyclicity of R is sufficient for convergence of L to M in case $\epsilon \in M$ (Proposition 3.3), it is not necessary when M is not suffix-closed.

Example 3.1 Consider the automata P and A as given in Fig. 1, where all the states of both P and A are final states.

Thus, $\mathcal{L}_m(P) = \mathcal{L}(P)$ and $\mathcal{L}_m(A) = \mathcal{L}(A)$ and, obviously, $\mathcal{L}(A) \subsetneq \mathcal{L}(P)$ (Here and in subsequent figures the entrance arrows indicate the initial states.) Observe that $T = \{q_1\}$, i.e., q_1 is the only state $q \in Q$ such that $\mathcal{L}(P_q) \subset \mathcal{L}(A)$ and the set $R = \{q_0, q_2\}$ is not acyclic. \square

Example 3.2 Here P and A are given by the automata of Fig. 2 and again all states (of P and A) are final states.

To verify that $\mathcal{L}(A) \subsetneq \mathcal{L}(P)$ note that

$$\mathcal{L}(P) = \overline{\delta\beta\alpha^*\gamma^*} = \delta\beta(\alpha\alpha)^*\gamma^* + \delta\beta\alpha(\alpha\alpha)^*\gamma^*$$

Fig 3

and that both $\overline{\beta(\alpha\alpha)^*\gamma^*}$ and $\overline{\delta\beta\alpha(\alpha\alpha)^*\gamma^*}$ are sublanguages of $\mathcal{L}(A)$.

Next note that

$$\mathcal{L}(P_{q_2}) = \alpha^*\gamma^* = (\alpha\alpha)^*\gamma^* + \alpha(\alpha\alpha)^*\gamma^*$$

and that $(\alpha\alpha)^*\gamma^* \subset \mathcal{L}(A_{r_1})$ and $\alpha(\alpha\alpha)^*\gamma^* \subset \mathcal{L}(A_{x_2})$.

Thus

$$\mathcal{L}(P_{q_2}) \subset \mathcal{L}(A_{r_1}) \cup \mathcal{L}(A_{x_2}) = \mathcal{L}(A_{\{r_1, x_2\}})$$

Note further that if $\delta(t, q_0) = q_2$ for $t \in \Sigma^*$, then $\xi(t, r_1) \in \{x_1, x_2\}$. \square

In Example 3.2 the language $L = \mathcal{L}(P)$ (that converges to $M = \mathcal{L}(A)$) satisfies the condition that the system P , starting at q_0 , reaches a state q such that

$$\mathcal{L}(P_q) \subset \mathcal{L}(A_\chi) \quad (3.5)$$

for some subset $\chi \subset \Sigma$. We shall see below that this is actually a necessary condition for convergence of L to M . Condition (3.5) is of course not sufficient for convergence as can be seen from the example in Fig. 3.

Here $\mathcal{L}(P)$ does not converge to $\mathcal{L}(A)$ although $\mathcal{L}(P_q) \subset \mathcal{L}(A_\chi)$.

Next we present an algorithm that tests the convergence of L to M for general regular languages L and M . The algorithm is based on the construction of a new recognizer for the language L in which the necessary condition that the automaton reaches a state that satisfies condition (3.5) is also sufficient. The complexity of the proposed algorithm is exponential in $|\Sigma|$, the dimension of the state set of A , but it is polynomial in $|Q|$, the dimension of the state set of P .

Theorem 3.2 Let $P = (Q, \Sigma, \delta, q_0, Q_m)$ and $A = (\Sigma, \Sigma, \xi, x_0, X_m)$ be given automata. The following algorithm verifies the convergence $\mathcal{L}_m(A) \subseteq \mathcal{L}_m(P)$.

Algorithm 3.3

- 1) Construct a deterministic automaton $B = (V, \Sigma, \alpha, v_0, V_m)$, where $V = Q \times 2^\Sigma$, $v_0 = (q_0, \{x_0\})$, $V_m = Q_m \times \Sigma$, and where $\alpha: \Sigma \times V \rightarrow V$ is defined as follows. Let $\chi \in 2^\Sigma$ be any element. Then see (3.6) at the bottom of the page. We assume that B is trim. Otherwise construct the maximal trim subautomaton of B .
- 2) Test whether there exists in B a state $v = (q, \chi) \in V$ such that $q \in Q_m$ and $\chi \cap X_m = \emptyset$. If such a state exists, $\mathcal{L}_m(A) \not\subseteq \mathcal{L}_m(P)$. Halt.
- 3) Compute the set $T \subset V$ defined by

$$T = \{v = (q, \chi) \in V \mid \mathcal{L}_m(P_q) \subset \mathcal{L}_m(A_\chi)\} \quad (3.7)$$

$$\alpha(\sigma, (q, \chi)) = \begin{cases} (\delta(\sigma, q), \chi') & \text{where } \chi' = \{x_0\} \cup \{x' \in \chi \mid (\exists x \in \chi) \xi(\sigma, x) = x'\} \\ \text{undefined} & \text{otherwise} \end{cases} \quad (3.6)$$

- 4) Test whether $V - \tilde{T}$ is acyclic (in B) (use, e.g., the algorithm of [7]).
- 5) If the answer to 4) is affirmative, then $\mathcal{L}_m(A) \Leftarrow \mathcal{L}_m(P)$. Otherwise not. Halt.

Proof: First observe from the definition of B that a string $t \in \Sigma^*$ is in $\mathcal{L}(B)$ if and only if $\alpha(t, (q_0, \{x_0\})) = (q, \chi)$, where

$$q = \delta(t, q_0) \quad (3.8)$$

and

$$\chi = \{x \in X \mid (\exists i \leq |t|) x = \xi(\text{su}f_i(t), x_0)\}. \quad (3.9)$$

Indeed, (3.8) holds since for each state $(q, \chi') \in V$ the transition $\alpha(\sigma, (q, \chi'))$ is if and only if $\delta(\sigma, q) = q'$. To see that also (3.9) holds, we proceed by induction on the length of strings. For $t = \epsilon$, (3.9) clearly holds with $\chi = \{x_0\}$. Suppose (3.9) holds for an arbitrary string t , so that

$$\chi_t = \{x \in X \mid (\exists i \leq |t|) x = \xi(\text{su}f_i(t), x_0)\}$$

and consider the string $t\sigma$ for an arbitrary $\sigma \in \Sigma$. Employing (3.6) and substituting the above expression for χ_t yields

$$\begin{aligned} \chi_{t\sigma} &= \{x_0\} \cup \{x' \in X \mid (\exists x \in \chi_t) \xi(\sigma, x) = x'\} \\ &= \{x_0\} \cup \{x' \in X \mid (\exists i \leq |t|) \xi(\sigma, \xi(\text{su}f_i(t), x_0)) = x'\} \\ &= \{x_0\} \cup \{x' \in X \mid (\exists i \leq |t\sigma|) \xi(\text{su}f_i(t\sigma), x_0) = x'\} \\ &= \{x' \in X \mid (\exists i \leq |t\sigma|) \xi(\text{su}f_i(t\sigma), x_0) = x'\}. \end{aligned}$$

An immediate consequence of (3.8) and (3.9) is that

$$\mathcal{L}(B) = \mathcal{L}(P) \quad (3.10)$$

and since $V_m = Q_m \times X$

$$\mathcal{L}_m(B) = \mathcal{L}_m(P) \quad (3.11)$$

Suppose now that there exists a state $v = (q, x) \in V$ such that $q \in Q_m$ and $\chi \cap X_m = \phi$. Let $t \in \Sigma^*$ be any string satisfying $\alpha(t, v_0) = v$. By (3.8) it follows that $q = \delta(t, q_0) \in Q_m$, i.e., $t \in \mathcal{L}_m(P)$. By (3.9) it follows that there is no $i \leq |t|$ such that $\xi(\text{su}f_i(t), x_0) \in X_m$. Thus, t has no suffix that belongs to $\mathcal{L}_m(A)$. It follows that $\mathcal{L}_m(P)$ does not converge to $\mathcal{L}_m(A)$. This proves the correctness of step 2).

Suppose next that every state $v = (q, \chi) \in V$ for which $q \in Q_m$ satisfies $\chi \cap X_m \neq \phi$. Then, in view of (3.8) and (3.9), every string $t \in \mathcal{L}_m(P)$ has a suffix that belongs to $\mathcal{L}_m(A)$. Clearly, if $|t| \leq |V - \tilde{T}|$, then the above implies that there exists $i \leq |V - \tilde{T}|$ such that $\text{su}f_i(t) \in \mathcal{L}_m(A)$. We shall show next that when $|V - \tilde{T}|$ is acyclic, there exists $i \leq |V - \tilde{T}|$ such that $\text{su}f_i(t) \in \mathcal{L}_m(A)$ also if $|t| > |V - \tilde{T}|$. If $\tilde{T} = \phi$ this is obvious because then V is acyclic and $|t| \leq |V| = |V - \tilde{T}|$ for all $t \in \mathcal{L}(B)$. When $\tilde{T} \neq \phi$, the acyclicity of $|V - \tilde{T}|$ implies that if $|t| > |V - \tilde{T}|$ then there exists $i < |V - \tilde{T}|$ such that $\alpha(\text{pr}_i(t), v_0) = v = (q, \chi) \in \tilde{T}$. Then, in view of (3.7)

$$\text{su}f_i(t) \in \mathcal{L}_m(P_q) \subset \mathcal{L}_m(A_\chi)$$

or, alternately

$$\text{su}f_i(t) \in \mathcal{L}_m(A_x) \quad (3.12)$$

for some $x \in \chi$. By (3.9) it then follows that there exists $j < i$ such that

$$x = \xi(\text{su}f_j(\text{pr}_i(t)), x_0). \quad (3.13)$$

Upon combining (3.12) and (3.13), we obtain that

$$\begin{aligned} \xi(\text{su}f_i(t), x) &= \\ \xi(\text{su}f_i(t), \xi(\text{su}f_j(\text{pr}_i(t)), x_0)) &= \\ \xi(\text{su}f_j(\text{pr}_i(t)) \cdot \text{su}f_i(t), x_0) &= \\ \xi(\text{su}f_j(t), x_0) \end{aligned}$$

which implies that

$$\text{su}f_j(t) \in \mathcal{L}_m(A). \quad (3.14)$$

Thus, the convergence time of $\mathcal{L}_m(P)$ to $\mathcal{L}_m(A)$ is bounded by $|V - \tilde{T}|$ and hence $\mathcal{L}_m(A) \Leftarrow \mathcal{L}_m(P)$.

To see that the acyclicity of $(V - \tilde{T})$ is necessary for convergence of $\mathcal{L}_m(P)$ to $\mathcal{L}_m(A)$, suppose that there exists a cycle C in $(V - \tilde{T})$. Since B is trim, every state of B is accessible from v_0 . Thus there exists a sequence $\{t_i\}$ of strings, $t_1 < t_2 < t_3 \dots$ such that for each i , $\alpha(t_i, v_0) = v_i = (q_i, \chi_i) \in C$. Suppose now that $\mathcal{L}_m(A) \Leftarrow \mathcal{L}_m(P)$ and let k be the convergence time. Choose a string t_i of the above sequence such that $n := |t_i| > k$. Since no state of C belongs to \tilde{T} , there exists $s \in \mathcal{L}_m(P_{q_i})$ such that $s \notin \mathcal{L}_m(A_x)$ for every $x \in \chi_i$. Now, $t_i s \in \mathcal{L}_m(P)$ and by the convergence assumption of $\mathcal{L}_m(P)$ to $\mathcal{L}_m(A)$, there exists $j \leq k$ such that

$$\text{su}f_j(t_i s) = \text{su}f_j(t_i) \cdot s \in \mathcal{L}_m(A).$$

Letting $x := \xi(\text{su}f_j(t_i), x_0)$, it follows that $s \in \mathcal{L}_m(A_x)$. But by (3.9) $x \in \chi_i$, a contradiction. \square

The complexity of steps 1), 2), and 4) of Algorithm 3.3 is $O(|Q|2^{|X|})$. The test whether $\mathcal{L}_m(P_q) \subset \mathcal{L}_m(A_\chi)$ can be performed by constructing a deterministic recognizer A^χ for $\mathcal{L}_m(A_\chi)$ (an algorithm of complexity $O(2^{|X|})$) and checking whether $\mathcal{L}_m(P_q) \subset \mathcal{L}_m(A^\chi)$ which can be done by a computation of complexity $O(|Q|2^{|X|})$. Thus, the complexity of step 3) as well as that of the complete algorithm is $O((|Q|2^{|X|})^2)$.

Remark 3.1: An alternate approach to verifying the convergence of $\mathcal{L}_m(P)$ to $\mathcal{L}_m(A)$ is based on the reversal of the automata P and A so as to obtain the reflections $\mathcal{L}_m(P)^R$ and $\mathcal{L}_m(A)^R$ of the languages $\mathcal{L}_m(P)$ and $\mathcal{L}_m(A)$. Then $\mathcal{L}_m(A) \Leftarrow \mathcal{L}_m(P)$ if and only if there exists a bounded language L (i.e., a language all of whose strings are of bounded length) such that $\mathcal{L}_m(P)^R \subset \mathcal{L}_m(A)^R \cdot L$. (Here $\mathcal{L}_m(A)^R \cdot L$ denotes the concatenation of the languages $\mathcal{L}_m(A)^R$ and L .) The reversed automata P^R and A^R are nondeterministic in general, and the algorithm for testing the convergence involves computing deterministic equivalents to P^R and A^R . Such an algorithm, whose complexity is $O((2^{|X|} + |Q|)^2)$, has recently been described in [9] and [18]. Algorithm 3.3 above, whose complexity is $O((|Q| \cdot 2^{|X|})^2)$, is superior to the algorithm in [9] and [18] since it is only of polynomial complexity in the size of Q (although it is also of second-degree exponential complexity in the size of X). Thus, Algorithm 3.3 can be regarded as relatively efficient or at least tractable when the specification can be described by a small automaton as opposed to the algorithm of [9] and [18], which is generally impractical.

Fig. 4.

Next we illustrate Algorithm 3.3 by employing it to verify the convergence problem of Example 3.2.

Example 3.3 (Verification of Convergence Problem of Example 3.2 — Algorithm 3.3):

Step 1: The automaton B is given in Fig. 4.

To illustrate property (3.9) let us examine state 2). Every string $t \in \Sigma^*$ that satisfies $\alpha(t, v_0) = (q_2, \{x_0, x_1, x_2\})$ is of the form $\delta\beta\alpha^i$ for some $i \geq 0$. If i is even, then the suffixes $\epsilon, \beta\alpha^i, \delta\beta\alpha^i$ satisfy the property $\xi(\epsilon, x_0) = x_0, \xi(\beta\alpha^i, x_0) = x_1$, and $\xi(\delta\beta\alpha^i, x_0) = x_2$. If i is odd, then these suffixes satisfy $\xi(\epsilon, x_0) = x_0, \xi(\beta\alpha^i, x_0) = x_2$, and $\xi(\delta\beta\alpha^i, x_0) = x_1$.

Step 2: Since in the automaton A of Fig. 2 $X_m = X$, we have $\{x\} \cap X_m = \{x\} \cap X = \{x\}$ for each state $x \in X$. Hence $\chi \cap X_m \neq \emptyset$ for each $(q, \chi) \in V$.

Step 3: It is easy to verify that

$$\tilde{T} = \{1, 2, 3\} \neq \emptyset.$$

Step 4: There does not exist a cycle (of B) in $V \cdot \tilde{T} = \{0\}$.

Step 5: $\mathcal{L}_m(A) \Leftarrow \mathcal{L}_m(P)$. \square

IV. LANGUAGE CONVERGENCE IN CONTROLLED DES

In the previous section we examined the problem of verification whether a language L (finitely) converges to a given language M . In the present section we shall deal with the problem of convergence of the language generated by a DES $P = (Q, \Sigma, \delta, q_0, Q_m)$ to a given specification of logical behavior given by a language $E \subset \Sigma^*$. Specifically, we shall examine the problem of existence of a nonblocking supervisor S such that $E \Leftarrow \mathcal{L}_m(S/P)$. Thus we formally define the following.

Controlled Convergence Problem (CCP): Synthesize a nonblocking supervisor S for P such that

$$E \Leftarrow \mathcal{L}_m(S/P). \quad (4.1)$$

We recall from [1] that a language $M, \emptyset \neq M \subset \mathcal{L}_m(P)$ can be realized by a nonblocking supervisor S , i.e., $\mathcal{L}_m(S/P) = M$, if and only if M satisfies the following two conditions:

- M is $\mathcal{L}_m(P)$ -closed, i.e.,

$$M = \bar{M} \cap \mathcal{L}_m(P). \quad (4.2)$$

- M is controllable with respect to $L(P)$, i.e.,

$$\bar{M}\Sigma_u \cap \mathcal{L}(P) \subset \bar{M}. \quad (4.3)$$

We further recall that, for a language N , the class $CL(\mathcal{L}_m(P) \cap N)$ of controllable and $\mathcal{L}_m(P)$ -closed sublanguages of $\mathcal{L}_m(P) \cap N$ has a unique supremal element \hat{N}_p . This implies that a nonblocking supervisor S exists such that $\mathcal{L}_m(S/P) \subset N$ if and only if $\hat{N}_p \neq \emptyset$. In view of the above observations we have the following immediate result.

Proposition 4.1: CCP is solvable if and only if there exists a controllable and $\mathcal{L}_m(P)$ -closed sublanguage $\phi \neq N \subset \mathcal{L}_m(P)$ such that $E \Leftarrow N$.

A special case of interest occurs when the process $P = (Q, \Sigma, \delta, q_0, Q_m)$ satisfies $Q_m = Q$, in which case $\mathcal{L}_m(P) = \mathcal{L}(P)$ and $\mathcal{L}_m(S/P) = \mathcal{L}(S/P)$. Condition (4.2) then becomes that M is prefix closed and, since the class of closed and controllable sublanguages of $\mathcal{L}(P)$ is closed under arbitrary intersections (see e.g., [1]), it contains a unique infimal element. Thus, in view of (2.12) when $Q_m = Q$, the solvability test of CCP simplifies to the following.

Let P^u be the automaton obtained from P upon deleting from it all controlled transitions, i.e., $P^u = (Q, \Sigma, \delta^u, q_0, Q_m)$, where

$$\delta^u(\sigma, q) = \begin{cases} \delta(\sigma, q) & \text{if } \sigma \in \Sigma_u \wedge \delta(\sigma, q) \neq \emptyset \\ \text{undefined} & \text{otherwise.} \end{cases} \quad (4.4)$$

Clearly $\mathcal{L}(P^u)$ is controllable and closed and for any supervisor S

$$\mathcal{L}(P^u) \subset \mathcal{L}(S/P).$$

Proposition 4.1 can now be replaced (for the case $Q_m = Q$) by the following proposition.

Proposition 4.2: Let $P = (Q, \Sigma, \delta, q_0, Q_m)$ with $Q_m = Q$ and let $E \subset \Sigma^*$ be given. Then CCP is solvable if and only if $E \Leftarrow \mathcal{L}(P^u)$.

The above proposition yields a simple procedure for solving CCP in the special case when $Q_m = Q$. First, one constructs P^u and checks whether $E \Leftarrow \mathcal{L}(P^u)$. This verification can be done with Algorithm 3.2 (which is of polynomial complexity) when E is suffix closed, and with Algorithm 3.3 otherwise. When $E \Leftarrow \mathcal{L}(P^u)$, then the most restrictive supervisor, i.e., the supervisor that disables all controlled events, is a solution of CCP because this supervisor satisfies

$$E \Leftarrow \mathcal{L}(S/P) = \mathcal{L}(P^u).$$

The above solution is, of course, not a very efficient one and in general better solutions might be sought. We shall return to this issue later.

Remark 4.1: In [9] and [18], a problem similar to CCP was discussed. A language L was called l -stabilizable w.r.t. E if there exists a sublanguage $H \subset L$, controllable w.r.t. L , such that $E \Leftarrow H$. The authors argued there that for a system $P = (Q, \Sigma, \delta, q_0, Q_m)$, $\mathcal{L}_m(P)$ is l -stabilizable w.r.t. a given language E if and only if $E \Leftarrow \mathcal{L}_m(P^u)$. The justification for this conclusion was the claim that $\mathcal{L}_m(P^u)$ is the infimal controllable sublanguage of $\mathcal{L}_m(P)$. When $Q_m = Q$, this claim is indeed true. It is false, however, in the general case when $Q_m \neq Q$, since in that case $\mathcal{L}_m(P^u)$ is not necessarily a controllable language. To solve the l -stabilizability problem as well as CCP in the general case, a different approach must be taken as discussed in detail below.

We turn next to the problem of solving CCP in the general case when $Q_m \neq Q$ and E is a general regular language. To this end we shall make use of two known algorithms that are briefly discussed below.

The first algorithm computes the supremal controllable and $\mathcal{L}_m(P)$ -closed sublanguages of a given language. Specifically, let $P = (Q, \Sigma, \delta, q_0, Q_m)$ be a DES and $M \subset \mathcal{L}_m(P)$ be a given regular language. Let $A = (X, \Sigma, \xi, x_0, X_m)$ be a deterministic recognizer for M ($\mathcal{L}_m(A) = M$). The construction of a deterministic recognizer for the supremal controllable (with respect to $\mathcal{L}(P)$) and $\mathcal{L}_m(P)$ -closed sublanguage of M is accomplished by an algorithm of complexity of $O(|Q||X|)$ as follows. First construct the synchronous composition $C' = P||A = (Q \times X, \Sigma, \alpha, (q_0, x_0), Q_m \times X_m)$ as described in Section II. Then $\mathcal{L}_m(C') = \mathcal{L}_m(P) \cap \mathcal{L}_m(A) = \mathcal{L}_m(P) \cap M = M$. The supremal $\mathcal{L}_m(P)$ -closed sublanguage of M is then given by $\mathcal{L}_m(C')$ (see [14, Appendix B]), where C' is given by the restriction

$$C' = C'|_{Q_m \times (X - X_m)}.$$

The complexity of constructing C' is $O(|Q||X|)$. By [2, Proposition, 6.1], the supremal controllable sublanguage of $\mathcal{L}_m(C')$ equals the supremal controllable and $\mathcal{L}_m(P)$ -closed sublanguage of M . A deterministic recognizer for the supremal controllable sublanguage of $\mathcal{L}_m(C')$ can be constructed by the algorithm of [11] (see also [12]), whose complexity is $O(|Q|^2 \cdot |X|^2)$. An algorithm of complexity $O(|Q||X|)$ has recently been given in [13]. Thus, the construction of the supremal controllable and $\mathcal{L}_m(P)$ -closed sublanguage of M can be accomplished with overall complexity $O(|Q||X|)$.

The second algorithm that we shall employ below appeared in [4] (see also [5], [9], [18]) and is briefly described next. Let $P = (Q, \Sigma, \delta, \cdot, Q_m)$ be a DES with unspecified initial state. Fix a subset $\hat{Q} \subset Q$ (which we shall regard as the set of legal states). The set \hat{Q} is called a strong attractor for a state $q \in Q$ if, when initialized at q , the system P always reaches a state in \hat{Q} after a bounded number of transitions. Formally, \hat{Q} is a strong attractor for $q \in Q$ if $\mathcal{A}(P|\hat{Q}, q)$ is acyclic and no state of $\mathcal{A}(P|\hat{Q}, q)$ is a deadlock state of P (i.e., a state at which no transition is defined). A set \hat{Q} is called a weak attractor for $q \in Q$ if there exists a supervisor S such that \hat{Q} is a strong attractor for q in (S/P) . Such a supervisor, when it exists, can be chosen to be static, i.e., for $s, t \in \mathcal{L}(P)$, $S(t) = S(s)$ whenever $\delta(s, q_0) = \delta(t, q_0) (= q)$. Note also that a static supervisor can be written as a map

$S : X \rightarrow 2^\Sigma$. The set of all states $q \in Q$ for which \hat{Q} is a weak attractor is called the region of weak attraction and is denoted by $\Omega_P(\hat{Q})$. If $\hat{Q} = \phi$, then $\Omega_P(\hat{Q}) := \phi$. In [4] and [5] algorithms are given for computation of $\Omega_P(\hat{Q})$ with complexity $O(|Q|^2)$. An algorithm of complexity $O(|Q|)$ has recently been presented in [9] and [18].

We return to our main discussion. To test the solvability of CCP, we first construct the automaton $B = (V, \Sigma, \alpha, v_0, V_m)$ as defined in Step 1) of Algorithm 3.3. In view of the fact that $\mathcal{L}(B) = \mathcal{L}(P)$ and $\mathcal{L}_m(B) = \mathcal{L}_m(P)$, [(3.10), (3.11)], it is clear that B can be regarded as a new model of our process. Thus, CCP is solvable with respect to P if and only if it is solvable with respect to B .

The automaton B offers an obvious advantage over P for testing the solvability of CCP in that its structure provides a simple way of identifying all strings of $\mathcal{L}_m(B)$ that do not have a suffix in E . Indeed, let $t \in \mathcal{L}_m(B)$ and $v = (q, \chi) \in V_m$ satisfy $\alpha(t, (q_0, \{x_0\})) = v$. Then, since $V_m = Q_m \times 2^X$, it follows that $q \in Q_m$ and, see (3.9), t has a suffix in E if and only if $\chi \cap X_m \neq \phi$. Let F be the set defined by

$$F = \{(q, \chi) \in V_m | q \in Q_m \text{ and } \chi \cap X_m \neq \phi\}. \quad (4.5)$$

Define B' as the automaton

$$B' = (V, \Sigma, \alpha, v_0, F)$$

which is obtained from B by restricting its set of final states to F . Suppose now that S is a solution to CCP with respect to B , i.e., $E \Leftarrow \mathcal{L}_m(S/B)$, and let $t \in \mathcal{L}_m(B) - \mathcal{L}_m(B')$. Since t has no suffix in E , it follows that $t \notin \mathcal{L}_m(S/B)$ and it follows further that $\mathcal{L}_m(S/B) \subset \mathcal{L}_m(B')$. Since $\mathcal{L}_m(S/B)$ is controllable with respect to $\mathcal{L}(B)$ and is $\mathcal{L}_m(B)$ -closed, we conclude that $\mathcal{L}_m(S/B) \subset \sup CL(\mathcal{L}_m(B'))$, where $\sup CL(\mathcal{L}_m(B'))$ is the supremal controllable (w.r.t. $\mathcal{L}(B)$) and $\mathcal{L}_m(B)$ -closed sublanguage of $\mathcal{L}_m(B')$. Define now the automaton

$$\hat{B} = (\hat{V}, \Sigma, \hat{\alpha}, \hat{v}_0, \hat{V}_m) \quad (4.6)$$

as a recognizer for $\sup CL(\mathcal{L}_m(B'))$. Such an automaton can be constructed by an algorithm of complexity $O(|Q| \cdot 2^{|X|})$ as was described earlier. From the algorithm it is also clear that \hat{B} is a subautomaton of B . Now, the inclusion $\mathcal{L}_m(S/B) \subset \mathcal{L}_m(\hat{B}) \subset \mathcal{L}_m(B)$ implies that $\mathcal{L}_m(S/B) = \mathcal{L}_m(S/\hat{B})$. Hence, CCP is solvable with respect to B only if it is solvable with respect to \hat{B} . To see the reverse implication, i.e., that solvability of CCP with respect to \hat{B} implies the solvability of CCP with respect to B , observe that $\mathcal{L}_m(\hat{B})$ is a controllable (w.r.t. $\mathcal{L}(B)$) and $\mathcal{L}_m(B)$ -closed sublanguage of $\mathcal{L}_m(B)$. Thus, there exists a supervisor \hat{S} such that $\mathcal{L}_m(\hat{S}/B) = \mathcal{L}_m(\hat{B})$. If there exists a supervisor S such that $E \Leftarrow \mathcal{L}_m(S/\hat{B})$, then $E \Leftarrow \mathcal{L}_m(S/(\hat{S}/B)) = \mathcal{L}_m(S \times \hat{S}/B)$, where $S \times \hat{S}$ is the supervisor that consists of the conjunction of S and \hat{S} (see e.g., [2]). We have just proved the following.

Lemma 4.1: For a DES P and a regular language E , let \hat{B} be the automaton defined by (4.6). Then CCP is solvable with respect to P if and only if CCP is solvable with respect to \hat{B} .

The following corollary is immediate.

Corollary 4.1: If $\mathcal{L}_m(\hat{B}) = \emptyset$ then CCP is unsolvable.

In Theorem 3.2 (see Algorithm 3.3) we have shown that the convergence $\mathcal{L}_m(A) \Leftarrow \mathcal{L}_m(P)$ is equivalent to the acyclicity of $V - \hat{T}$ where \hat{T} [see (3.7)] consists of all states $v = (q, \chi)$ such that $\mathcal{L}_m(P_q) \subset \mathcal{L}_m(A_\chi)$. Similarly, we construct now a subset \hat{T} of states of \hat{B} such that for each $v = (q, \chi) \in \hat{T}$ there exists a supervisor S with the property that $\mathcal{L}_m(S/P_q) \subset \mathcal{L}_m(A_\chi)$. We will then show that the solvability of CCP is equivalent to the possibility of preventing the system \hat{B} from executing cycles in $\hat{V} - \hat{T}$.

For a state $v = (q, \chi)$ of \hat{B} it follows from (4.2) and (4.3) that there exists a nonblocking supervisor S such that $\mathcal{L}_m(S/P_q) \subset \mathcal{L}_m(A_\chi)$ if and only if the class of controllable (with respect to $\mathcal{L}(P_q)$) and $\mathcal{L}_m(P_q)$ -closed sublanguages of $\mathcal{L}_m(P_q) \cap \mathcal{L}_m(A_\chi)$ does not consist of the empty language. To check this condition we proceed as follows. First note that A_χ is not a deterministic automaton since it has in general more than one initial state. Hence we begin by constructing a deterministic recognizer $A^\chi = (W, \Sigma, \beta, w_0, W_m)$ for $\mathcal{L}_m(A_\chi)$, i.e., $\mathcal{L}_m(A^\chi) = \mathcal{L}_m(A_\chi)$. Next, by the algorithm described earlier we construct a deterministic automaton D^ν such that

$$\mathcal{L}_m(D^\nu) = \sup CL(\mathcal{L}_m(P_q) \cap \mathcal{L}_m(A^\chi)). \quad (4.7)$$

The required supervisor S such that $\mathcal{L}_m(S/P_q) \subset \mathcal{L}_m(A_\chi)$ exists if and only if $\mathcal{L}_m(D^\nu) \neq \emptyset$. The construction of D^ν requires $O(|Q| \cdot 2^{|X|})$ computations since the number of states of A^χ is bounded by $2^{|X|}$ and the number of states of P_q is $|Q|$.

Now, let \hat{T} be the set of states defined by

$$\hat{T} = \{v \in \hat{V} \mid \mathcal{L}_m(D^\nu) \neq \emptyset\}. \quad (4.8)$$

Since the number of states of \hat{B} is bounded by $|Q| \cdot 2^{|X|}$ (the number of states of B) the construction of \hat{T} requires $O((|Q| \cdot 2^{|X|})^2)$ computations.

The final step in our computation is the employment of the algorithm of [9] and [18] to compute the set $\Omega_B(\hat{T})$. The complexity of this algorithm is $O(|Q| \cdot 2^{|X|})$.

We now have the following necessary and sufficient condition for the solvability of CCP.

Theorem 4.1: Let P be a DES, and let $E \subset \Sigma^*$ be a regular language. Let \hat{B} and \hat{T} be the automaton and the set of states as defined in (4.6) and (4.8), respectively. Then CCP is solvable if and only if $v_0 \in \Omega_B(\hat{T})$.

Proof: Only If. By Lemma 4.1 CCP is solvable with respect to P if and only if it is solvable with respect to \hat{B} . Suppose that CCP is solvable so that there exists a nonblocking supervisor S such that $E \Leftarrow \mathcal{L}_m(S/\hat{B})$. We shall show that the assumption that $v_0 \notin \Omega_B(\hat{T})$ leads to a contradiction. First we shall show that, under S , there are no deadlock states in $\hat{V} - \hat{T}$. Indeed, let $\hat{v} = (q, \chi) \in \hat{V} - \hat{T}$ and $t \in \mathcal{L}(S/\hat{B})$ be such that $\hat{\alpha}(t, \hat{v}_0) = \hat{v}$. Suppose that \hat{v} is a deadlock state, i.e., $t_s \in$

$\mathcal{L}(S/\hat{B}) \Rightarrow s = \epsilon$. If $q \in Q - Q_m$, then $(q, \chi) \notin \hat{V}_m$, implying that $t \notin \mathcal{L}_m(S/\hat{B})$. Thus $\mathcal{L}(S/\hat{B}) \neq \mathcal{L}_m(S/\hat{B})$, contradicting the nonblocking property of S . If $q \in Q_m$ then $\epsilon \in \mathcal{L}_m(P_q)$. By definition of \hat{B} , $\chi \cap X_m \neq \emptyset$ so that $\epsilon \in \mathcal{L}_m(A_\chi)$, implying that $\epsilon \in \mathcal{L}_m(P_q) \cap \mathcal{L}_m(A_\chi)$. Since the language $\{\epsilon\}$ is trivially $\mathcal{L}_m(P_q)$ -closed and controllable with respect to $\mathcal{L}(P_q)$, it follows that $\{\epsilon\} \in CL(\mathcal{L}_m(P_q) \cap \mathcal{L}_m(A_\chi))$, so that $\mathcal{L}_m(D^\nu) \neq \emptyset$. This implies that $\hat{v} \in \hat{T}$, a contradiction.

Since (S/\hat{B}) has no deadlock states in $\hat{V} - \hat{T}$, the assumption that $\hat{v}_0 \notin \Omega_B(\hat{T})$ implies that (S/B) has a cycle in $\hat{V} - \hat{T}$. With the employment of the same arguments as in the proof of Theorem 3.2, it is not difficult to show that the existence of a cycle in $\hat{V} - \hat{T}$ contradicts the assumption that $E \Leftarrow \mathcal{L}_m(S/\hat{B})$.

If. The proof of the "if" part of the theorem consists of the following algorithm for construction of the supervisor S that satisfies the condition that $E \Leftarrow \mathcal{L}_m(S/\hat{B})$ whenever $\hat{v}_0 \in \Omega_B(\hat{T})$.

Algorithm 4.1:

Step 1) Define the supervisor $S_1 : V \rightarrow 2^{\Sigma^*}$ as a static supervisor such that T is a strong attractor for $\Omega_B(\hat{T})$ with respect to S_1/\hat{B} . The existence of this supervisor follows from the definition of $\Omega_B(\hat{T})$.

Step 2) For each $\hat{v} \in \hat{V}$, let D^ν be the automaton defined earlier (see (4.7)).

The required supervisor is given by $S : L(\hat{B}) \rightarrow 2^{\Sigma^*}$ as found in (4.9) at the bottom of the page.

The supervisor S is obviously well defined because for each $t \in \mathcal{L}(\hat{B})$ it defines a unique set of controlled events to be disabled. Next, note that under the supervision of S , the system B reaches a state $v \in T$ within a number of transitions bounded by $|\hat{V} - \hat{T}|$ because for states in $\Omega_B(\hat{T}) - \hat{T}$ S acts as S_1 . When a state $\hat{v} = (q, \chi) \in T$ is reached, then it is guaranteed by S that all marked strings generated by \hat{B} (starting at \hat{v}) belong to

$$\mathcal{L}_m(D^\nu) = \sup CL(\mathcal{L}_m(P_q) \cap \mathcal{L}_m(A^\chi)) \subset \mathcal{L}_m(A_\chi).$$

It thus follows that for $t \in \mathcal{L}_m(S/\hat{B})$, $|t| \geq |\hat{V} - \hat{T}|$, there exists $i \leq |\hat{V} - \hat{T}|$ such that $\alpha(pr_i(t), \hat{v}_0) = \hat{v} = (q, \chi) \in \hat{T}$ and $\text{suf}_i(t) \in \mathcal{L}_m(A_\chi)$. By (3.12)–(3.14) it follows that there exists $j \leq i$ such that $\text{suf}_j(t) \in E$. If $|t| < |\hat{V} - \hat{T}|$, the existence of i ($\leq |\hat{V} - \hat{T}|$) such that $\text{suf}_i(t) \in E$ follows from the definition of \hat{B} . This concludes the proof. \square

The complexities of computing the automaton \hat{B} and the set \hat{T} are $O(|Q| \cdot 2^{|X|})$ and $O((|Q| \cdot 2^{|X|})^2)$, respectively. The computation of $\Omega_B(\hat{T})$ requires $O(|Q| \cdot 2^{|X|})$ computations. Thus, the complexity of verifying the solvability of CCP (i.e., checking the condition $\hat{v}_0 \in \Omega_B(\hat{T})$) is $O((|Q| \cdot 2^{|X|})^2)$. In case CCP is solvable, the supervisor defined by (4.9) is a solution of CCP.

$$\begin{aligned} S_1(\hat{v}) & \quad \text{where } \hat{v} = \hat{\alpha}(t, \hat{v}_0) & \quad \text{if } \{\forall_i\} \hat{\alpha}(pr_i(t), \hat{v}_0) \notin \hat{T} \\ S(t) = & \quad \{\sigma \in \Sigma_c \mid \text{suf}_{i_0}(t)\sigma \notin \mathcal{L}(D^\nu)\}, & \quad \text{if there exists } i \text{ such that} \\ & \quad \text{where } i_0 \text{ is the least integer } i & \quad \hat{\alpha}(pr_i(t), \hat{v}_0) \in \hat{T} \\ & \quad \text{that satisfies } \hat{\alpha}(pr_i(t), \hat{v}_0) \in \hat{T} & \end{aligned} \quad (4.9)$$

When E is suffix closed, the solvability of CCP can be verified by an algorithm of linear complexity (i.e., of complexity $O(|Q||X|)$) as described below. The correctness of the following algorithm follows from Theorems 3.1 and 4.1.

Theorem 4.2: Let $P = (Q, \Sigma, \delta, q_0, Q_m)$ be a given DES, and let E be a suffix-closed regular language. Let $A = (X, \Sigma, \xi, x_0, X_m)$ be a deterministic automaton such that $\mathcal{L}_m(A) = E$. Then the following algorithm verifies the solvability of CCP.

Algorithm 4.2:

- Step 1) For each $q \in Q$ construct a deterministic automaton D^q such that $\mathcal{L}_m(D^q)$ is the supremal controllable (w.r.t. $\mathcal{L}(P_q)$) and $\mathcal{L}_m(P_q)$ -closed sublanguage of $\mathcal{L}_m(P_q) \cap \mathcal{L}_m(A)$.
- Step 2) Compute the set Y of states defined by

$$Y := \{q \in Q \mid \mathcal{L}_m(D^q) \neq \emptyset\}.$$

- Step 3) By the algorithm of [9], [18] compute the set $\Omega_P(Y)$.

- Step 4) CCP is solvable if and only if $q_0 \in \Omega_P(Y)$. \square

The set Y can be constructed with the algorithm of [13] using the same method as was described in Section III for the computation of the set T . The complexity of constructing the set Y as well as the overall complexity of Algorithm 4.2 is $O(|Q||X|)$.

Algorithms 4.1 and 4.2, which constitute tests for solvability of CCP, also provide a construction of nonblocking supervisors that guarantee convergence of the closed-loop language to the specification E whenever CCP is solvable. The synthesis is, however, neither optimal nor unique since, in general, there does not exist a least restrictive supervisor that guarantees convergence. Specifically, there does not, in general, exist a supervisor S such that $E \Leftarrow \mathcal{L}_m(S/P)$ and such that if S is any supervisor satisfying $E \Leftarrow \mathcal{L}_m(S/P)$, then $\mathcal{L}_m(S/P) \subset \mathcal{L}_m(\hat{S}/P)$. To see this, consider the following simple example. Let $\mathcal{L}_m(P) = \alpha^*\beta$ and let $E = \beta$. Assume further that $\Sigma_c = \{\alpha\}$ and $\Sigma_u = \{\beta\}$. The solvability of CCP is obvious, and for any $k \geq 0$ there is a supervisor S_k such that $\mathcal{L}_m(S_k/P) = \alpha^k\beta$ (which clearly satisfies $\beta \Leftarrow \alpha^k\beta$). But for $k_1 \leq k_2$, $\alpha^{k_1}\beta \subset \alpha^{k_2}\beta$ and k can be arbitrarily large!

The issue of optimal supervisors (in contexts other than "minimally restrictive") is discussed in [17].

V. ASYMPTOTIC BEHAVIOR OF DES

In nonterminating systems, i.e., systems that operate indefinitely, one can distinguish between their transient and permanent (or asymptotic) behaviors. Intuitively, the asymptotic behavior of a system consists of all strings that the system can execute after having already performed an arbitrarily large number of transitions.

For a language $L \subset \Sigma^*$ we define its asymptotic suffix, denoted L_∞ as

$$L_\infty := \{s \in \Sigma^* \mid \forall l \geq 0, \exists t_l \in \Sigma^*, |t_l| \geq l \wedge t_l s \in L\}. \quad (5.1)$$

Clearly, L_∞ is an empty language whenever L is a bounded language (see Remark 3.1). It is also easy to see that L_∞ is suffix closed for every language $L \subset \Sigma^*$.

Let $P = (Q, \Sigma, \delta, q_0, Q_m)$ be a DES. The asymptotic behavior of P is defined as $\mathcal{L}_m(P)_\infty$. A recognizer for $\mathcal{L}_m(P)_\infty$ can be constructed as follows. Let $cy(P)$ be the set of all states of P that are accessible from q_0 and belong to a cycle of P , that is

$$cy(P) := \{q \in Q \mid (\exists s, t \in \Sigma^*) q = \delta(t, q_0), s \neq \epsilon \wedge \delta(s, q) = q\}. \quad (5.2)$$

Let $Q_\infty := \mathcal{A}(P, cy(P))$ and let $Q_{m\infty} := Q_m \cap Q_\infty$. Define

$$P_\infty := (Q_\infty, \Sigma, \delta, Q_\infty, Q_{m\infty}). \quad (5.3)$$

The following proposition states that P_∞ is a recognizer for $\mathcal{L}_m(P)_\infty$.

Proposition 5.1: $\mathcal{L}_m(P)_\infty = \mathcal{L}_m(P_\infty)$.

Proof: $\mathcal{L}_m(P)_\infty \subset \mathcal{L}_m(P_\infty)$. Let $t \in \mathcal{L}_m(P)_\infty$ be any string. By (5.1) there exists a string $w, |w| > |Q|$, such that $wt \in \mathcal{L}_m(P)$. Let $q_0, q_1, \dots, q_l, l = |w|$, be the path associated with w . Since $l > |Q|$, there exists a state $q \in Q$ that occurs along this path at least twice, i.e., there exist $i_1, i_2, 0 \leq i_1 < i_2 \leq l$ such that $q = q_{i_1} = q_{i_2}$. Thus, $q \in cy(P)$ and $q' := \delta(w, q_0) \in \mathcal{A}(P, cy(P)) = Q_\infty$. Since $wt \in \mathcal{L}_m(P)$ and P is deterministic, it follows that

$$t \in \mathcal{L}_m(Q_\infty, \Sigma, \delta, q', Q_{m\infty}) \subset \mathcal{L}_m(Q_\infty, \Sigma, \delta, Q_\infty, Q_{m\infty}) = \mathcal{L}_m(P_\infty).$$

$\mathcal{L}_m(P)_\infty \supset \mathcal{L}_m(P_\infty)$. Let $w \in \mathcal{L}_m(P_\infty)$. Then $w \in \mathcal{L}_m(Q_\infty, \Sigma, \delta, q, Q_{m\infty})$ for some $q \in Q_\infty$. Thus see the equation at the bottom of the page.

By (5.1) this implies that $w \in \mathcal{L}_m(P)_\infty$ concluding the proof. \square

The construction of the set $cy(P)$ can be accomplished by the well-known algorithm for computing strongly connected components of P (see [7, p. 64]) whose complexity (under our assumption that $|\Sigma| = \mathcal{O}(1)$) is $O(|Q|)$. The construction of $\mathcal{A}(P, cy(P))$ requires $O(|Q|)$ computations. Thus, the complexity of the construction of P_∞ is linear in the number of states of P .

Our next goal will be to show that for a given system P , the convergence of $\mathcal{L}_m(P)$ to a given language E can be determined by testing the asymptotic behavior of P . The following proposition gives a necessary condition for the convergence $E \Leftarrow \mathcal{L}_m(P)$ in terms of the asymptotic behavior of P .

Proposition 5.2: Let P be a given DES, and let $E \subset \Sigma^*$ be a given language. If $E \Leftarrow \mathcal{L}_m(P)$, then $\mathcal{L}_m(P)_\infty \subset \text{suf}(E)$.

$$\begin{aligned} & \exists u \in \Sigma^*, \exists q' \in cy(P), \delta(u, q') = q && \text{(definition of } Q_\infty) \\ \Rightarrow & \exists (t, s \in \Sigma^*) q' = \delta(t, q_0), s \neq \epsilon \text{ and } q' = \delta(s, q') && \text{(follows by (5.2))} \\ \Rightarrow & ts^*uw \in \mathcal{L}_m(P). \end{aligned}$$

Proof: Assume that $E \Leftarrow \mathcal{L}_m(P)$, let the convergence time be k and let $s \in \mathcal{L}_m(P)_\infty$ be any string. By (5.1), for each $i \geq 0$ there exists $t_i \in \Sigma^*$, $|t_i| \geq i$, such that $t_i s \in \mathcal{L}_m(P)$. Choose $t_i > k$. Since there exists $j \leq k$ such that $\text{suf}_j(t_i s) \in E$, it follows that

$$s = \text{suf}_{|t_i|}(t_i s) = \text{suf}_{|t_i|-j}(\text{suf}_j(t_i s)) \in \text{suf}(E)$$

concluding the proof. \square

The following lemma states that every regular language $L \subset \Sigma^*$ converges to L_∞ .

Lemma 5.1: For a DES $P = (Q, \Sigma, \delta, q_0, Q_m)$, $\mathcal{L}_m(P)_\infty \Leftarrow \mathcal{L}_m(P)$.

Proof: Since the language $\mathcal{L}_m(P)_\infty$ is suffix closed it follows that $\epsilon \in \mathcal{L}_m(P)_\infty$. Thus for each $t \in \mathcal{L}_m(P)$, $\text{suf}_{|t|}(t) = \epsilon \in \mathcal{L}_m(P)_\infty$ implying that if $|t| < |Q|$ there exists $i \leq |Q|$ such that $\text{suf}_i(t) \in \mathcal{L}_m(P)_\infty$.

Let $t \in \mathcal{L}_m(P)$, $|t| > |Q|$. Since the number of states of P is $|Q|$, there exists $i, i \leq |Q|$, such that $\delta(\text{pr}_i(t), q_0) = q$ where $q \in \text{cy}(P) \subset Q_\infty$. Since by Proposition 5.1 $\mathcal{L}_m(P)_\infty = \mathcal{L}_m(P_\infty)$, it then follows that $\text{suf}_i(t) \in \mathcal{L}_m(P_\infty) = \mathcal{L}_m(P)_\infty$. Hence the convergence time of $\mathcal{L}_m(P)$ to $\mathcal{L}_m(P)_\infty$ is bounded by $|Q|$, concluding the proof. \square

It should be noted that if L is not a regular language, then the convergence $L_\infty \Leftarrow L$ does not necessarily hold. Consider, for example, the language $\{\alpha^k \beta^k \gamma^* \mid \forall k \geq 0\}$.

Proposition 5.2 and Lemma 5.1 yield the following.

Corollary 5.1: Let P be a DES. Then $\mathcal{L}_m(P)_\infty$ is the infimal (in the sense of language inclusion) suffix-closed language that $\mathcal{L}_m(P)$ converges to, i.e.,

$$\mathcal{L}_m(P)_\infty = \cap \{M \subset \Sigma^* \mid \text{suf}(M) = M \text{ and } M \Leftarrow \mathcal{L}_m(P)\}.$$

A sufficient condition for the convergence $E \Leftarrow \mathcal{L}_m(P)$ is given by the following proposition.

Proposition 5.3: For a DES P and a language $E \subset \Sigma^*$, if $\mathcal{L}_m(P)_\infty \subset E$, then $E \Leftarrow \mathcal{L}_m(P)$.

Proof: By Lemma 5.1, $\mathcal{L}_m(P)_\infty \Leftarrow \mathcal{L}_m(P)$. Thus, if $\mathcal{L}_m(P)_\infty \subset E$, it follows directly by (2.12) that also $E \Leftarrow \mathcal{L}_m(P)$. \square

By combining Propositions 5.2 and 5.3 for the special case of suffix-closed languages we obtain the following necessary and sufficient condition for $E \Leftarrow \mathcal{L}_m(P)$.

Theorem 5.1: Let P be a DES and let $E \subset \Sigma^*$ be a suffix-closed language. Then $E \Leftarrow \mathcal{L}_m(P)$ if and only if

$$\mathcal{L}_m(P)_\infty \subset E. \quad (5.4)$$

Next we turn to the problem of supervisory control. In the previous section we considered the problem of language convergence, that is, the problem of synthesizing a supervisor that guarantees convergence of the supervised language to a specified legal language. We shall now be interested in the less restrictive control problem wherein only the asymptotic behavior of the supervised process is required to lie in a specified legal language. Thus, we shall consider the following.

Asymptotic Control Problem (ACP): Let P be a given DES and let $E \subset \Sigma^*$ be a given language. Synthesize a nonblocking supervisor S such that

$$\mathcal{L}_m(S/P)_\infty \subset E. \quad (5.5)$$

In the case when E is a suffix-closed language there is an obvious equivalence between ACP and CCP. This equivalence is stated in the following reinterpretation of Theorem 5.1.

Proposition 5.4: Let E be suffix closed. Then ACP is solvable if and only if CCP is solvable.

Let us now examine the solvability of ACP in the case when E is not suffix closed. Since L_∞ is suffix closed for any language L , ACP is solvable (i.e., there exists a nonblocking supervisor that satisfies (5.5)) if and only if there exists a suffix-closed sublanguage $M \subset E$ and a nonblocking supervisor S such that

$$\mathcal{L}_m(S/P)_\infty \subset M. \quad (5.6)$$

By Theorem 5.1, a supervisor S satisfies (5.6) if and only if

$$M \Leftarrow \mathcal{L}_m(S/P). \quad (5.7)$$

Thus, to determine the solvability of ACP, it is sufficient to check whether CCP is solvable with respect to the supremal suffix-closed sublanguage of E . The existence of the supremal suffix-closed sublanguage of E follows from the closeness of the set of suffix-closed languages under arbitrary unions.

Proposition 5.5: For a language E , ACP is solvable if and only if CCP is solvable with respect to the supremal suffix-closed sublanguage of E .

We conclude this section with an algorithm for computing the supremal suffix-closed sublanguage of a given regular language E .

Algorithm 5.1:

Input) A deterministic automaton

$$A = (X, \Sigma, \xi, x_0, X_m)$$

such that (without loss of generality) $\xi(\sigma, x) \neq x_0$ for all $\sigma \in \Sigma$, $x \in X$.

Output) A deterministic recognizer for the supremal suffix-closed sublanguage of $\mathcal{L}_m(A)$.

Construct a deterministic automaton

$$C = (U, \Sigma, \beta, u_0, U_m)$$

where $U = 2^X$, $u_0 = \{x_0\}$, $U_m = \{u \in U \mid (u - \{x_0\}) \subset X_m\}$ and $\beta: \Sigma \times U \rightarrow U$ is defined by

$$\beta(\sigma, u) = \begin{cases} \{x_0\} \cup \{\xi(\sigma, x) \mid x \in u\} & \text{if } \xi(\sigma, x)! \text{ for all } x \in u \\ \text{undefined} & \text{otherwise.} \end{cases} \quad (5.8)$$

Proposition 5.6: $\mathcal{L}_m(C)$ is the supremal suffix-closed sublanguage of $\mathcal{L}_m(A)$.

Proof: First observe that for any two states $u, w \in U$ such that $u \subset w$ (as elements of 2^X), $\beta(\sigma, w)!$ only if $\beta(\sigma, u)!$, and if $\beta(\sigma, w)!$ then $\beta(\sigma, u) \subset \beta(\sigma, w)$. Moreover, if $\beta(\sigma, u)!$ and $x \in u$, then $\xi(\sigma, x)!$

Let $s = \sigma_1 \cdots \sigma_n \in \mathcal{L}_m(C)$ be any string, and let u_0, \dots, u_n be the associated path in C , i.e., $u_i = \beta(\sigma_i, u_{i-1})$, $i = 1, \dots, n$ and $u_n \in U_m$. Then since $u_0 = \{x_0\}$, it follows from the above observation that there exists a path x_0, \dots, x_n in A such that $x_i = \xi(\sigma_i, x_{i-1})$ and

$x_i \in u_i - \{x_0\}$ for all $i = 1, \dots, n$. From the definition of U_m , $x_n \in u_n - \{x_0\} \subset X_m$, so that $s \in \mathcal{L}_m(A)$, implying that $\mathcal{L}_m(C) \subset \mathcal{L}_m(A)$.

To see that $\mathcal{L}_m(C)$ is suffix closed, consider $\text{suf}_j(s) = \sigma_{j+1} \dots \sigma_n$ for some $0 \leq j \leq n$. We must show that $\text{suf}_j(s) \in \mathcal{L}_m(C)$. Note that $u_0 \subset u_j$, whence since $u_{j+1} = \beta(\sigma_{j+1}, u_j)$ is defined, so is $\hat{u}_1 := \beta(\sigma_{j+1}, u_0)$ and $\hat{u}_1 \subset u_{j+1}$. Proceeding inductively, we obtain a sequence of states $u_0, \hat{u}_1, \dots, \hat{u}_{n-j}$ with $\hat{u}_1 = \beta(\sigma_{j+1}, u_0)$, $\hat{u}_{i+1} = \beta(\sigma_{i+j+1}, \hat{u}_i)$ and $\hat{u}_i \subset u_{i+j}$. Since $\hat{u}_{n-j} \subset u_n \in U_m$, we conclude that $\hat{u}_{n-j} \in U_m$, whence $\text{suf}_j(s) \in \mathcal{L}_m(C)$ as claimed.

Finally, to see that $\mathcal{L}_m(C)$ is the supremal suffix-closed sublanguage of $\mathcal{L}_m(A)$, we must show that if $s = \sigma_1 \dots \sigma_n \in \mathcal{L}_m(A)$ is a string such that $\text{suf}_j(s) \in \mathcal{L}_m(A)$ for all $j = 0, \dots, n$, then $s \in \mathcal{L}_m(C)$. Suppose that $s \notin \mathcal{L}_m(C)$. Let $l, 1 \leq l \leq n$, be the smallest integer such that $u_j = \beta(\sigma_j, u_{j-1})$ is defined for all $j = 1, \dots, l-1$ but $\beta(\sigma_l, u_{l-1})$ is undefined. This implies [see (5.8)] that there exists $k, 0 \leq k \leq l-1$, and a sequence of states $x_0, x_1, \dots, x_{l-k-1}$ such that $x_j = \xi(\sigma_{k+j}, x_{j-1})$ for all $j = 1, \dots, l-k-1$ and $\xi(\sigma_l, x_{l-k-1})$ is undefined. But then $\text{suf}_k(s) \notin \mathcal{L}(A)$, a contradiction. \square

Concurrent Vector Discrete-Event Systems

Yong Li, *Member, IEEE*, and W. M. Wonham, *Fellow, IEEE*

Abstract—The vector discrete-event system (VDES) is a compact serial discrete-event system model, in which the system state is represented by a vector with integer components and the transitions by integer vector addition [13], [14]. Continuing the study of VDES, we introduce in this paper concurrent VDES, extending the base VDES model to capture strict concurrency, or possible simultaneity of events. We characterize the effect of strict concurrency on control, and show how to synthesize nondeterministic controllers allowing maximal concurrency of a controlled VDES plant.

I. INTRODUCTION

CONCURRENCY is a critical issue in designing computer operating systems, data base management systems, and distributed computer and communication networks [4], [7], [1]. It is one of the key characteristics of real-time systems in general [18]. Researchers in the computer and communication areas have recognized that, compared to serial systems (in which events occur serially), concurrent systems present special challenges. The simultaneous event occurrences in a concurrent system make it harder to enforce the orderly flow of events according to a specification of desired behavior.

This paper studies concurrency from a control-theoretic perspective. We adopt the vector discrete-event system (VDES) introduced in [13] and [14] as the base model for controlled plants, incorporate simultaneity of events, and study its effect on controller synthesis. We call the presence of simultaneous events strict concurrency or simply concurrency.

As background, we first define VDES and review some concepts of VDES control.

VDES is a compact serial discrete-event system model. The state of a VDES is coordinatized by state variables x_1, x_2, \dots, x_n ranging over the integers \mathcal{Z} . The state space is the set of n -dimensional integer vectors

$$\mathcal{X} := \left\{ X \begin{matrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{matrix} \mid x_i \in \mathcal{Z} \right\} = \mathcal{Z}^n.$$

The event set Σ is partitioned into disjoint subsets Σ_c and Σ_u , the controllable-event subset and uncontrollable-event subset, respectively. The state transition is described by a partial function

$$\delta: \Sigma \times \mathcal{X} \rightarrow \mathcal{X}: (\alpha, X) \mapsto X + E_\alpha \quad (1)$$

Manuscript received July 22, 1993; revised May 2, 1994. Paper recommended by Associate Editor, S. Lafontaine. This work was supported in part by the Natural Sciences and Engineering Research Council of Canada.

where $E_\alpha \in \mathcal{X}$ is the displacement vector for α . For $X \in \mathcal{X}$ we write $X \geq 0$ if $x_i \geq 0$ ($i = 1, 2, \dots, n$). $\delta(\alpha, X)$ is defined, denoted by $\delta(\alpha, X)!$, if

$$X + E_\alpha \geq 0.$$

A VDES is formally defined as a 4-tuple

$$G = (\Sigma, \mathcal{X}, \delta, X_0) \quad (2)$$

where X_0 is the initial state.

A state-feedback controller for G is a function

$$f: \mathcal{X} \rightarrow \Gamma \subseteq 2^\Sigma \quad (3)$$

where Γ is the set of control patterns defined as

$$\Gamma := \{\gamma \mid \Sigma_u \subseteq \gamma \subseteq \Sigma\}. \quad (4)$$

An event α is enabled at a state X if $\alpha \in f(X)$; otherwise, α is disabled.

We describe system behavior by predicates. A predicate on the state space \mathcal{X} is a function $P: \mathcal{X} \rightarrow \{0, 1\}$. The predicate operators “ \neg ” (negation), “ \wedge ” (conjunction), and “ \vee ” (disjunction) are defined as follows

$$(\neg P)(X) = 1 \Leftrightarrow P(X) = 0$$

$$(P_1 \wedge P_2)(X) = 1 \Leftrightarrow P_1(X) = 1 \text{ and } P_2(X) = 1$$

$$P_1 \vee P_2 = \neg((\neg P_1) \wedge (\neg P_2)).$$

A partial order is induced on the set of predicates on \mathcal{X} according to

$$P_1 \preceq P_2 \Leftrightarrow P_1 \wedge P_2 = P_1.$$

In this paper we identify a predicate P on \mathcal{X} with the subset of \mathcal{X} induced by P

$$\{X \in \mathcal{X} \mid P(X) = 1\}.$$

We will employ the expressions “ $X \in P$ ” and “ $P(X) = 1$ ” interchangeably.

For each $\alpha \in \Sigma$ the predicate transformation M_α , the weakest liberal precondition [16], is defined for a predicate P on \mathcal{X} by

$$M_\alpha(P)(X) := \begin{cases} 1 & \text{if } \delta(\alpha, X)! \text{ and } \delta(\alpha, X) \in P, \\ & \text{or if not } \delta(\alpha, X)! \\ 0 & \text{otherwise.} \end{cases}$$

For a predicate P on \mathcal{X} , we define a predicate $R(G, P)$ which characterizes the set of states reachable from X_0 by way of states satisfying P :

- 1) if $X_0 \in P$, then $X_0 \in R(G, P)$;
 - 2) if $X \in R(G, P)$, $\alpha \in \Sigma$, $\delta(\alpha, X)!$ and $\delta(\alpha, X) \in P$, then $\delta(\alpha, X) \in R(G, P)$;
 - 3) every state in $R(G, P)$ is obtained as in 1) and 2).
- We call a predicate P on \mathcal{X} controllable with respect to G if

$$P \preceq R(G, P) \quad \text{and} \quad (\forall \alpha \in \Sigma_u) P \preceq M_\alpha(P). \quad (5)$$

Note that the empty (or identically "false") predicate is trivially controllable.

For a VDES plant G under the control of a controller f , we define the closed-loop predicate $R(f/G)$ as follows [13]:

- 1) $X_0 \in R(f/G)$;
- 2) if $X \in R(f/G)$, $\alpha \in \Sigma$, $\delta(\alpha, X)!$ and $\alpha \in f(X)$, then $\delta(\alpha, X) \in R(f/G)$;
- 3) every state in $R(f/G)$ is obtained as in 1) and 2).

It was shown in [13] that a predicate P can be synthesized by a deterministic controller f for a serial VDES model G (i.e., $R(f/G) = P$) if and only if P is nonempty and controllable.

A controller f is called balanced [13] if for any $X, X' \in R(f/G)$ and any $\alpha \in \Sigma$ with $\delta(\alpha, X)!$ and $\delta(\alpha, X) = X'$ we have that $\alpha \in f(X)$. A balanced controller is the one which, among controllers synthesizing the same closed-loop predicate, enables the most events at any reachable state. It can be checked that any controller may be replaced by a balanced controller without changing the reachable set [9, A.2]. By concentrating on balanced controllers, we gain technical convenience in our proofs without loss of generality.

In the serial VDES model, the event-occurrence condition is defined for single events (in Σ) only; it is assumed that at any given instant of time, at most one event can occur. Also, at each state, the controller (3) issues a predetermined control pattern; such a controller is deterministic.

In this paper we first extend the serial VDES (2) to include concurrency (that is, to allow simultaneous occurrences of events); this extended VDES model is called concurrent VDES (CVDES) (Section II). Then we study the control of CVDES by both deterministic (Section III) and nondeterministic (Sections IV and V) controllers. A nondeterministic controller issues, at each state, a control pattern which is "randomly" selected from a set of control patterns. It is shown that nondeterministic controllers are more powerful than their deterministic counterparts in the presence of concurrency. We also discuss how to synthesize nondeterministic controllers which allow the controlled CVDES to operate with maximal concurrency according to a specified criterion.

In the control literature, simultaneous events in DES (but not VDES, which had not yet been introduced) were treated in a preliminary way in the thesis [8], via the ideas of well-posed supervisor, well-posed language, and concurrency product. It was shown that the supremal well-posed sublanguage of a given language need not exist, hence there need not exist an optimal supervisor in the presence of simultaneous events. These results were reported in [10] and [11], where nondeterminism was introduced to obtain an optimal solution. The completion of a set of state-feedback controls (SFBC), forming a poset but not a lattice, using nondeterminism (exponentiation) to construct a supremal element, was proposed

Fig. An ATM model.

independently in [2]. In [12] the optimal control problem for VDES with strict concurrency was formalized in the style of [10], [2], and [11], and the optimal nondeterministic SFBC obtained. The current paper completes [12] with full proofs of the authors' earlier results. We remark that the nonexistence, in the presence of strict concurrency, of a supremal deterministic SFBC, as distinct from merely multiple, maximal SFBC, was pointed out by Krogh for controlled Petri nets (CPN), when the latter were introduced in [5]. The existence of a unique maximal nondeterministic feedback policy, in the context of the forbidden state problem for CPN, was later noted in [3] and [6].

Throughout this paper, we use the example of an asynchronous transfer mode (ATM) switch. A general high-level model of an ATM switch [15] is shown in Fig. 1. It consists of N input-port controllers (IPC), an interconnection network and N output-port controllers (OPC). IPC and OPC are composed of buffers for incoming and outgoing ATM cells,¹ respectively, and the control logic for these buffers. The interconnection network is responsible for switching incoming cells to their destination output ports. The outgoing cells to an OPC arrive from K routing networks (RN). The buffer within an OPC has capacity C' ; while the buffer is full, any arriving cell will be discarded. An OPC can disable the transmission of cells from a RN by backward signaling.

In this paper we focus on a single OPC, modelling the buffer within the OPC and synthesizing control strategies for the buffer. For definiteness, assume that $K = 3$ and $C' = 5$.

We first model the buffer as the one-dimensional serial VDES G shown by its Petri-net graph in Fig. 2, with $E_{\alpha_1} = E_{\alpha_2} = E_{\alpha_3} = 1$, $E_{\alpha_4} = -1$, and $X_0 = 0$. In this model, α_i ($i = 1, 2, 3$) are controllable and α_4 is uncontrollable. The state transition graph of the buffer is displayed in Fig. 3. The control specification is that the buffer must not overflow, i.e., $(X \leq 5)$. Then the (optimal) controller enforcing this specification in G is easy to obtain

$$f^*(X) := \begin{cases} \{\alpha_1, \alpha_2, \alpha_3, \alpha_4\} & \text{if } X < 5 \\ \{\alpha_4\} & \text{otherwise.} \end{cases} \quad (6)$$

In the serial model G , no two events can occur simultaneously, e.g., cells from two RN's never arrive at the OPC at the same time. This assumption is not realistic, considering the independence and high-rate of transmission of cells from

¹ An ATM cell is a segment of a 53-byte data stream.

Fig. 2. The VDES model for an OPC buffer.

Fig. 3. The serial state transition graph of an OPC buffer

RN's in an ATM switch. In this paper we will show how to incorporate simultaneity into the VDES model of the OPC buffer and how to synthesize controllers in the presence of simultaneous events.

II. CONCURRENCY

We formalize concurrency by extending a VDES G to include simultaneous events. Define the extended event set by

$$\Sigma_{con} := 2^\Sigma.$$

An event $e = \langle \alpha_1, \alpha_2, \dots, \alpha_k \rangle \in \Sigma_{con}$ represents the simultaneous occurrence of $\alpha_1, \alpha_2, \dots, \alpha_k$. We define a simultaneous event as an unordered set: all its component events are thought of as occurring at the same instant of time, with no causal ordering among them. We reserve the symbol " $\langle \dots \rangle$ " for simultaneous events simply to differentiate them from ordinary (uninterpreted) subsets of Σ ; apart from this, " $\langle \dots \rangle$ " and " $\{ \dots \}$ " have the same mathematical meaning as subsets. In particular, $\emptyset \in \Sigma_{con}$ is the null simultaneous event, denoting that no event in Σ occurs. Our definition of simultaneous event rules out multiple simultaneous occurrences of the same event, but our results could easily be extended to accommodate that situation.

For $\alpha \in \Sigma$, $\langle \alpha \rangle \in \Sigma_{con}$ is a singleton event; with slight abuse of notation, we write $\langle \alpha \rangle \in \Sigma_{con}$ as α whenever no confusion results, as they really represent the same physical event.

Define a companion vector J_α for E_α

$$J_\alpha(i) := \begin{cases} -E_\alpha(i) & \text{if } E_\alpha(i) < 0 \\ 0 & \text{otherwise.} \end{cases} \quad (i = 1, 2, \dots, n) \quad (7)$$

We can regard $J_\alpha(i)$ as the minimal value of x_i required for the occurrence of α . Then define the occurrence condition of the simultaneous event e as

$$\delta_{con}(e, X)! \Leftrightarrow X \geq \sum_{\alpha \in e} J_\alpha. \quad (8)$$

This condition ensures that the resources represented by state variables are sufficient to support the simultaneous occurrence of all component events in e . We define the displacement vector for e as

$$E_e := \sum_{\alpha \in e} E_\alpha$$

Fig. 4. The concurrent state transition graph of an OPC buffer.

and extend the state transition function as

$$\delta_{con}: \Sigma_{con} \times \mathcal{X} \rightarrow \mathcal{X}: (e, X) \mapsto X + E_e. \quad (9)$$

Note that δ_{con} is an extension of δ in (1) in the sense that

$$\delta_{con}(\alpha, X) \mapsto \delta(\alpha, X).$$

On this understanding, from now on we drop the subscript "con" from δ_{con} and write simply δ . The extended model is called concurrent VDES (CVDES) and is denoted by

$$G_{con} := (\Sigma_{con}, \mathcal{X}, \delta, X_0). \quad (10)$$

As an illustration, consider the one-dimensional VDES model for the OPC buffer in Fig. 2. The extended event set $\Sigma_{con} = 2^\Sigma$ with $\Sigma := \{\alpha_1, \alpha_2, \alpha_3, \alpha_4\}$. For instance, $e := \langle \alpha_1, \alpha_2, \alpha_4 \rangle \in \Sigma_{con}$ denotes the event that two cells from RN 1 and RN 2 arrive at the OPC at the same time as a cell is transmitted from the OPC. The simultaneous event e is defined at every state except $X = 0$ since

$$\sum_{\alpha \in e} J_\alpha = 1.$$

The state transition graph of G_{con} is shown in Fig. 4, where e_1 denotes α_4 ; e_2 denotes the events

$$\alpha_i \quad (i = 1, 2, 3)$$

e_3 denotes

$$\langle \alpha_i, \alpha_j, \alpha_4 \rangle \quad (i, j = 1, 2, 3, i \neq j)$$

e_4 denotes the events

$$\langle \alpha_i, \alpha_j \rangle \quad (i, j = 1, 2, 3; i \neq j)$$

e_5 denotes

$$\langle \alpha_1, \alpha_2, \alpha_3, \alpha_4 \rangle$$

and e_6 denotes $\langle \alpha_1, \alpha_2, \alpha_3 \rangle$.

The following simple properties of CVDES will be used later.

Claim 1: Let $e \in \Sigma_{con}$, and $e_1 \subseteq e$, $e_2 := e - e_1$. If $\delta(e, X)!$ then $X_1 := \delta(e_1, X)!$ and $\delta(e_2, X_1)!$, and then $\delta(e, X) = \delta(e_2, X_1)$.

Proof: Let $e_1 \subseteq e$ and $\delta(e, X)!$. Then

$$X \geq \sum_{\alpha \in e} J_\alpha \geq \sum_{\alpha \in e_1} J_\alpha$$

with J_α being the companion vector E_α as defined in (7). So, $\delta(e_1, X)!$, according to (8). From (7)

$$(\forall \alpha) E_\alpha \geq -J_\alpha.$$

Thus

$$X_1 := \delta(e_1, X) = X + \sum_{\alpha \in e_1} E_\alpha \geq X + \sum_{\alpha \in e_1} (-J_\alpha) \geq \sum_{\alpha \in e_2} J_\alpha$$

since

$$X \geq \sum_{\alpha \in e} J_\alpha = \sum_{\alpha \in e_1} J_\alpha + \sum_{\alpha \in e_2} J_\alpha.$$

So, $\delta(e_2, X_1)!$, as required. By the definition, $\delta(e, X) = \delta(e_2, X_1)$. \square

We call $w \in \Sigma^*$ an instance event string of the simultaneous event $e \in \Sigma_{con}$ if each element of e occurs exactly once in w . For example, $w = \alpha_1 \alpha_2 \alpha_3$ is an instance event string of $e = \langle \alpha_1, \alpha_2, \alpha_3 \rangle$.

Claim 2: Let w be an instance event string of $e \in \Sigma_{con}$. Then for all $X \in \mathcal{X}$, $\delta(e, X)!$ only if $\delta(w, X)!$, and then $\delta(w, X) = \delta(e, X)$.

Proof: By the definition of δ . \square

Claim 3: Let $S \subseteq \Sigma$ and P be a predicate which is controllable wrt G . Assume $X \in P$. Then

$$\begin{aligned} (\forall e \in 2^S)(\delta(e, X) \in P \text{ or not } \delta(e, X)!) \\ \Leftrightarrow (\forall e \in 2^{\Sigma_{con}})(\delta(e, X) \in P \text{ or not } \delta(e, X)!) \end{aligned}$$

Proof: (\Rightarrow) Automatic. \square

(\Leftarrow) Let $e \in 2^S$ and $\delta(e, X)!$. To show that $\delta(e, X) \in P$, let $e_1 := e \cap \Sigma_c$, $e_2 := e - e_1$. By Claim 1

$$X_1 := \delta(e_1, X)!, \quad \delta(e_2, X_1)!$$

and

$$\delta(e, X) = \delta(e_2, X_1).$$

By hypothesis, $X_1 \in P$. Let $w \in \Sigma_u^*$ be an instance event string of e_2 . Since P is controllable, by Claim 2

$$\delta(e_2, X_1) = \delta(w, X_1) \in P$$

namely $\delta(e, X) \in P$, as claimed. \square

For CVDES, a controller controls singleton events in Σ_c directly; a simultaneous event can be controlled if and only if at least one of its component events is represented in Σ_c . Thus the uncontrollable events in G_{con} are $\Sigma_{con,u} := 2^{\Sigma_u}$ (so, $\emptyset \in \Sigma_{con,u}$), and the controllable events are $\Sigma_{con,c} := \Sigma_{con} - \Sigma_{con,u}$.

Moreover, a simultaneous event is disabled by a controller if and only if one or more of its component events is disabled; or equivalently, a simultaneous event is enabled if and only if all of its component events are enabled. We formalize this requirement by defining Γ_{con} , the set of admissible control patterns of G_{con} . A control pattern of G_{con} will be an element

$\eta \in 2^{\Sigma_{con}}$. Thus each η is a set of simultaneous events, interpreted as enabled in Σ_{con} . Formally

$$\Gamma_{con} := \{\eta \mid \eta = 2^\gamma, \Sigma_u \subseteq \gamma \subseteq \Sigma\} \quad (11)$$

or equivalently

$$\Gamma_{con} := \{\eta \mid \eta = 2^\gamma, \gamma \in \Gamma\}.$$

Therefore, each control pattern $\eta \in \Gamma_{con}$ contains among its singleton events all uncontrollable events in Σ_u ; and η is generated by its singleton events. Denote the set of singleton events in a control pattern $\eta \in \Gamma_{con}$ by $\bar{\eta}$. Then $\eta = 2^{\bar{\eta}}$; we call this property of control patterns control dependency. Note that the null simultaneous event $\emptyset \in \Sigma_{con}$ is included in each control pattern η . This can be interpreted to mean that “no event occurs” is always allowed.

For the OPC buffer example, $\Sigma_{con,u} = \{\emptyset, \alpha_4\}$ and a control pattern in Γ_{con} takes one of the forms

$$\{\emptyset, \alpha_4\}$$

$$\{\emptyset, \alpha_4, \alpha_i, e_{i,4}\} \quad i = 1, 2, 3$$

$$\{\emptyset, \alpha_4, \alpha_i, \alpha_j, e_{i,4}, e_{j,4}, e_{i,j}, e_{i,j,4}\} \quad i, j = 1, 2, 3: i \neq j$$

$$\{\emptyset, \alpha_4, \alpha_1, \alpha_2, \alpha_3, e_{1,4}, e_{2,4}, e_{3,4}, e_{1,2}, e_{1,3}, e_{2,3}, e_{1,2,3}, e_{1,2,4}, e_{2,3,4}, e_{1,2,3,4}\}$$

where $e_{i,j}, e_{i,j,k}, e_{1,2,3,4}$ denote $\langle \alpha_i, \alpha_j \rangle, \langle \alpha_i, \alpha_j, \alpha_k \rangle, \langle \alpha_1, \alpha_2, \alpha_3, \alpha_4 \rangle$, respectively.

Note that a simultaneous event is included in a control pattern above if and only if its component events are included: In the case of the simultaneous event, say $e_{1,2}$, this means that two cells from RN 1 and RN 2 are allowed to arrive at the OPC at the same time instant if (and only if) these two RN's are both enabled for transmission by the OPC at that time.

Define a controller for G_{con} as $f': \mathcal{X} \rightarrow \Gamma_{con}$. Let $R(f'/G_{con})$ be the closed-loop predicate (i.e., the set of reachable states in the closed-loop system) synthesized by f' in G_{con} .²

A question of interest is the following.

Q_1 . For a given predicate P on \mathcal{X} , how to synthesize a controller f' such that $R(f'/G_{con}) = P$?

When the serial model G is extended to G_{con} to include concurrency, the control action of a controller $f: \mathcal{X} \rightarrow \Gamma$ for G is extended accordingly and is captured by a controller f_{con} for G_{con}

$$(\forall X \in \mathcal{X}) f_{con}(X) := 2^{f(X)}.$$

At a state X , f_{con} enables all singleton events enabled by f at X , as well as all simultaneous events generated by these singleton events. We call this controller the concurrent extension of f . Conversely, for any $f': \mathcal{X} \rightarrow \Gamma_{con}$, if we define a controller $f: \mathcal{X} \rightarrow \Gamma$ by

$$(\forall X \in \mathcal{X}) f(X) := \bar{f}'(X)$$

²The formal definition of $R(f'/G_{con})$ can be given in the same way as that of $R(f/G)$ in Section 1.

where $\bar{f}'(X)$ denotes the singleton-event set of $f'(X)$, then $f_{con} = f'$ since

$$(\forall X \in \mathcal{X}) f'(X) = 2^{\bar{f}'(X)}.$$

This controller f is called the serial reduction of f' . We say that f' is balanced if its serial reduction is.

It should be pointed out that, in implementation, the physical control action of a controller f_{con} is identical to that of its serial reduction f ; both directly enable the same set of singleton events. But, owing to control dependence, f_{con} also implicitly enables all simultaneous events generated by enabled singleton events. As far as the closed-loop predicate is concerned, f_{con} is more permissive for G_{con} than f is for G , simply because the former allows more events to occur at any state than the latter. We say that concurrency has no effect on the control action of f if $R(f/G) = R(f_{con}/G_{con})$; in this case, the synthesis of f_{con} for G_{con} is reduced to that of f for G .

Another question of interest is then the following.

Q_2 . Under what condition does concurrency have no effect on the control action of f ?

We address Q_1 and Q_2 in the next section.

III. CONCURRENT WELL-POSEDNESS

We have seen in Section I that the balanced controller (6) synthesizes the controllable specification $P = (X \leq 5)$ in the serial model G for the OPC buffer. We now show that there is no balanced controller which synthesizes P in the concurrent model G_{con} (Fig. 4). Suppose otherwise, and let f' be such a controller. Then $X_1, X_5 \in R(f'/G_{con})$. Since f' is balanced, we have that $\alpha_i \in f'(X_i)$ ($i = 1, 2, 3$). By control dependence, $e_{1,2,3} \in f'(X_1)$. But $\delta(e_{1,2,3}, X) = 4 + 3 = 7 \notin P$, a contradiction.

This shows that controllability alone is no longer a sufficient condition for a predicate to be synthesized as a closed-loop predicate for a CVDES plant; and that $R(f/G) = R(f_{con}/G_{con})$ is not always true.

A predicate P is concurrently well-posed (CWP) wrt G_{con} if for any $X \in P$ and any $\alpha, \beta \in \Sigma$ with $\delta(\alpha, X) \in P$, $\delta(\beta, X) \in P$ and $\delta(\langle \alpha, \beta \rangle, X)!$, we have $\delta(\langle \alpha, \beta \rangle, X) \in P$.

It can be easily checked that the specification P for the ATM example is not CWP.

The following theorem answers questions Q_1 and Q_2 posed in the previous section, and asserts that CWP together with controllability is a necessary and sufficient condition to guarantee that there exists a (balanced) controller synthesizing P in G_{con} ; and that when the closed-loop predicate synthesized by a controller for G is CWP, concurrency has no effect on its control action.

Theorem 4: 1) There exists a balanced controller $f': \mathcal{X} \rightarrow \Gamma_{con}$ such that

$$R(f'/G_{con}) = P$$

if and only if P is nonempty, controllable, and CWP.

2) Let $f: \mathcal{X} \rightarrow \Gamma$ be a balanced controller for G and f_{con} be its concurrent extension. Then

$$R(f/G) = R(f_{con}/G_{con})$$

if and only if $R(f/G)$ is CWP.

Proof: 1) (IF) Let the predicate P be nonempty, controllable, and CWP. Define a controller f by

$$(\forall \alpha \in \Sigma_c) f_\alpha(X) := \begin{cases} 1 & \text{if } \delta(\alpha, X)! \text{ and } \delta(\alpha, X) \in P \\ 0 & \text{otherwise.} \end{cases} \quad (12)$$

Then as shown in the proof of [13] Theorem 6, $R(f/G) = P$. It is easy to check that f thus defined is balanced. It remains to show that $R(f/G) = R(f_{con}/G_{con})$. We only need to show that $R(f_{con}/G_{con}) \preceq R(f/G)$, as the reverse inequality is automatic. First note that $X_0 \in R(f/G)$, $X_0 \in R(f_{con}/G_{con})$. For induction on the length of event strings in Σ_{con}^* , suppose that $X \in R(f/G)$, $X \in R(f_{con}/G_{con})$. Let $e \in \Sigma_{con}$, $\delta(e, X)!$ and $e \in f_{con}(X)$ (i.e., $(\forall \alpha \in e) \alpha \in f(X)$). We wish to show that

$$\delta(e, X) \in R(f/G). \quad (13)$$

The proof is again by induction, this time on the cardinality of e .

When $|e| = 1$, $e = \alpha$ for some $\alpha \in \Sigma$. In this case, (13) is true since $\alpha \in f_{con}(X)$ implies $\alpha \in f(X)$.

When $|e| = 2$, $e = \langle \alpha_1, \alpha_2 \rangle$ for some $\alpha_1, \alpha_2 \in \Sigma$. Since $\langle \alpha_1, \alpha_2 \rangle \in f_{con}(X)$, $\alpha_1, \alpha_2 \in f(X)$ and

$$\delta(\alpha_1, X), \delta(\alpha_2, X) \in R(f/G) = P.$$

But P is CWP by assumption, so

$$\delta(\langle \alpha_1, \alpha_2 \rangle, X) \in P = R(f/G).$$

Now, suppose that (13) is true for $|e| \leq k+1$. We show that it is also true for $|e| = k+2$. Let $e = e' \cup \langle \beta_1, \beta_2 \rangle$ with $|e'| = k$. Since $\delta(e, X)!$ we know from Claim 1 that $e', e - \langle \beta_1 \rangle$ and $e - \langle \beta_2 \rangle$ are all defined at X . It is easy to see that, when e is enabled by f_{con} at X , so are $e', e' \cup \langle \beta_1 \rangle$ and $e' \cup \langle \beta_2 \rangle$. We then have by the induction hypothesis

$$\delta(e', X) \in R(f/G)$$

$$\delta(e' \cup \langle \beta_1 \rangle, X) \in R(f/G)$$

$$\delta(e' \cup \langle \beta_2 \rangle, X) \in R(f/G)$$

that is

$$\delta(\langle \beta_1 \rangle, \delta(e', X)) \in R(f/G)$$

$$\delta(\langle \beta_2 \rangle, \delta(e', X)) \in R(f/G).$$

Again, since $P (= R(f/G))$ is CWP it follows that

$$\delta(e' \cup \langle \beta_1, \beta_2 \rangle, X) = \delta(\langle \beta_1, \beta_2 \rangle, \delta(e', X)) \in R(f/G)$$

if we notice that $\delta(\langle \beta_1, \beta_2 \rangle, \delta(e', X))!$ (Claim 1).

(ONLY IF) Let

$$R(f_{con}/G_{con}) = P$$

for a balanced controller f_{con} . By an argument similar to the proof of [13] Theorem 6, we can check that P is controllable. It remains to show that P is CWP. Let $X \in P$ and $\delta(\langle \alpha, \beta \rangle, X)!$ with

$$\delta(\alpha, X) \in P, \quad \delta(\beta, X) \in P.$$

Then

$$X, \delta(\alpha, X), \delta(\beta, X) \in R(f_{con}/G_{con}).$$

Fig. 5. A VDES example.

Fig. 6. The state transition graph of the VDES example.

But f_{con} is balanced, so

$$\alpha, \beta \in f_{con}(X)$$

and therefore, by control dependence

$$\langle \alpha, \beta \rangle \in f_{con}(X).$$

We then have

$$\delta(\langle \alpha, \beta \rangle, X) \in R(f_{con}/G_{con}) = P$$

and that P is CWP.

2) Easily follows from 1). \square

The above result indicates that when P is both controllable and CWP the construction of a balanced controller f_{con} synthesizing P in G_{con} is reduced to that of a controller f synthesizing P in G ; such a controller f can be constructed as in (12).

If there exists a supremal element in the set of all controllable and CWP subpredicates of a given predicate specifying legal states, an optimal solution can be found to the deterministic-controller synthesis problem for G_{con} . Unfortunately, such a supremal element may not exist. To see this, consider the Petri-net graph G in Fig. 5, with both α and β controllable. The state transition graph for G_{con} is shown in Fig. 6. Let

$$P_1 := \{X_0, X_1\}$$

$$P_2 := \{X_0, X_3\}$$

$$P := P_1 \vee P_2.$$

It can be easily checked in Fig. 6 that both P_1 and P_2 are controllable and CWP. But P is not CWP (although it is controllable), since $\delta(\alpha, X_0) = X_3 \in P$, $\delta(\beta, X_0) = X_1 \in P$, but $\delta(\langle \alpha, \beta \rangle, X_0) = X_5 \notin P$.

This shows that optimal deterministic control is not always possible,³ revealing the irregular nature of concurrency in our model. However, as we show in the next section, this irregularity is present only for deterministic control; optimality is always achievable with nondeterministic control.

IV. NONDETERMINISTIC CONTROL WITH CONCURRENCY

In the previous section we showed that there is no balanced deterministic controller synthesizing the specification P in the concurrent model G_{con} of the OPC buffer. Even though we can find unbalanced deterministic controllers synthesizing P in G_{con} , these controllers could be too restrictive to be of practical use. For instance, the OPC which permanently enables α_1 and disables α_2 and α_3 (i.e., only RN 1 is allowed to transmit cells to the OPC) will synthesize P in G_{con} , but this controller is obviously undesirable. In fact, owing to control dependence, any unbalanced deterministic controller synthesizing P will, at the state X_4 , enable one predetermined RN and disable the other two; and at X_3 , enable one or two predetermined RN's and disable the rest. This type of predetermined preference shown by the deterministic controller is undesirable, if not unacceptable, for the OPC design. (Suppose RN 1 is enabled and RN 2, RN 3 are disabled at X_1 . Then it is possible that the OPC oscillates between the states X_4 and X_5 , denying transmission by RN 2 and RN 3 indefinitely.) However, this restriction can be removed by use of nondeterministic control. For instance, instead of enabling a predetermined controllable event we can randomly⁴ enable one of the three controllable events whenever the state X_4 is reached. Similarly, we can randomly enable two controllable events at the state X_3 . The actual random selection mechanism might depend on, say, relative sizes of queues for the waiting cells in the three routing networks; but we omit details of implementation here.

The above discussion indicates that nondeterministic control can be more powerful than its deterministic counterpart in the presence of concurrency. In the following, we formalize nondeterministic control and exploit its power.

A nondeterministic controller (NDC) for G is a function $f_n: X \rightarrow 2^I$. A nondeterministic controller (NDC) for G_{con} is a function $f'_n: X \rightarrow 2^{\Gamma_{con}}$. Intuitively, the control pattern issued by an NDC f_n (or, f'_n) at X is a randomly chosen element among the elements of $f_n(X) \subseteq I$ (or, $f'_n(X) \subseteq \Gamma_{con}$).

Subject to concurrency in the plant (modeled by G_{con}), a (physical) NDC modeled by f_n will behave like a (physical) NDC modeled by $f_{n,con}$ defined as

$$(\forall X \in X) f_{n,con}(X) := \{2^\gamma \mid \gamma \in f_n(X)\}$$

because of control dependence. We call $f_{n,con}$ the concurrent extension of f_n . Conversely, for any NDC f'_n for G_{con} , if we

³One special case where the optimal controller exists for a specification P in G_{con} is when $\text{sup}C(P)$ turns out to be CWP. In this case, $\text{sup}C(P)$ is also the supremal element of the set of controllable and CWP subpredicates of P . Then we can construct an optimal controller f'_{con} such that $R(f'_{con}/G_{con}) = \text{sup}C(P)$.

⁴Here "randomly" just means "according to some hidden or unmodeled mechanism of selection."

define an NDC f_n for G as

$$(\forall X \in \mathcal{X}) f_n(X) := \{\bar{\eta} \mid \eta \in f'_n(X)\}$$

where $\bar{\eta}$ denotes the set of singleton events of η , then $f'_n = f_{n,con}$. We call f_n the serial reduction of f'_n . It should be emphasized that, in implementation, the physical control actions of f_n and $f_{n,con}$ are the same; they directly enable at any state a pattern γ of singleton events selected from the same subset of Γ . But, owing to control dependence, $f_{n,con}$ implicitly also enables at that state all simultaneous events generated by γ .

For a VDES plant G under the control of the NDC f_n , we define the closed-loop predicate $R(f_n/G)$ as follows:

- 1) $X_0 \in R(f_n/G)$;
- 2) if $X \in R(f_n/G)$, $\alpha \in \Sigma$, $\delta(\alpha, X)!$ and $(\exists \gamma \in f_n(X)) \alpha \in \gamma$, then $\delta(\alpha, X) \in R(f_n/G)$;
- 3) every state in $R(f_n/G)$ is obtained as in 1) and 2).

Similarly, we can define the closed-loop predicate $R(f'_n/G_{con})$.

To extend the definition of balanced deterministic controllers, we call an NDC f_n for G balanced if the following two technical conditions hold.

- 1) For any $X, X' \in R(f_n/G)$ and $\alpha \in \Sigma$ with $\delta(\alpha, X)!$ and $X' = \delta(\alpha, X)$, there exists a control pattern $\gamma \in f_n(X)$ such that $\alpha \in \gamma$.

- 2) There is no redundant control pattern; that is, for any state X and $\gamma_1, \gamma_2 \in f_n(X)$, if $\gamma_1 \subseteq \gamma_2$ then $\gamma_1 = \gamma_2$.

We call an NDC $f_{n,con}$ balanced if f_n is, and confine attention to balanced NDC.

Theorem 5: Let P be a predicate on \mathcal{X} with $X_0 \in P$. There exists a balanced NDC $f_n: \mathcal{X} \rightarrow 2^\Gamma$ such that

$$R(f_{n,con}/G_{con}) = P$$

if and only if P is controllable.

Proof: (IF) Assume that P is controllable with respect to G . Let $f: \mathcal{X} \rightarrow \Gamma$ be defined as in (12). Then $R(f/G) = P$. We define an NDC $f'_n: \mathcal{X} \rightarrow 2^\Gamma$ as

$$f'_n(X) = \{\Sigma_u \cup \{\alpha\} \mid \alpha \in f(X) \cap \Sigma_c\}. \quad (14)$$

Each control pattern γ in $f'_n(X)$ has the form $\Sigma_u \cup \{\alpha\}$, α being a controllable event which is enabled by f at X . We need to show that

$$R(f'_{n,con}/G_{con}) = P.$$

First, we show that

$$P \preceq R(f'_{n,con}/G_{con}).$$

By the assumption, $X_0 \in P$, and by the definition, $X_0 \in R(f'_{n,con}/G_{con})$. For a proof by induction, suppose that $X \in P$ with

$$X = \delta(\alpha, X')$$

for some $X' \in R(f/G) = P$ and $X' \in R(f'_{n,con}/G_{con})$. By the definition, $\alpha \in f(X')$, $\alpha \in \gamma$ for some $\gamma \in f'_n(X')$, and $\langle \alpha \rangle \in \eta$ for some $\eta \in f'_{n,con}(X')$. By the induction hypothesis

$$X \in R(f'_{n,con}/G_{con}).$$

This proves $P \preceq R(f'_{n,con}/G_{con})$. Next we prove the reverse inequality. Again, by the assumption, $X_0 \in P$, and by the definition, $X_0 \in R(f'_{n,con}/G_{con})$. For a proof by induction, suppose that

$$X \in R(f'_{n,con}/G_{con})$$

with

$$X = \delta(e, X'), \quad X' \in R(f'_{n,con}/G_{con}), \quad X' \in P$$

and

$$e \in \eta \text{ for some } \eta \in f'_{n,con}(X').$$

We show that $X \in P$. By the definition of $f'_{n,con}$

$$e \subseteq \Sigma_u \cup \{\alpha\}$$

for some α satisfying

$$\alpha \in \Sigma_c \cap f(X').$$

Case 1: $\alpha \notin e$. In this case, $e \subseteq \Sigma_u$. Since P is controllable with respect to G

$$\delta(w, X') \in P$$

with w any instance event string of e . So from Claim 2

$$X = \delta(e, X') = \delta(w, X') \in P$$

Case 2: $\alpha \in e$. Since $\alpha \in \Sigma_c \cap f(X')$, we have

$$\delta(\alpha, X') \in R(f/G) = P.$$

Let w be an instance event string of $e - \{\alpha\}$. Since $e - \{\alpha\} \subseteq \Sigma_u$, and P is controllable with respect to G , there follows

$$\delta(w, \delta(\alpha, X')) \in R(f/G) = P.$$

We then have from Claim 2 that

$$\delta(e, X') = \delta(w, \delta(\alpha, X')) \in P.$$

This completes the proof that

$$R(f'_{n,con}/G_{con}) \preceq P.$$

It is straightforward to check that f'_n is balanced.

(ONLY IF) Let $f_{n,con}$ be a balanced NDC. The definition of admissible control patterns implies that uncontrollable events are always enabled by $f_{n,con}$. It then follows easily that $R(f_{n,con}/G_{con})$ is controllable. \square .

The above result has two implications. One is that (balanced) NDC's synthesize the same set of closed-loop predicates in G_{con} as deterministic controllers in the serial model G : nondeterminism of controllers "offsets" the effect of concurrency on control. In other words, in contrast to deterministic control, the CWP condition is not required for a predicate to be synthesized by a nondeterministic controller; the NDC f'_n constructed in (14) always synthesizes a controllable predicate P . Since for any predicate P there exists a supremal controllable subpredicate of P [13], the second implication is that we can construct a balanced NDC f_n whose concurrent extension $f_{n,con}$ synthesizes the largest possible closed-loop subpredicate of P in G_{con} . In fact, there may be many

such controllers f_n . For the ATM example, the concurrent extensions of both f_n^1 and f_n^2 defined below synthesize the specification P in G_{con} .

$$f_n^1(X) := \{\{\alpha_1, \alpha_2, \alpha_3, \alpha_4\}\} \quad (X = 0, 1, 2)$$

$$f_n^1(X) := \{\{\alpha_1, \alpha_4\}, \{\alpha_2, \alpha_4\}, \{\alpha_3, \alpha_4\}\} \quad (X = 3, 4)$$

$$f_n^1(X) := \{\{\alpha_4\}\} \quad (X \geq 5)$$

$$f_n^2(X) := f_n^1(X) \quad (X \neq 3)$$

$$f_n^2(X) := \{\{\alpha_1, \alpha_2, \alpha_4\}, \{\alpha_1, \alpha_3, \alpha_4\}, \{\alpha_2, \alpha_3, \alpha_4\}\} \quad (X = 3).$$

The NDC f_n^2 differs from f_n^1 at the state $X = 3$ only, where it enables two controllable events instead of only one. Therefore, the concurrent extension of f_n^2 allows more concurrency than f_n^1 in the concurrent model G_{con} .

In the next section we investigate how to pick, among all NDC's synthesizing a given predicate, one which optimizes another performance measure—namely, concurrency.

V. NONDETERMINISTIC CONTROLLERS ALLOWING MAXIMUM CONCURRENCY

For the controlled CVDES G_{con} , concurrency is measured by the simultaneity allowed by a controller. A deterministic controller f_{con} allows greater concurrency of the plant than another deterministic controller g_{con} if

$$(\forall X \in \mathcal{X}) f_{con}(X) \supseteq g_{con}(X)$$

i.e., at any state there are more events enabled by f_{con} than by g_{con} .

We now introduce a measure of concurrency permitted to the controlled plant by NDC's. For a set S and two elements $A, B \in 2^{(2^S)}$, we write $A \leq B$ (wrt S) if

$$(\forall a \in A)(\exists b \in B)a \subseteq b.$$

For a predicate P define a relation " \leq " on the set of all NDC's of G by

$$f_n \leq g_n (rel P) \text{ if } (\forall X \in P) f_n(X) \leq g_n(X) \text{ (wrt } \Sigma).$$

Similarly, define for P a relation " \leq " on the set of NDC's of G_{con} by

$$f_{n,con} \leq g_{n,con} (rel P) \text{ if } (\forall X \in P) f_{n,con}(X) \leq g_{n,con}(X) \text{ (wrt } \Sigma_{con}).$$

The meaning of " \leq " is easy to see: $f_{n,con} \leq g_{n,con} (rel P)$ implies that at any state X of P , for any control pattern which is chosen by $f_{n,con}$ there is a control pattern chosen by $g_{n,con}$ which specifies more enabled simultaneous events. Therefore, the relation " \leq " on the set of NDC's for G_{con} imposes an ordering on the degree of permissiveness and concurrency they allow of the plant. It is easy to check that

$$f_n \leq g_n (rel P) \Leftrightarrow f_{n,con} \leq g_{n,con} (rel P).$$

The following simple result says that the ordering " \leq " on the set of NDC's induces a consistent ordering among the closed-loop predicates.

Claim 6: If $f_{n,con} \leq g_{n,con} (rel R(f_{n,con}/G_{con}))$ then

$$R(f_{n,con}/G_{con}) \preceq R(g_{n,con}/G_{con}).$$

□

For a controllable predicate P , let f_n^o be defined as in (14). Define

$$F^+(P) := \{f_n \mid f_n^o \leq f_n (rel P)\}.$$

$F^+(P)$ comprises all controllers which are more permissive in their control action than f_n^o . It follows from Claim 6 and the fact $R(f_{n,con}^o/G_{con}) = P$ that

$$(\forall f_n \in F^+(P)) P \preceq R(f_{n,con}/G_{con}). \quad (15)$$

For a controllable predicate P , we also define

$$F^-(P) := \{f_n \mid (\forall X \in P)(\forall \gamma \in f_n(X))(\forall e \in 2^\gamma) \cdot \delta(e, X) \in P \text{ or not } \delta(e, X)!\}.$$

$F^-(P)$ comprises all controllers whose concurrent extensions enable only legal simultaneous events. It follows that

$$(\forall f_n \in F^-(P)) R(f_{n,con}/G_{con}) \preceq P. \quad (16)$$

The next result says that the concurrent extensions of balanced controllers in $F^-(P) \cap F^+(P)$ are exactly the controllers which synthesize P in G_{con} ; $F^-(P)$ determines a lower range, and $F^+(P)$ an upper range, of such controllers.

Theorem 7: Assume that P is controllable and $X_0 \in P$. Then for any balanced controller $f_{n,con}$

$$R(f_{n,con}/G_{con}) = P \Leftrightarrow f_n \in F^-(P) \cap F^+(P).$$

Proof: (\Leftarrow) Directly follows from (15) and (16).

(\Rightarrow) Assume for a balanced controller $f_{n,con} : \mathcal{X} \rightarrow 2^{\Gamma_{con}}$

$$R(f_{n,con}/G_{con}) = P.$$

To show that $f_n \in F^+(P)$, suppose for a contradiction that

$$\text{not } (f_n^o \leq f_n) (rel P).$$

Then

$$(\exists X \in P) \text{ not } (f_n^o(X) \leq f_n(X))$$

that is

$$(\exists X \in P)(\exists \gamma \in f_n^o(X))(\forall \gamma_1 \in f_n(X)) \text{ not } (\gamma \subseteq \gamma_1).$$

Since all candidate control patterns in $f_n^o(X)$ have the form

$$\Sigma_u \cup \{\alpha\}$$

there follows

$$(\exists X \in P)(\exists \alpha \in \Sigma_c)(\Sigma_u \cup \{\alpha\} \in f_n^o(X) \& (\forall \gamma \in f_n(X)) \alpha \notin \gamma).$$

So

$$(\exists X \in P)(\exists \alpha \in \Sigma_c) \delta(\alpha, X)! \& \delta(\alpha, X) \in P \& (\forall \gamma \in f_n(X)) \alpha \notin \gamma.$$

But this contradicts the assumption that $f_{n,con}$ (or f_n) is balanced.

The conclusion that $f_n \in F^-(P)$ follows directly from the assumption that $R(f_{n,con}/G_{con}) = P$ and the definition of $F^-(P)$. \square

For a controllable predicate P , denote the balanced controllers in $F^+(P) \cap F^-(P)$ by $F(P)$.

Lemma 8: $F(P)$ is a poset with respect to the relation " \leq ".

Proof: It is easy to see that the relation " \leq " is both reflexive and transitive.

To show that it is also antisymmetric, let $f_n, g_n \in F(P)$ with

$$f_n \leq g_n, g_n \leq f_n \quad (rel P).$$

We show that $f_n = g_n (rel P)$. For any $X \in P$, let $\gamma \in f_n(X)$. Then $\gamma \subseteq \gamma_1$ for some $\gamma_1 \in g_n(X)$ since $f_n \leq g_n$. Also, since $g_n \leq f_n$, we have $\gamma_1 \subseteq \gamma_2$ for some $\gamma_2 \in f_n(X)$. So $\gamma \subseteq \gamma_1 \subseteq \gamma_2$. Since f_n is balanced, there is no redundant control pattern in $f_n(X)$. Thus $\gamma = \gamma_2$, implying that $\gamma = \gamma_1$. This proves that

$$(\forall \gamma \in f_n(X))(\exists \gamma_1 \in g_n(X))\gamma = \gamma_1$$

or, equivalently

$$f_n(X) \subseteq g_n(X).$$

Repeating the above argument with f and g interchanged, we get

$$f_n(X) \supseteq g_n(X).$$

So

$$(\forall X \in P)f_n(X) = g_n(X)$$

i.e., $f_n = g_n (rel P)$. \square

By the definitions of $F(P)$ and f_n^o , we know that f_n^o is the infimal element of the poset $F(P)$. We now construct the supremal element of $F(P)$.

For a controllable predicate P on \mathcal{X} and $X \in P$ define

$$M(X) := \{c \mid c \subseteq \Sigma_c \text{ and } (\forall c' \in 2^c)\delta(c', X) \in P \text{ or not } \delta(c', X)!\}$$

and

$$N(X) := \{\Sigma_u \cup c \mid c \in M(X) \text{ and } (\forall c' \in M(X))c \subseteq c' \Rightarrow c = c'\}.$$

Then define a controller f_n^* as

$$f_n^*(X) := \begin{cases} N(X) & X \in P \\ \Sigma_u & \text{otherwise.} \end{cases} \quad (17)$$

Notice that $f_n^*(X)$ does not contain any redundant control patterns.

Assume that for given state X , predicate P on \mathcal{X} and $e, e' \subseteq \Sigma_c$, checking $\delta(e, X) \in P, \delta(e, X)!$, $e \subseteq e'$, and $e = e'$ are basic computational steps. Then the complexities of computing both $M(X)$ and $N(X)$ are $O(2^{|\Sigma_c|} \times 2^{|\Sigma_c|})$. (Note that $|M(X)| \leq 2^{|\Sigma_c|}$.) The computational complexity of f_n^* is thus $O(|P| \times 2^{2|\Sigma_c|})$.

Theorem 9: The NDC f_n^* defined in (17) is the supremal element in $F(P)$.

Proof: We first show that $f_n^* \in F^+(P) \cap F^-(P)$. That $f_n^* \in F^+(P)$ follows from the fact that for any $X \in P$

$$(\forall \gamma \in f_n^o(X))(\exists \gamma' \in f_n^*(X))\gamma \subseteq \gamma'$$

$$f_n^o(X) \leq f_n^*(X).$$

That $f_n^* \in F^-(P)$ follows directly from the definition and Claim 3. It is also easy to see from the definition that f_n^* is balanced. Thus $f_n^* \in F(P)$.

Let $f_n \in F(P)$. Then $f_n \in F^-(P)$, and

$$(\forall X \in P)(\forall \gamma \in f_n(X))(\forall c \in 2^{\gamma})\delta(c, X) \in P \text{ or not } \delta(c, X)!.$$

From Claim 3

$$(\forall X \in P)(\forall \gamma \in f_n(X))(\forall c \in 2^{\gamma \cap \Sigma_c})\delta(c, X) \in P \text{ or not } \delta(c, X)!.$$

Therefore

$$(\forall X \in P)(\forall \gamma \in f_n(X))(\exists \gamma' \in N(X))\gamma \subseteq \gamma'$$

and $f_n \leq f_n^* (rel P)$. It follows that f_n^* is the supremal element in $F(P)$. \square

Therefore, for a nonempty controllable predicate P , $f_{n,con}^*$ will synthesize P and, among all controllers doing so, it will allow the plant G_{con} to have maximally concurrent closed-loop behavior.

For the ATM example, $\Sigma_c = \{\alpha_1, \alpha_2, \alpha_3\}$, and

$$M(X) = \begin{cases} \{\emptyset, \{\alpha_1\}, \{\alpha_2\}, \{\alpha_3\}, \{\alpha_1, \alpha_2\}, \\ \{\alpha_1, \alpha_3\}, \{\alpha_2, \alpha_3\}, \{\alpha_1, \alpha_2, \alpha_3\}\} & X \leq 2 \\ \{\emptyset, \{\alpha_1\}, \{\alpha_2\}, \{\alpha_3\}, \{\alpha_1, \alpha_2\}, \\ \{\alpha_1, \alpha_3\}, \{\alpha_2, \alpha_3\}\} & X = 3 \\ \{\emptyset, \{\alpha_1\}, \{\alpha_2\}, \{\alpha_3\}\} & X = 4 \\ \{\emptyset\} & X = 5 \end{cases}$$

$$f_n^*(X) := N(X) = \begin{cases} \{\{\alpha_1, \alpha_2, \alpha_3, \alpha_4\}\} & X \leq 2 \\ \{\{\alpha_1, \alpha_2, \alpha_4\}, \{\alpha_1, \alpha_3, \alpha_4\}, \\ \{\alpha_2, \alpha_3, \alpha_4\}\} & X = 3 \\ \{\{\alpha_1, \alpha_4\}, \{\alpha_2, \alpha_4\}, \\ \{\alpha_3, \alpha_4\}\} & X = 4 \\ \{\{\alpha_4\}\} & X = 5 \end{cases}$$

$$f_n^*(X) := \{\{\alpha_4\}\}, \quad X > 5$$

The control actions of $f_{n,con}^*$ are: for $X \leq 2$, enables all three RN's for transmission; at $X = 3$, randomly enables two RN's; at $X = 4$, randomly enables one RN; and for $X \geq 5$, disables all RN's. This is intuitively the best that any controller can possibly achieve in the presence of concurrency.

VI. CONCLUSIONS

The VDES is a compact model for a useful class of discrete-event control systems and allows computationally-efficient control synthesis [13], [14]. Continuing the study of VDES, this paper explored another feature of VDES: concurrency, or possible simultaneous occurrence of events. We formalized concurrency by extending the event set from Σ to $\Sigma_{con} := 2^\Sigma$; an extended event $e = \langle \alpha_1, \alpha_2, \dots, \alpha_k \rangle$ in Σ_{con} represents the simultaneous occurrence of $\alpha_1, \alpha_2, \dots, \alpha_k$. The VDES model incorporating concurrency is called concurrent VDES (CVDES).

It was shown that, owing to the effect of concurrency on control, a nonempty predicate on the state space can be synthesized by a (balanced) deterministic controller in a CVDES if and only if it is controllable and satisfies an additional condition called concurrent well-posedness. Since concurrently well-posed predicates are not closed under disjunction, it is not always possible to synthesize an optimal deterministic controller for a CVDES.

This led us to nondeterministic control of CVDES. It was shown that controllability is a necessary and sufficient condition for a predicate to be synthesized by a balanced nondeterministic controller in a CVDES. Therefore, optimal nondeterministic-controller synthesis (in terms of closed-loop predicate) is always achievable. Next we characterized the set of nondeterministic controllers synthesizing a given controllable predicate P , denoted by $F(P)$. A partial order was defined on this set to compare degrees of concurrency of the closed-loop system allowed by nondeterministic controllers. Finally, we proposed a formula for constructing the supremal element of $F(P)$. If P is a given legal specification, then the supremal element in $F(\text{sup}C(P))$ is a nondeterministic controller enforcing P which is optimal not only in the sense of reachable states but also in the sense of concurrency permitted to the controlled CVDES.

We remark that the results in this paper can be easily adapted to any automaton DES for which Claims 1, 2, and 3 can be established.

In future research it may be worthwhile to exploit the specific structure of CVDES so that the supremal element of $F(\text{sup}C(P))$ can be constructed in a computationally-efficient way, along the lines of [14].

Throughout this paper, we used a simple ATM example to demonstrate concepts and results. Though a small part of a complex system, this example does show that concurrency can arise naturally from and pose unique problems for the control of real-world systems such as telecommunication networks. For future research, it will be interesting to model larger systems using CVDES and address control specifications of wider scope.

He received the B.Eng. degree in computer science and automation from Chongqing University, Sichuan, in 1982, and the M.A.Sc. and Ph.D. degrees from the University of Toronto, Ontario, Canada, in 1986 and 1991, respectively, both in electrical engineering.

He joined Northern Telecom, Brampton, Ontario, in 1990, and has been with Bell-Northern Research, Ottawa, Ontario, since 1994. His current research interests include control of discrete-event systems,

software engineering for large-scale real-time systems, and telecommunications.

Dr. Li was a recipient of the Connaught Scholarship from the University of Toronto.

W. M. Wonham (M'64-SM'76-F'77) received the B.S. degree in engineering physics from McGill University, Montreal, P.Q., Canada, in 1956 and the Ph.D. degree in control engineering from the University of Cambridge, Cambridge, England, in 1961.

From 1961 to 1969, he was associated with the Control and Information Systems Laboratory at Purdue University, West Lafayette, IN, the Research Institute for Advanced Studies (RIAS) of the Martin Marietta Co., the Division of Applied Mathematics at Brown University, Providence, RI, and (as a National Academy of Sciences Research Fellow) with the Office of Control Theory and Application of NASA's Electronics Research Center. In 1970, he joined the Systems Control Group of the Department of Electrical Engineering at the University of Toronto, Ontario, Canada. He currently holds the J. Roy Cockburn Chair. In addition, he has held visiting academic appointments with the Department of Electrical Engineering at Massachusetts Institute of Technology, Cambridge; the Department of Systems Science and Mathematics at Washington University, St. Louis, MO; the Department of Mathematics of the University of Bremen; the Mathematics Institute of the Academia Sinica, Beijing; the Indian Institute of Technology, Kanpur; and other institutions. His research interests have lain in the areas of stochastic control and filtering, the geometric theory of linear multivariable control, and more recently in discrete event systems from the viewpoint of formal logic and language. He has authored or coauthored about 60 research papers as well as the book *Linear Multivariable Control: A Geometric Approach*.

Dr. Wonham is a Fellow of the Royal Society of Canada. In 1987, he was the recipient of the IEEE Control Systems Science and Engineering Award, and in 1990 was a Brouwer Medalist of the Netherlands Mathematical Society.

Structure of Model Uncertainty for a Weakly Corrupted Plant

Tong Zhou and Hidenori Kimura, *Fellow, IEEE*

Abstract—In this paper, we investigate the structure of the transfer function set which includes all eliminate the transfer functions deduced from the plant available information. It is shown that when an upper bound of the plant transfer function's H^∞ -norm has been supplied, and the noise contaminating the time domain identification experiment data is not too significant, such a transfer function set can be parameterized by a linear fractional transformation of two transfer function matrices. One of them is a fixed transfer function matrix which is completely determined by the plant available information and the noise magnitude. The other is a norm bounded, structure fixed, free transfer function matrix. Moreover, it is shown that the problem of analytically obtaining the fixed complexity nominal model that best approximates this transfer function set is as difficult as the μ -synthesis problem.

I. INTRODUCTION

ROBUSTNESS is one of the principal properties expected for control system, due to the high complexity of plant, plant parameter variation according to operation conditions, etc. In order to carry out such a study quantitatively, an initial step is to develop a mechanism to measure the size of the uncertainty of the plant nominal model error. Afterwards, it is necessary to investigate the problem of designing controllers for transfer function set defined by this mechanism and the problem of identifying the transfer function set measured by this mechanism from plant physically obtainable information.

In the last decade, most of the research effort has been focused on the problem of developing controller design theory and uncertainty measure mechanism. For example, gap metric, graph metric, H^∞ -norm, L^1 -norm, etc., have been developed to measure the uncertainty of nominal model error, and parametric uncertainty, additive unstructured uncertainty, multiplicative unstructured uncertainty, coprime factor unstructured uncertainty, etc., have been exploited to describe the model of a control plant with a nominal model, while H^∞ optimization theory, structured singular value theory (or μ), quadratic stability theory, etc., have been developed for robust controller design [4], [5], [8], [16], [18]. However, it is until recent years that the problem of identifying transfer function set measured by a mechanism suitable for robust

controller design from plant available information has begun to receive a considerable amount of attention, e.g., [3], [9], [12], [14], [15], [19], [21], [25], [26], [30], [32], [34], and [37]–[39].

Several approaches have been proposed to attack this problem. Briefly, these approaches can be divided into two kinds. One of them is a stochastic approach in which the uncertainty bound of the nominal model error is sometimes called “soft bound” [12], [24]. The other is a deterministic approach, and in this case, the nominal model error uncertainty bound is called “hard bound” [14], [15], [32], [21], [38], [39].

In a deterministic approach, there are two kinds of philosophy in identifying the transfer function set of a plant from its available information. One of them is to obtain the smallest transfer function set which can include all of the transfer functions that are deduced from the available information about the plant. This philosophy has a strong information theory support, because it means that with the increment of the information about the plant, the uncertainty about the plant dynamics will decrease [31], [35]. Another one is to find the smallest transfer function set that can not be falsified by the plant available information. This philosophy is based on a scientific principle which says that a model is correct if it can explain the observed plant input–output characteristics, and among the models that can not be falsified by the knowledge about the plant, the best choice is the “simplest” or “most powerful” model [25], [33]. The former is called worst case deterministic approach and the concepts are first proposed by Helmicki *et al.* in the field of identification for robust control [15]. The latter has been attacked by Zhou and Kimura. In that case, the problem of identifying the smallest unfalsified transfer function set has been reduced to a convex optimization problem, which is computationally tractable, under the condition that the denominator of the plant nominal model has been prescribed [37]–[39].

While it is generally impossible to obtain the “actual” model of a plant even in the ideal case, i.e., when a plant is linear and time invariant, because perfect information about a plant is usually not obtainable from measurement, due to the finiteness of identification experiment time length and unavoidable noise existent in identification experiment data, both the transfer function sets, which are deduced by the philosophy of unfalsified modeling and the philosophy of worst case deterministic approach, respectively, will play important roles in robust controller design. This is based on

IEEE Log Number 9408277.

the following arguments. That is, the worst case deterministic approach will give a transfer function set that can guarantee the actual plant performances when a controller is designed such that the desirable performances are met for all of the transfer functions belonging to the transfer function set, provided that the actual plant dynamics can be appropriately approximated by a transfer function. On the other hand, the unfalsified modelling will bring out a transfer function set that a controller should be designed to make every transfer function in that transfer function set satisfy the desirable performances in order to let the actual plant achieve these performances.

In unfalsified modelling, the well known Carathéodory–Fejér extrapolation theorem (or Schur–Takagi–AAK Theorem) plays an essential role [13], [22], [2]. The importance of this theorem in identification and model validation has been independently found by Poolla *et al.* and Zhou *et al.* [28], [36], [37].

It is still a challenging problem, however, to obtain the smallest transfer function set which can include all eliminate the transfer functions that are deduced from the available information of a plant and is compatible with robust controller design, although a number of robustly convergent algorithms have been proposed, e.g., [14], [15]. Basically, such a problem is to approximate a function set by a single function belonging to a prescribed set, e.g., this function should be in \mathcal{H}^∞ , and/or it should have a complexity as low as possible for the convenience of robust controller design, etc. Therefore, the structure of the transfer function set will play essential roles in finding out the identification algorithm. For instance, in information-based complexity theory, it is well known that if a function set is symmetric, then it will be best approximated by its center, no matter what metric is used in measuring the approximation error, provided that there is no restriction imposed on the function that is used to approximate the function set [31].

In this paper, we investigate the problem concerning the structure of the transfer function set which includes all of the possible transfer functions of a plant, based on some kinds of the plant obtainable information. It is shown that when an upper bound of the \mathcal{H}^∞ -norm of the plant transfer function has been given and the plant time-domain input–output has been measured over a finite time interval, if it is only the plant output that has been contaminated by a not too significant magnitude bounded noise, then this transfer function set can be described by a linear fractional transformation of two transfer function matrices, one of them is completely determined by the plant available information and the noise magnitude and is therefore fixed, another one is uncertain but norm bounded and structure fixed. Moreover, it is also shown that the problem of obtaining the fixed complexity plant nominal model that best approximates this transfer function set has an equal level of difficulty as that met in μ -synthesis problem.

An outline of this paper is as follows. In Section II, the problem is formulated. The structure of the transfer function set is investigated in Section III, while the application of the main results to identification for robust control is discussed in Section IV. Finally, conclusions of this paper are given in Section V.

Many of the results of Section III of this paper have appeared, without proof, in [40].

Notations

\mathcal{R}	The set of real numbers.
\mathcal{C}	The set of complex numbers.
$\mathcal{R}^{m \times n}$	The set of $m \times n$ real matrices.
$\mathcal{C}^{m \times n}$	The set of $m \times n$ complex matrices.
\mathcal{D}	The closed unit disk defined as $\mathcal{D} = \{z \mid z \leq 1\}$.
I_k	Identity matrix of $k \times k$ dimension. In cases in which confusion will not result, the subscript k is omitted.
	Scalar 0 or matrix with suitable dimension and all elements being zero.
$\text{diag}\{\alpha_1, \alpha_2, \dots, \alpha_n\}$	Diagonal matrix or block diagonal matrix defined by scalars or matrices $\alpha_1, \alpha_2, \dots, \alpha_n$.
X^t	Transpose of vector or matrix X .
$\det(X)$	The determinant of a square matrix X .
$\bar{\sigma}(X)$	The maximal singular value of matrix X .
\mathcal{H}^∞	Transfer function set or transfer function matrix set formed by transfer function or transfer function matrix that is analytic on the closed unit disk $\mathcal{D} = \{z \mid z \leq 1\}$.
$\ F\ $	The \mathcal{H}^∞ -norm of transfer function $F(z) \in \mathcal{H}^\infty$ which is defined as

$$\|F(z)\|_\infty = \max_{|z| \leq 1} |F(z)|.$$

\mathcal{BH}^∞	Transfer function set which consists of all transfer functions that are analytic when $ z \leq 1$ and have \mathcal{H}^∞ -norm not greater than 1, i.e., $\mathcal{BH}^\infty = \{g(z) \mid \ g(z)\ _\infty \leq 1\}$.
-----------------------	---

Linear fractional transformation (LFT)

$$\mathcal{F}_1 \left(\begin{bmatrix} P_{11} & P_{12} \\ P_{21} & P_{22} \end{bmatrix}, K \right) = P_{11} + P_{12}K(I - P_{22}K)^{-1}P_{21}.$$

Homographic transformation (HM)

$$\mathcal{HM} \left(\begin{bmatrix} P_{11} & P_{12} \\ P_{21} & P_{22} \end{bmatrix}, K \right) = (P_{11}K + P_{12})(P_{21}K + P_{22})^{-1}.$$

Structured singular value ($\mu_N(M)$): For given positive integers $c_1, c_2, \dots, c_T; r_1, r_2, \dots, r_S; m_1, m_2, \dots, m_F$, define a matrix structure

$$\begin{aligned} \mathcal{X} = \{ \Delta \mid \Delta = & \text{diag}\{\delta_1 I_{c_1}, \dots, \delta_S I_{c_T}, \gamma_1 I_{r_1}, \dots, \\ & \gamma_S I_{r_S}, \Delta_1, \dots, \Delta_F\}, \\ & \delta_i \in \mathcal{R}, \gamma_j \in \mathcal{C}, \Delta_k \in \mathcal{C}^{m_k \times m_k}, \\ & 1 \leq i \leq T, 1 \leq j \leq S, 1 \leq k \leq F \}. \end{aligned}$$

Then, the structured singular value of matrix M with dimension

$$\left(\sum c_i + \sum r_i + \sum m_i \right) \times \left(\sum c_i + \sum r_i + \sum_{i=1}^F m_i \right)$$

is defined as

$$\mu_{\lambda}(M) := \begin{cases} \frac{1}{\min \{ \bar{\sigma}(\Delta), \Delta \in \mathcal{X}, \det(1 - M\Delta) = 0 \}}, \\ 0, & \text{if there is no } \Delta \in \mathcal{X} \text{ which makes} \\ & I - M\Delta \text{ singular.} \end{cases}$$

II. PROBLEM FORMULATION

Mathematically, the problem of identifying a nominal model and its error uncertainty bound in the worst case by a deterministic approach is a problem to best approximate a function set by a suitable single function under a metric compatible with robust controller design. While the transfer function that best approximates the prescribed transfer function set gives the plant nominal model, the approximation error will provide the uncertainty bound of the plant nominal model error. Both of them are essential in robust controller design. On the other hand, some restrictions are generally imposed on the function that is used to approximate the function set, which is determined by this function's intended application. For example, in robust controller design, a lower complexity nominal model is commonly highly appreciated; moreover, it is usually required to let the plant nominal model have the same number of unstable poles as that of the plant "actual" transfer function; and so on. In these senses, such an identification problem differs significantly from the traditional identification problem, in which it is desirable to find some parameters that minimizes the "prediction error" of the nominal model which is defined by *a priori* chosen model structure and the parameters to be found [24], [7].

To approximate a function set, it is preferable to investigate the structure of the function set first, because the structure of the function set plays an essential role in developing the approximation algorithm. For example, a symmetric function set will always be best approximated by its center, no matter what metric is utilized to measure the approximation error, and it is generally hard to find out the optimal approximation algorithm for a function set with arbitrary structure [31]. In worst-case deterministic identification, the function set is a transfer function set and every transfer function belonging to it is deduced from the plant physically obtainable information.

Generally, two kinds of information can be obtained from a plant. One of them is in frequency domain and another in time domain.

Plant frequency domain information can be obtained by applying sinusoidal input with frequency corresponding to the frequency point of interest.

The problem that will be investigated here is formulated as follows.

Assume that the plant is linear time invariant and stable. Moreover, assume that the \mathcal{H}^{∞} -norm of the plant transfer function is not greater than γ . Given a series of time domain identification experiment data of the plant

$$(u_0, y_0), (u_1, y_1), \dots, (u_n, y_n), \quad u_0 \neq 0$$

which is corrupted by an additive magnitude bounded noise series

$$(v_0, v_1, v_2, \dots, v_n), \quad v_i \in \mathcal{R}, |v_i| \leq \kappa, 0 \leq i \leq n$$

in the plant output y_i , $0 \leq i \leq n$. The problem is to find out all of the transfer functions that do not contradict the aforementioned information about the plant.

From the problem formulation, it is obvious that the transfer function set that consists of all the plant possible transfer functions can be approximated, which means that a single transfer function can be found that approximates the transfer function set with a finite error. For instance, the zero transfer function will approximate this transfer function set with an error not greater than γ , provided that the error is measured by \mathcal{H}^{∞} -norm. Moreover, when the plant perfect information is supplied, that is, when $\kappa \rightarrow 0$ and $n \rightarrow \infty$, the transfer function set will degenerate into one transfer function. In fact, this transfer function is the plant actual transfer function. Furthermore, compared with the maximal magnitude of the plant unit impulse response M and its relative stability margin ρ which are widely used as the *a priori* information about the plant in the literature dealing with worst-case deterministic identification problem, e.g., [14] and [15], an upper bound of the \mathcal{H}^{∞} -norm of the plant transfer function is easier to obtain. Note that when a plant is linear time invariant and stable, according to the well known maximum-modulus theorem [29], an upper bound of the plant transfer function's \mathcal{H}^{∞} -norm can be obtained by measuring the plant frequency response, which is generally possible. In these senses, the formulated problem is well-posed.

III. STRUCTURE OF THE TRANSFER FUNCTION SET

Under the condition that the plant is linear and time invariant during the identification experiment, the uncertainty about the plant transfer function results from two factors. First, the measure time length of identification experiment is limited, which means that n is generally a finite integer. Therefore, we can only obtain finite sampling points of the plant unit impulse response. The plant remainder unit impulse response will make us uncertain about its transfer function. Second, there always exists effect of noise during identification experiment, which implies that we can only obtain the intervals in which the first n sampling points of the actual plant unit impulse response exist, and we are also uncertain about the real value of the first n sampling points of the plant unit impulse response.

As the first step, we shall investigate the uncertainty on the plant transfer function caused by the finite length of identification experiment time length.

This problem is closely connected to a classical extrapolation problem, Schur extrapolation problem [2], [6], [17]. First, we introduce the following results which are obtained by Adamjan *et al.* [1] and [22].

AAK Theorem: For given real number g_0, g_1, \dots, g_n , define

$$\bar{G} = \begin{bmatrix} g_n & g_{n-1} & g_1 & g_0 \\ g_{n-1} & g_{n-2} & g_0 & 0 \\ \vdots & \vdots & & \\ g_1 & g_0 & 0 & \\ g_0 & 0 & 0 & \end{bmatrix}$$

If $\bar{\sigma}(\bar{G}) < \gamma$, then

$$g(z) = \gamma z^{n+1} \frac{p(\frac{1}{z})\epsilon(z) + q(\frac{1}{z})}{q(z)\epsilon(z) + p(z)}, \quad \epsilon(z) \in \mathcal{BH}^\infty \quad (1)$$

exhausts all the transfer functions

$$g(z) = g_0 + g_1 z + g_2 z^2 + \cdots + g_n z^n + z^{n+1} \sum_{j=1}^{\infty} h_j z^j, \quad (2)$$

$$\leq \gamma. \quad (3)$$

Moreover, every transfer function which has the form expressed in (1) satisfies the conditions represented in (2) and (3). Here

$$p(z) = \sum_{j=1}^{\infty} p_j z^{j-1}, \quad q(z) = \sum_{j=1}^{\infty} q_j z^{j-1},$$

$$p = [p_1 \ p_2 \ \cdots]^t = \gamma R e, \quad q = [q_1 \ q_2 \ \cdots]^t = T G R e.$$

$$R = (\gamma^2 I - G^2)^{-1}, \quad e = [1 \ 0 \ 0 \ \cdots]^t,$$

$$G = \begin{bmatrix} g_n & g_{n-1} & \cdots & g_1 & g_0 & 0 & \cdots \\ g_{n-1} & g_{n-2} & \cdots & g_0 & 0 & 0 & \cdots \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots \\ g_1 & g_0 & \cdots & 0 & 0 & 0 & \cdots \\ g_0 & 0 & \cdots & 0 & 0 & 0 & \cdots \\ 0 & 0 & \cdots & 0 & 0 & 0 & \cdots \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots \end{bmatrix},$$

$$T = \begin{bmatrix} 0 & 0 & 0 & \cdots \\ 1 & 0 & 0 & \cdots \\ 0 & 1 & 0 & \cdots \\ 0 & 0 & 1 & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix}.$$

In retrospect, the aforementioned extrapolation problem is an extension of the Carathéodory–Fejér extrapolation problem and has been well investigated by Schur *et al.* Moreover, it is well known as a classical moment problem related to the Nevanlinna–Pick interpolation problem [1], [2], [13], [22]. This classical moment problem has found wide applications in broad-band matching, cascade synthesis, network and semiconductor modeling, etc. [17]. The ideas and concepts developed in solving these classical moment problems have accepted a wide attention in control community, also. For example, the concepts of Hankel operator, Toeplitz operator, J-lossless factorization, J-spectral factorization, etc., have been widely used in solving the so-called \mathcal{H}^∞ optimization problem, robust stabilization problem, model reduction problem, etc. [5], [10], [11], [16], [20], [23]. The solution of this extrapolation problem was first given by Adamjan *et al.* in the explicit form expressed in (1) [1], [22], and a proof based on elementary matrix manipulation can be found in [41].

Based on the AAK Theorem, we investigate the uncertainty on the plant transfer function caused by the unmeasured plant output.

Theorem 1: Assume that $Y_0^t Y_0 < \gamma^2 U^t U$. Then, every transfer function which is consistent with the given input–output data $(u_i, y_i^0) \mid_{i=0}^n$, $u_0 \neq 0$, and has \mathcal{H}^∞ -norm not greater than γ can be represented by

$$g(z) = \gamma \frac{\sum_{j=1}^{n+1} \hat{q}_j^0 z^{j-1} + (\sum_{j=1}^{n+1} \hat{p}_j^0 z^{n+2-j}) \epsilon(z)}{\sum_{j=1}^{n+1} \hat{p}_j^0 z^{j-1} + (\sum_{j=1}^{n+1} \hat{q}_j^0 z^{n+2-j}) \epsilon(z)}, \quad \epsilon(z) \in \mathcal{BH}^\infty.$$

Moreover, every transfer function belonging to transfer function set

$$\begin{aligned} \mathcal{G}_n(\gamma) &= \{g(z) \mid g(z) \\ &= \gamma \frac{\sum_{j=1}^{n+1} \hat{q}_j^0 z^{j-1} + (\sum_{j=1}^{n+1} \hat{p}_j^0 z^{n+2-j}) \epsilon(z)}{\sum_{j=1}^{n+1} \hat{p}_j^0 z^{j-1} + (\sum_{j=1}^{n+1} \hat{q}_j^0 z^{n+2-j}) \epsilon(z)}, \\ &\quad \epsilon(z) \in \mathcal{BH}^{mfly}\} \end{aligned}$$

has \mathcal{H}^∞ -norm not greater than γ and matches the given input–output data. Here

$$p^0 = [\hat{p}_1^0 \ \hat{p}_2^0 \ \cdots \ \hat{p}_{n+1}^0]^t = \gamma U (\gamma^2 U^t U - Y_0^t Y_0)^{-1} e,$$

$$\hat{q}^0 = [\hat{q}_1^0 \ \hat{q}_2^0 \ \cdots \ \hat{q}_{n+1}^0]^t = Y_0 (\gamma^2 U^t U - Y_0^t Y_0)^{-1} e,$$

$$U = \begin{bmatrix} u_0 & 0 \\ u_1 & u_0 \\ \vdots & \vdots \\ u_n & u_{n-1} \end{bmatrix}$$

$$Y_0 = \begin{bmatrix} y_n^0 & y_{n-1}^0 \\ \vdots & \vdots \\ 1 & 0 \\ 0 & \vdots \\ 0 & 0 \end{bmatrix}.$$

Proof: For a plant with transfer function $G(z) = \sum_{j=0}^{\infty} g_j z^j$, if $(u_i, y_i^0) \mid_{i=0}^n$ are the input–output pairs of the plant, then, it is necessary that

$$\begin{bmatrix} y_0^0 & g_0 & 0 & \cdots & u_0 \\ y_1^0 & g_1 & g_0 & \cdots & u_1 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ y_n^0 & g_n & g_{n-1} & \cdots & u_n \end{bmatrix} \quad (4)$$

that is

$$\begin{bmatrix} y_0^0 & y_0^0 \\ y_1^0 & y_0^0 \\ \vdots & \vdots \\ y_n^0 & y_{n-1}^0 \end{bmatrix} = \begin{bmatrix} g_0 & 0 & \cdots & 0 \\ g_1 & g_0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ g_n & g_{n-1} & \cdots & g_0 \end{bmatrix} \begin{bmatrix} u_0 & 0 & \cdots & 0 \\ u_1 & u_0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ u_n & u_{n-1} & \cdots & u_0 \end{bmatrix} \quad (5)$$

Since $u_0 \neq 0$, we have

$$\hat{G} = Y_0 U^{-1} = U^{-1} Y_0. \quad (6)$$

Here

$$\hat{G} = \begin{bmatrix} g_0 & 0 & \cdots & 0 \\ g_1 & g_0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ g_n & g_{n-1} & \cdots & g_0 \end{bmatrix}.$$

On the other hand, it can also be proved that if

$$\hat{G} = Y_0 U^{-1} = U^{-1} Y_0, \quad (7)$$

then, when $u_i |_{i=0}^n$ are applied to the plant, the output of the plant will be $y_i^0 |_{i=0}^n$.

Therefore, a plant with transfer function $g(z) = \sum_{j=0}^{\infty} g_j z^j$ has input-output pairs $(u_i, y_i^0) |_{i=0}^n$, $u_0 \neq 0$, if and only if

$$\hat{G} = Y_0 U^{-1} = U^{-1} Y_0. \quad (8)$$

Note that

$$\begin{bmatrix} g_n & \cdots & g_1 & g_0 \\ g_{n-1} & \cdots & g_0 & 0 \\ \vdots & \ddots & \vdots & \vdots \\ g_0 & \cdots & 0 & 0 \end{bmatrix} = \begin{bmatrix} 0 & \cdots & 0 & 1 \\ 0 & \cdots & 1 & 0 \\ \vdots & \ddots & \vdots & \vdots \\ 1 & \cdots & 0 & 0 \end{bmatrix} \cdot \begin{bmatrix} g_0 & 0 & \cdots & 0 \\ g_1 & g_0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ g_n & g_{n-1} & \cdots & g_0 \end{bmatrix}. \quad (9)$$

Let

$$T_1 = \begin{bmatrix} 0 & \cdots & 0 & 1 \\ 0 & \cdots & 1 & 0 \\ \vdots & \ddots & \vdots & \vdots \\ 1 & \cdots & 0 & 0 \end{bmatrix}$$

then using the same notations as those in the AAK Theorem, we have

$$\bar{G} = T_1 G = T_1 Y_0 U^{-1} = T_1 U^{-1} Y_0. \quad (10)$$

From

$$G = \begin{bmatrix} \bar{G} & 0 \\ 0 & 0 \end{bmatrix}$$

we conclude

$$G^2 = \begin{bmatrix} \bar{G} & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} \bar{G} & 0 \\ 0 & 0 \end{bmatrix} = \begin{bmatrix} \bar{G}^2 & 0 \\ 0 & 0 \end{bmatrix}. \quad (11)$$

$$R = (\gamma^2 I - G^2)^{-1} = \begin{bmatrix} (\gamma^2 I_{n+1} - \bar{G}^2)^{-1} & 0 \\ 0 & \gamma^{-2} I_{\infty} \end{bmatrix}, \quad (12)$$

$$\begin{aligned} p &= \gamma R e = \begin{bmatrix} \gamma(\gamma^2 I_{n+1} - \bar{G}^2)^{-1} & 0 \\ 0 & \gamma^{-1} I_{\infty} \end{bmatrix} \begin{bmatrix} \hat{e} \\ 0 \end{bmatrix} \\ &= \begin{bmatrix} \gamma(\gamma^2 I_{n+1} - \bar{G}^2)^{-1} \hat{e} \\ 0 \end{bmatrix}, \end{aligned} \quad (13)$$

$$\begin{aligned} q &= T G R e = T \begin{bmatrix} \bar{G} & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} (\gamma^2 I_{n+1} - \bar{G}^2)^{-1} & 0 \\ 0 & \gamma^{-2} I_{\infty} \end{bmatrix} \begin{bmatrix} \hat{e} \\ 0 \end{bmatrix} \\ &= \begin{bmatrix} \bar{G}(\gamma^2 I_{n+1} - \bar{G}^2)^{-1} \hat{e} \\ 0 \end{bmatrix}. \end{aligned} \quad (14)$$

Note that

$$\bar{G}^2 = \bar{G}^t \bar{G} = U^{-t} Y_0^t Y_0 U^{-1}. \quad (15)$$

Define

$$\bar{p} = \gamma(\gamma^2 I_{n+1} - \bar{G}^2)^{-1} \hat{e} = \gamma U(\gamma^2 U^t U - Y_0^t Y_0)^{-1} U^t \hat{e}, \quad (16)$$

$$\bar{q} = \bar{G}(\gamma^2 I_{n+1} - \bar{G}^2)^{-1} \hat{e} = T_1 Y_0(\gamma^2 U^t U - Y_0^t Y_0)^{-1} U^t \hat{e}. \quad (17)$$

On the other hand

$$U^t e = \begin{bmatrix} u_0 & 0 & \cdots & 0 \\ u_1 & u_0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ u_n & u_{n-1} & \cdots & u_0 \end{bmatrix}^t \begin{bmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{bmatrix} = u_0 \begin{bmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{bmatrix} = u_0 \hat{e} \quad (18)$$

which implies that

$$\bar{p} = u_0 p^0, \quad (19)$$

$$\bar{q} = u_0 T_1 \hat{q}^0. \quad (20)$$

Therefore

$$p(z) = \sum_1^{\infty} p_j z^{j-1} = u_0 \sum_1^{n+1} p_j^0 z^{j-1}, \quad (21)$$

$$p\left(\frac{1}{z}\right) = u_0 \sum_1^{n+1} p_j^0 z^{1-j}, \quad (22)$$

$$q(z) = \sum_1^{\infty} q_j z^{j-1} = u_0 \sum_1^{n+1} \hat{q}_j^0 z^{n+2-j}, \quad (23)$$

$$q\left(\frac{1}{z}\right) = u_0 \sum_1^{\infty} \hat{q}_j^0 z^{j-(n+2)}. \quad (24)$$

From the AAK Theorem, we conclude that every transfer function which is consistent with $(u_i, y_i^0) |_{i=0}^n$, $u_0 \neq 0$, and has \mathcal{H}^{∞} -norm not greater than γ can be represented as

$$\begin{aligned} g(z) &= \gamma z^{n+1} \frac{u_0 \sum_1^{n+1} \hat{q}_j^0 z^{-(n+2)} + (u_0 \sum_1^{n+1} \hat{p}_j^0 z^{1-j}) \epsilon(z)}{u_0 \sum_1^{n+1} \hat{p}_j^0 z^{j-1} + (u_0 \sum_1^{n+1} \hat{q}_j^0 z^{n+2-j}) \epsilon(z)} \\ &= \gamma \frac{\sum_1^{n+1} \hat{q}_j^0 z^{j-1} + (\sum_1^{n+1} \hat{p}_j^0 z^{n+2-j}) \epsilon(z)}{\sum_1^{n+1} \hat{p}_j^0 z^{j-1} + (\sum_1^{n+1} \hat{q}_j^0 z^{n+2-j}) \epsilon(z)}, \\ &\quad \epsilon(z) \in \mathcal{BH}^{\infty} \end{aligned} \quad (25)$$

and every transfer function belonging to transfer function set $\mathcal{G}_n(\gamma)$ has \mathcal{H}^{∞} -norm not greater than γ and is consistent with the given input-output data.

This completes the proof. \blacksquare

Theorem 1 implies that when there is no noise contaminating the identification data, then all of the transfer functions

that are consistent with the identification experiment data and have \mathcal{H}^∞ -norm not greater than γ can be expressed by a homographic transformation of two transfer function matrices, one of them is a fixed transfer function matrix which is completely determined by the upper bound of the plant transfer function's \mathcal{H}^∞ -norm and the identification experiment data, another one is a free transfer function except that its \mathcal{H}^∞ -norm is bounded by 1.

The results in Theorem 1 can be extended to the most general case, i.e., when $Y_0^t Y_0 \leq \gamma^2 U^t U$. According to the input-output extrapolation-minimization theorem [28], [36], [37] (in [28], it is called the extension theorem), in the case that $\bar{\sigma}(Y_0 U^{-1}) = \gamma$, there is only one transfer function that is consistent with the prescribed input-output pairs and has \mathcal{H}^∞ -norm not greater than γ , represent it as $f(z)$. In fact, in this case, the \mathcal{H}^∞ -norm of this transfer function is equal to γ . This fact implies that when $\bar{\sigma}(Y_0 U^{-1}) = \gamma$, we can completely determine the plant transfer function from its input-output data, provided that there is no noise existent in the identification experiment data (however, this is extremely rare in actual identification process). Note that $f(z) \in \mathcal{G}_n(\gamma + \alpha)$ for arbitrary $\alpha > 0$, and $\mathcal{G}_n(\gamma + \alpha_1) \subset \mathcal{G}_n(\gamma + \alpha_2)$ whenever $\alpha_1 < \alpha_2$ (this will be shown in the next corollary), it can be proved that $\{f(z)\} = \lim_{\alpha \rightarrow 0^+} \mathcal{G}_n(\gamma + \alpha) = \mathcal{G}_n(\gamma)$, which is to be shown. A detailed statement of this proof can be found in [41].

The condition $Y_0^t Y_0 \leq \gamma^2 U^t U$ for the transfer function set parameterization is natural. From the input-output extrapolation-minimization theorem [28], [36], [37], it can be claimed that if $Y_0^t Y_0 > \gamma^2 U^t U$, then no transfer function exists that matches the given input-output data and has \mathcal{H}^∞ -norm not greater than γ . Therefore, to prevent the transfer function set $\mathcal{G}_n(\gamma)$ from being void, it is necessary to make the assumption $Y_0^t Y_0 \leq \gamma^2 U^t U$.

Now, we would like to investigate some of the properties of the transfer function set $\mathcal{G}_n(\gamma)$ defined in Theorem 1. First, we discuss the relation between $\mathcal{G}_n(\gamma)$ and γ .

Corollary 1: Let matrices U , Y_0 and vector ϵ be the same as those defined in Theorem 1. Assume that $\gamma_1^2 U^t U > Y_0^t Y_0$, $\gamma_2^2 U^t U > Y_0^t Y_0$. Define transfer function sets $\mathcal{G}_n(\gamma_1)$, $\mathcal{G}_n(\gamma_2)$ through γ_1 , U , Y_0 ; γ_2 , U , Y_0 , respectively, as $\mathcal{G}_n(\gamma)$ in Theorem 1. If $\gamma_1 \geq \gamma_2$, then $\mathcal{G}_n(\gamma_1) \supseteq \mathcal{G}_n(\gamma_2)$.

Proof: Let

$$= U^{-1} \begin{bmatrix} y_0^0 & \gamma \\ y_1^0 \end{bmatrix} \quad (26)$$

From Theorem 1, it is obvious that

$$\mathcal{G}_n(\gamma_1) = \{g(z) \mid g(z) = g_0 + g_1 z + \cdots + g_n z^n + z^n \sum_{i=0}^{\infty} h_i z^i, \quad \|g(z)\|_\infty \leq \gamma_1\} \quad (27)$$

$$\mathcal{G}_n(\gamma_2) = \{g(z) \mid g(z) = g_0 + g_1 z + \cdots + g_n z^n + z^n \sum_{i=0}^{\infty} h_i z^i, \quad \|g(z)\|_\infty \leq \gamma_2\} \quad (28)$$

Since $\gamma_1 \geq \gamma_2$, we have

$$\mathcal{G}_n(\gamma_1) \supseteq \mathcal{G}_n(\gamma_2). \quad (29)$$

This completes the proof. ■

Corollary 1 tells us that when we apply sinusoidal input to a plant in order to obtain an upper bound of the \mathcal{H}^∞ -norm of the plant transfer function, and we are not sure about it, then, it is safer to choose a larger one, in order that the actual plant transfer function is included in the transfer function set that will be approximated.

The next corollary suggests that if there is no noise in the identification experiment data and the identification experiment data length intends to infinity, then the transfer function set $\mathcal{G}_n(\gamma)$ which is deduced from the plant available information will degenerate into one transfer function, i.e., the plant actual transfer function.

Corollary 2: For given input-output data $(u_i, y_i^0) \mid_{i=0}^{n1}$, $(u_i, y_i^0) \mid_{i=0}^{n2}$, and a positive number γ , define matrices U_{n1} , Y_{n10} ; U_{n2} , Y_{n20} ; transfer function sets $\mathcal{G}_{n1}(\gamma)$, $\mathcal{G}_{n2}(\gamma)$ as those in Theorem 1. If $u_0 \neq 0$, $Y_{n10}^t Y_{n10} < \gamma^2 U_{n1}^t U_{n1}$, $Y_{n20}^t Y_{n20} < \gamma^2 U_{n2}^t U_{n2}$, $n2 \leq n1$, then, $\mathcal{G}_{n1}(\gamma) \subseteq \mathcal{G}_{n2}(\gamma)$.

Proof: Let

$$\begin{aligned} & \begin{bmatrix} g_0 \\ g_1 \end{bmatrix} \\ & = U_{n2}^{-1} \begin{bmatrix} y_1^0 \\ \vdots \\ y_{n2}^0 \end{bmatrix} \end{aligned} \quad (30)$$

Since $n1 \geq n2$, from the structure of matrices U_{n1} , U_{n2} , it is obvious that

$$U_{n1} \begin{bmatrix} U_{n2} & 0 \\ X_1 & X_2 \end{bmatrix} \quad (31)$$

Here

$$\begin{aligned} X_1 &= \begin{bmatrix} u_{n2+1} & u_{n2} & \cdots & u_1 \\ u_{n2+2} & u_{n2+1} & \cdots & u_2 \end{bmatrix} \\ & \quad \begin{bmatrix} u_{n1} & u_{n1-1} & \cdots & u_{n1-n2} \end{bmatrix} \\ X_2 &= \begin{bmatrix} u_0 & 0 & \cdots & 0 \\ u_1 & u_0 & \cdots & 0 \end{bmatrix} \\ & \quad \begin{bmatrix} u_{n1-n2-1} & u_{n1-n2-2} & \cdots & u_0 \end{bmatrix} \end{aligned}$$

Therefore

$$U_{n1}^{-1} = \begin{bmatrix} U^{-1} & 0 \\ -X_2^{-1} X_1 U_{n2}^{-1} & X_2^{-1} \end{bmatrix} \quad (32)$$

Hence

$$g_i' = g_i, \quad 0 \leq i \leq n2. \quad (33)$$

From Theorem 1, we have

$$\mathcal{G}_{n1}(\gamma) = \left\{ q(z) \mid q(z) = q_0 + q_1 z + \dots + q_{n1} z^{n1} + z^{n1+1} \sum_{i=0}^{\infty} h_i z^i, \quad \|q(z)\|_{\infty} \leq \gamma \right\} \quad (34)$$

$$\mathcal{G}_{n2}(\gamma) = \left\{ q(z) \mid q(z) = q_0 + q_1 z + \dots + q_{n2} z^{n2} + z^{n2+1} \sum_{i=0}^{\infty} h_i z^i, \quad \|q(z)\|_{\infty} \leq \gamma \right\} \quad (35)$$

From $n1 \geq n2$, we conclude that

$$\mathcal{G}_{n1}(\gamma) \subseteq \mathcal{G}_{n2}(\gamma) \quad (36)$$

This completes the proof. ■

Corollary 2 also implies that as the information about the plant increasing, the "size" of the transfer function set that includes all of the possible plant transfer functions or the uncertainty about the plant transfer function will generally decrease. This is consistent with physical intuition.

From the above investigation, we see that all of the possible plant transfer functions are parameterized by a fixed homographic transformation with a norm bounded free transfer function and the transfer function set that consists of all the plant possible transfer functions will monotonically degenerate into the actual plant transfer function as the identification experiment time increasing to infinity in the case that the measured plant input/output pairs are not corrupted by noise.

Now, we investigate the variation of the homographic transformation in the face of noise that is existent in the measured plant output.

First we consider the change of vectors p^0, q^0 defined in Theorem 1.

The next well known fact plays an important role in developing the relation between the variation of vector p^0, q^0 and the noise in the measured plant output.

Fact 1 For matrices $A \in \mathbb{R}^{n \times n}, B \in \mathbb{R}^{n \times m}$ if $(I_n + AB)^{-1}$ exists, then $B(I_m + 1B)^{-1} = (I_n + B1)^{-1}B$.

For brevity, we assume without loss of generality that $\gamma = 1$ ¹.

The variation of vectors p^0, q^0 according to the noise existent in the measured plant output is indicated in Theorem 2.

Theorem 2 Assume that $y_t^* = y_t + v_t, |v_t| \leq \kappa, 0 \leq t \leq n$. Moreover assume that $\max_{|t| < \kappa} \sigma(Y, U^{-1}) < 1$. Let

$$p^* = U(U^t U - Y_r^t Y_r)^{-1} e, \quad q^* = Y_r(U^t U - Y_r^t Y_r)^{-1} e$$

$$p = U(U^t U - Y^t Y)^{-1} e, \quad q = Y(U^t U - Y^t Y)^{-1} e$$

Then, for all possible vectors p^* and q^*

$$\begin{bmatrix} p^* \\ q^* \end{bmatrix} = \begin{bmatrix} p \\ q \end{bmatrix} - \begin{bmatrix} U^t - Y^t & \\ -Y & U \end{bmatrix}^{-1} W_1 \bar{\Lambda} \left[I_{2(n+1)} + W_1 \begin{bmatrix} U^t - Y^t & \\ -Y & U \end{bmatrix}^{-1} W_1 \bar{\Lambda} \right]^{-1} W_1 \begin{bmatrix} p \\ q \end{bmatrix}$$

¹When $\gamma \neq 1$ we can normalize the plant output and the noise magnitude in order to make $\gamma = 1$. In detail we may use $y_t/\gamma, \kappa/\gamma$ instead of y_t, κ respectively.

Here, $\bar{\Lambda}$ is a norm bounded uncertain matrix defined by

$$\bar{\Lambda} = \text{diag}\{\delta_0 I_{2(n+1)^2}, \delta_1 I_{2(n+1)^2}, \dots, \delta_n I_{2(n+1)^2}\}, \quad \delta_i \in \mathcal{R}, |\delta_i| \leq 1, 0 \leq i \leq n$$

and the other matrices are constant real matrices defined by $u_i, |i|=0, y_i, |i|=0, y_i^*, |i|=0, n$ and κ as

$$Y_t = \begin{bmatrix} y_0^* & 0 & 0 \\ y_1^* & y_0^* & 0 \\ \vdots & \vdots & \vdots \\ y_n^* & y_{n-1}^* & y_0^* \end{bmatrix}, \quad Y = \begin{bmatrix} y_0 & 0 & 0 \\ y_1 & y_0 & 0 \\ \vdots & \vdots & \vdots \\ y_n & y_{n-1} & y_0 \end{bmatrix},$$

$$W_t = \begin{bmatrix} 0 & E_t \\ F_t^t & 0 \end{bmatrix} \bar{T}_t, \quad W_r = \bar{T}_r \begin{bmatrix} E_r^t & 0 \\ 0 & E_r \end{bmatrix}$$

$$I_t = [I_{n+1} \quad I_2 \quad I_2^t] \quad E_t = \kappa [I_{n+1} \quad I_{n+1} \quad I_{n+1}]^t,$$

$$I_2 = \underbrace{\begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{bmatrix}}_{n+1} \Bigg\}^{n+1}$$

$$\bar{T}_t = [I_{2(n+1)} \quad I_{2(n+1)} \quad I_{2(n+1)}] \quad \bar{T}_r = [\bar{\gamma}_0 \quad \bar{\gamma}_1 \quad \bar{\gamma}_n]^t,$$

$$\bar{\gamma}_0 = \text{diag}\{I_{n+1} \quad 0 \quad 0 \quad I_{n+1} \quad 0 \quad 0\},$$

$$\bar{\gamma}_1 = \text{diag}\{0 \quad I_{n+1} \quad 0 \quad 0 \quad I_{n+1} \quad 0\},$$

$$\bar{\gamma}_n = \text{diag}\{0 \quad 0 \quad I_{n+1} \quad 0 \quad 0 \quad I_{n+1}\}$$

and U, Y has the same definitions as those in Theorem 1.

Proof. Let

$$N = \begin{bmatrix} U^t & -Y^t \\ -Y & U \end{bmatrix}, \quad N_r = \begin{bmatrix} U^t & -Y_r^t \\ -Y_r & U \end{bmatrix} \quad (37)$$

It is obvious that N, N_r are invertible if and only if $U^t U - Y^t Y, U^t U - Y_r^t Y_r$ are invertible.

Since $\max_{|t| < \kappa} \sigma(Y_r, U^{-1}) < 1$ by assumption, we claim that $U^t U - Y_r^t Y_r$ is invertible and $U^t U - Y^t Y$ is invertible for all Y .

On the other hand, from the property of matrices U, Y, Y_r , that is, $Y U = Y_r U$ are commutative [38], it can be proved that

$$N^{-1} = \begin{bmatrix} U(U^t U - Y^t Y)^{-1} & Y^t(U U^t - Y Y^t)^{-1} \\ Y(U^t U - Y^t Y)^{-1} & U(U U^t - Y Y^t)^{-1} \end{bmatrix}, \quad (38)$$

$$N_r^{-1} = \begin{bmatrix} U(U^t U - Y_r^t Y_r)^{-1} & Y_r^t(U U^t - Y_r Y_r^t)^{-1} \\ Y_r(U^t U - Y_r^t Y_r)^{-1} & U(U U^t - Y_r Y_r^t)^{-1} \end{bmatrix} \quad (39)$$

Define

$$M = \begin{bmatrix} U \\ Y \end{bmatrix} (U^t U - Y^t Y)^{-1}, \quad M_r = \begin{bmatrix} U \\ Y_r \end{bmatrix} (U^t U - Y_r^t Y_r)^{-1}. \quad (40)$$

Then, it is clear

$$M = N^{-1} \begin{bmatrix} I_{n+1} \\ 0 \end{bmatrix}, \quad M_r = N_r^{-1} \begin{bmatrix} I_{n+1} \\ 0 \end{bmatrix}. \quad (41)$$

On the other hand, we have

$$\begin{aligned} N_r^{-1} &= \left[\begin{bmatrix} U^t & -Y^t \\ -Y & U \end{bmatrix} + \begin{bmatrix} 0 & (Y - Y_r)^t \\ Y - Y_r & 0 \end{bmatrix} \right]^{-1} \\ &= \left[I_{2(n+1)} + N^{-1} \begin{bmatrix} 0 & E^t \\ E & 0 \end{bmatrix} \right]^{-1} N^{-1} \\ &= N^{-1} - N^{-1} \begin{bmatrix} 0 & E^t \\ E & 0 \end{bmatrix} [I_{2(n+1)}] \\ &\quad + N^{-1} \begin{bmatrix} 0 & E^t \\ E & 0 \end{bmatrix}^{-1} N^{-1} \end{aligned} \quad (42)$$

in which

$$E = Y - Y_r = \begin{bmatrix} v_0 & 0 & \cdots & 0 \\ v_1 & v_0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ v_n & v_{n-1} & \cdots & v_0 \end{bmatrix}. \quad (43)$$

Therefore

$$\begin{aligned} M_r &= N_r^{-1} \begin{bmatrix} I_{n+1} \\ 0 \end{bmatrix} \\ &= \left\{ N^{-1} - N^{-1} \begin{bmatrix} 0 & E^t \\ E & 0 \end{bmatrix} \right. \\ &\quad \cdot \left. \left[I_{2(n+1)} + N^{-1} \begin{bmatrix} 0 & E^t \\ E & 0 \end{bmatrix} \right]^{-1} N^{-1} \right\} \begin{bmatrix} I_{n+1} \\ 0 \end{bmatrix} \\ &= M - N^{-1} \begin{bmatrix} 0 & E^t \\ E & 0 \end{bmatrix} [I_{2(n+1)}] \\ &\quad + N^{-1} \begin{bmatrix} 0 & E^t \\ E & 0 \end{bmatrix}^{-1} M. \end{aligned} \quad (44)$$

Let $\delta_i = \frac{1}{\kappa} v_i$, $0 \leq i \leq n$. Since $v_i \in \mathcal{R}$, $|v_i| \leq \kappa$, we have $\delta_i \in \mathcal{R}$, $|\delta_i| \leq 1$, $0 \leq i \leq n$.

From the structure of matrix E , we have

$$\begin{aligned} E^t &= \begin{bmatrix} v_0 & v_1 & \cdots & v_n \\ 0 & v_0 & \cdots & v_{n-1} \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & v_0 \end{bmatrix} = \sum_{i=0}^n v_i T_2^i \\ &= [I_{n+1} \quad T_2 \quad T_2^2 \quad \cdots \quad T_2^n] \\ &\quad \cdot \begin{bmatrix} \frac{v_0}{\kappa} I_{n+1} & & & \\ & \frac{v_1}{\kappa} I_{n+1} & & \\ & & \ddots & \\ & & & \frac{v_n}{\kappa} I_{n+1} \end{bmatrix} \begin{bmatrix} \kappa I_{n+1} \\ \kappa I_{n+1} \\ \vdots \\ \kappa I_{n+1} \end{bmatrix} \\ &= E_l \tilde{\Lambda} E_r. \end{aligned} \quad (45)$$

Here, T_2^0 is defined as I_{n+1} , and $\tilde{\Lambda} = \text{diag}\{\delta_0 I_{n+1} \quad \delta_1 I_{n+1} \quad \cdots \quad \delta_n I_{n+1}\}$.

Therefore

$$\begin{aligned} \begin{bmatrix} 0 & E^t \\ E & 0 \end{bmatrix} &= \begin{bmatrix} 0 & E_l \tilde{\Lambda} E_r \\ E_r^t \tilde{\Lambda} E_l^t & 0 \end{bmatrix} \\ &= \begin{bmatrix} 0 & E_l \\ E_r^t & 0 \end{bmatrix} \begin{bmatrix} \tilde{\Lambda} & 0 \\ 0 & \tilde{\Lambda} \end{bmatrix} \begin{bmatrix} E_l^t & 0 \\ 0 & E_r \end{bmatrix}. \end{aligned} \quad (46)$$

Note that

$$\begin{aligned} \begin{bmatrix} \tilde{\Lambda} & 0 \\ 0 & \tilde{\Lambda} \end{bmatrix} &= \text{diag}\{\delta_0 I_{n+1} \quad \delta_1 I_{n+1} \quad \cdots \\ &\quad \delta_n I_{n+1} \quad \delta_0 I_{n+1} \quad \delta_1 I_{n+1} \quad \cdots \quad \delta_n I_{n+1}\} \\ &= \delta_0 \text{diag}\{I_{n+1} \quad 0 \quad \cdots \quad 0 \quad I_{n+1} \quad 0 \quad \cdots \quad 0\} \\ &\quad + \delta_1 \text{diag}\{0 \quad I_{n+1} \quad 0 \quad \cdots \quad 0 \quad I_{n+1} \quad 0 \quad \cdots \quad 0\} \\ &\quad + \cdots + \delta_n \text{diag}\{0 \quad \cdots \quad 0 \quad I_{n+1} \quad 0 \quad \cdots \quad I_{n+1}\} \\ &= [I_{2(n+1)}] \cdot \text{diag}\{\delta_0 I_{2(n+1)} \quad \delta_1 I_{2(n+1)} \quad \cdots \\ &\quad \delta_n I_{2(n+1)}\} [\tilde{S}_0 \quad \tilde{S}_1 \quad \cdots \quad \tilde{S}_n]^t \\ &= \tilde{T}_l \tilde{\Lambda} \tilde{T}_r, \end{aligned} \quad (47)$$

we have

$$\begin{aligned} \begin{bmatrix} 0 & E^t \\ E & 0 \end{bmatrix} &= \begin{bmatrix} 0 & E_l \\ E_r^t & 0 \end{bmatrix} \tilde{T}_l \tilde{\Lambda} \tilde{T}_r \begin{bmatrix} E_l^t & 0 \\ 0 & E_r \end{bmatrix} \\ &= W_l \tilde{\Lambda} W_r, \end{aligned} \quad (48)$$

Therefore

$$\begin{aligned} M_r &= M - N^{-1} W_l \tilde{\Lambda} W_r [I_{2(n+1)} + N^{-1} W_l \tilde{\Lambda} W_r]^{-1} M \\ &= M - N^{-1} W_l \tilde{\Lambda} [I_{2(n+1)} + W_r N^{-1} W_l \tilde{\Lambda}]^{-1} W_r M \end{aligned} \quad (49)$$

Since

$$\begin{bmatrix} p \\ \hat{q} \end{bmatrix} = \begin{bmatrix} U(U^t U - Y^t Y)^{-1} \\ Y(U^t U - Y^t Y)^{-1} \end{bmatrix} = M \epsilon, \quad (50)$$

$$\begin{bmatrix} \hat{p} \\ \hat{q} \end{bmatrix} = \begin{bmatrix} U(U^t U - Y_r^t Y_r)^{-1} \\ Y_r(U^t U - Y_r^t Y_r)^{-1} \end{bmatrix} = M_r \epsilon \quad (51)$$

we conclude

$$\begin{aligned} \begin{bmatrix} \hat{p} \\ \hat{q} \end{bmatrix} &= \begin{bmatrix} p \\ \hat{q} \end{bmatrix} - \begin{bmatrix} U^t & -Y^t \\ -Y & U \end{bmatrix}^{-1} W_l \tilde{\Lambda} \\ &\quad \cdot \left[I_{2(n+1)} + W_r \begin{bmatrix} U^t & -Y^t \\ -Y & U \end{bmatrix}^{-1} W_l \tilde{\Lambda} \right]^{-1} W_r \begin{bmatrix} \hat{p} \\ \hat{q} \end{bmatrix}. \end{aligned} \quad (52)$$

This completes the proof. ■

Theorem 2 suggests that when there exists magnitude bounded noise in the measured plant output, then, if the noise is not too significant, the parameters that describe the possible plant transfer function can be represented by a linear fractional transformation of two matrices. One of them is completely determined by the measured plant input-output pairs and the noise magnitude and is therefore fixed, another one is free, except that its structure is fixed and its maximum singular value is bounded by one.

Let

$$\Phi(z) = \begin{bmatrix} \sum_{j=1}^{n+1} \hat{p}_j^* z^{n+2-j} & \sum_{j=1}^{n+1} \hat{q}_j^* z^{j-1} \\ \sum_{j=1}^{n+1} \hat{q}_j^* z^{n+2-j} & \sum_{j=1}^{n+1} \hat{p}_j^* z^{j-1} \end{bmatrix}$$

then, according to Theorem 1 and the discussion followed it, a transfer function, say, $q(z)$, which has \mathcal{H}^∞ -norm not greater than 1 and matches the input-output data $(u_i, y_i)_{i=0}^n$, has the form

$$q(z) = \mathcal{HM}(\Phi(z), c(z)), \quad c(z) \in \mathcal{BH}^\infty$$

provided that $Y_t^t Y_t \leq U^t U$

Let

$$Z_1 = [z^{n+1} \ z^n \ \dots \ z]^t, \quad Z_2 = [1 \ z \ \dots \ z^n]^t$$

we have

$$\Phi(z) = \begin{bmatrix} \hat{p}^{rt} Z_1 & \hat{q}^{rt} Z_2 \\ \hat{q}^{rt} Z_1 & \hat{p}^{rt} Z_2 \end{bmatrix} = \begin{bmatrix} \hat{p}^{rt} & q^{rt} \\ q^{rt} & \hat{p}^{rt} \end{bmatrix} \begin{bmatrix} Z_1 \\ Z_2 \end{bmatrix} \quad (53)$$

On the other hand

$$\begin{aligned} [p^{rt} \ q^{rt}] &= \begin{bmatrix} p^t \\ q^t \end{bmatrix}^t \\ &= \left\{ \begin{bmatrix} p \\ q \end{bmatrix} - \begin{bmatrix} U^t & -Y^t \\ -Y & U \end{bmatrix}^{-1} W_t \bar{\Lambda} \right. \\ &\quad \left. \begin{bmatrix} I_{2(n+1)} \\ I_{2(n+1)} \end{bmatrix} \right. \\ &\quad \left. + W_t \begin{bmatrix} U^t & -Y^t \\ -Y & U \end{bmatrix}^{-1} W_t \bar{\Lambda} \right\}^t \\ &= [p^t \ q^t] - [p^t \ q^t] W_t^t \begin{bmatrix} I_{2(n+1)} \\ I_{2(n+1)} \end{bmatrix} + \bar{\Lambda} W_t^t \\ &\quad \begin{bmatrix} U^t & -Y^t \\ -Y & U \end{bmatrix}^{-1} W_t^t \\ &\quad \bar{\Lambda} W_t^t \begin{bmatrix} U & -Y \\ -Y & U \end{bmatrix}^{-1} \\ &= [p^t \ q^t] - [p^t \ q^t] W_t^t \bar{\Lambda} [I_{2(n+1)} + W_t^t \\ &\quad \begin{bmatrix} U & -Y \\ -Y & U \end{bmatrix}^{-1} W_t^t \bar{\Lambda}]^{-1} \\ &\quad W_t^t \begin{bmatrix} U & Y \\ -Y & U \end{bmatrix}^{-1} \end{aligned} \quad (54)$$

Let

$$I_3 = \begin{bmatrix} 0 & I_{n+1} \\ I_{n+1} & 0 \end{bmatrix}$$

then

$$[q^{rt} \ \hat{p}^{rt}] = [\hat{p}^{rt} \ q^{rt}] T_1 \quad (55)$$

Therefore

$$\begin{aligned} \begin{bmatrix} p^{rt} & q^{rt} \\ q^{rt} & \hat{p}^{rt} \end{bmatrix} &= \begin{bmatrix} N_{11} & 0 \\ 0 & N_{11} \end{bmatrix} \begin{bmatrix} I_{2(n+1)} \\ I_3 \end{bmatrix} \\ &\quad + \begin{bmatrix} N_{12} & 0 \\ 0 & N_{12} \end{bmatrix} \begin{bmatrix} \bar{\Lambda} & 0 \\ 0 & \bar{\Lambda} \end{bmatrix} \begin{bmatrix} I_{4(n+1)} \\ I_3 \end{bmatrix} \\ &\quad - \begin{bmatrix} N_{22} & 0 \\ 0 & N_{22} \end{bmatrix} \begin{bmatrix} \bar{\Lambda} & 0 \\ 0 & \bar{\Lambda} \end{bmatrix}^{-1} \\ &\quad \begin{bmatrix} N_{21} & 0 \\ 0 & N_{21} \end{bmatrix} \begin{bmatrix} I_{2(n+1)} \\ I_3 \end{bmatrix} \end{aligned} \quad (56)$$

Here, $N_{11} = [\hat{p}^t \hat{q}^t]$, $N_{12} = -[\hat{p}^t \hat{q}^t] W_t^t$, $N_{21} = W_t^t$, $\begin{bmatrix} -U & Y^t \\ Y & -U^t \end{bmatrix}^{-1}$, and $N_{22} = W_t^t \begin{bmatrix} U & -Y^t \\ -Y & U^t \end{bmatrix}^{-1} W_t^t$

On the other hand, a simple computation shows that

$$\begin{aligned} \begin{bmatrix} \bar{\Lambda} & 0 \\ 0 & \bar{\Lambda} \end{bmatrix} &= diag\{\delta_0 I_{2(n+1)}, \delta_1 I_{2(n+1)}, \\ &\delta_n I_{2(n+1)}, \delta_0 I_{2(n+1)}, \delta_1 I_{2(n+1)}, \delta_n I_{2(n+1)}\} \\ &= T_1 \Lambda T_1 \end{aligned}$$

in which

$$\Lambda = diag\{\delta_0 I_{4(n+1)}, \delta_1 I_{4(n+1)}, \delta_n I_{4(n+1)}\}, \quad (57)$$

$$T_1 = [I_{4(n+1)}, I_{4(n+1)}, I_{4(n+1)}], \quad (58)$$

$$I_1 = [S_0 \ S_1 \ \dots \ S_n]^t \quad (59)$$

$$S_0 = diag\{I_{2(n+1)} \ 0 \ 0 \ I_{2(n+1)} \ 0 \ 0\}, \quad (60)$$

$$S_1 = diag\{0 \ I_{2(n+1)} \ 0 \ 0 \ I_{2(n+1)} \ 0 \ 0\} \quad (61)$$

$$S_n = diag\{0 \ 0 \ I_{2(n+1)} \ 0 \ 0 \ I_{2(n+1)}\} \quad (62)$$

Let

$$R_{11} = \begin{bmatrix} N_{11} & 0 \\ 0 & N_{11} \end{bmatrix} \begin{bmatrix} I_{2(n+1)} \\ I_1 \end{bmatrix}, \quad R_{12} = \begin{bmatrix} N_{12} & 0 \\ 0 & N_{12} \end{bmatrix},$$

$$R_{21} = \begin{bmatrix} N_{21} & 0 \\ 0 & N_{21} \end{bmatrix} \begin{bmatrix} I_{2(n+1)} \\ I_1 \end{bmatrix}, \quad R_{22} = \begin{bmatrix} N_{22} & 0 \\ 0 & N_{22} \end{bmatrix}$$

Then

$$\begin{aligned} \begin{bmatrix} p^{rt} & q^{rt} \\ q^{rt} & \hat{p}^{rt} \end{bmatrix} &= R_{11} + R_{12} T_1 \Lambda T_1 [I_{4(n+1)} - R_{22} T_1 \Lambda]^{-1} R_{21} \\ &= R_{11} + R_{12} I_1 \Lambda [I_{4(n+1)} - T_1 R_{22} T_1 \Lambda]^{-1} I_1 R_{21} \end{aligned} \quad (63)$$

Therefore

$$\begin{aligned} \Phi(z) &= \begin{bmatrix} p^{rt} & q^{rt} \\ q^{rt} & \hat{p}^{rt} \end{bmatrix} \begin{bmatrix} Z_1 & 0 \\ 0 & Z_2 \end{bmatrix} \\ &= \{R_{11} + R_{12} T_1 \Lambda [I_{4(n+1)} - T_1 R_{22} T_1 \Lambda]^{-1} T_1 R_{21}\} \\ &\quad \begin{bmatrix} Z_1 & 0 \\ 0 & Z_2 \end{bmatrix} \\ &= W_{11}(z) + W_{12} \Lambda [I_{4(n+1)} - W_{22} \Lambda]^{-1} W_{21}(z) \end{aligned} \quad (64)$$

Here

$$W_{11}(z) = R_{11} \begin{bmatrix} Z_1 & 0 \\ 0 & Z_2 \end{bmatrix}, \quad W_{12} = R_{12} T_1,$$

$$W_{21}(z) = T_1 R_{21} \begin{bmatrix} Z_1 & 0 \\ 0 & Z_2 \end{bmatrix}, \quad W_{22} = T_1 R_{22} T_1$$

From the construction, it is obvious that $W_{11}(z)$ is a transfer function matrix belonging to \mathcal{H}^∞ with dimension 2×2 , W_{12}

is a matrix belonging to $\mathcal{R}^{2 \times 4(n+1)^4}$, $W_{21}(z)$ is a transfer function matrix belonging to \mathcal{H}^∞ with dimension $4(n+1)^4 \times 2$, while matrix W_{22} belongs to $\mathcal{R}^{4(n+1)^4 \times 4(n+1)^4}$.

From the above discussion, the following theorem is obtained.

Theorem 3: Let

$$W(z) = \begin{bmatrix} W_{11}(z) & W_{12} \\ W_{21}(z) & W_{22} \end{bmatrix}$$

then, $\Phi(z) = \mathcal{F}_l(W(z), \Lambda)$.

The above theorem makes it clear that when there exists magnitude bounded noise in the measured plant output, and the noise is not too significant, the homographic transformation that describes all of the plant possible transfer functions, can be parameterized as a linear fractional transformation of a fixed transfer function matrix and a structure fixed, norm bounded, but free matrix.

The next theorem is the main results of this paper.

Theorem 4: Partition $W_{11}(z)$, W_{12} , $W_{21}(z)$ as

$$W_{11}(z) = \begin{bmatrix} W_{11}^{11}(z) & W_{11}^{12}(z) \\ W_{11}^{21}(z) & W_{11}^{22}(z) \end{bmatrix}, \quad W_{12} = \begin{bmatrix} W_{12}^{11} \\ W_{12}^{21} \end{bmatrix},$$

$$W_{21}(z) = [W_{21}^{11}(z) \quad W_{21}^{12}(z)]$$

in which $W_{11}^{11}(z)$ has a dimension 1×1 , W_{12}^{11} has a dimension $1 \times 4(n+1)^4$, $W_{21}^{11}(z)$ has a dimension $4(n+1)^4 \times 1$, and the others have compatible dimensions. Moreover, see the matrices at the bottom of the page. If $\max_{|z| \leq \kappa} \bar{\sigma}((Y + E)U^{-1}) < 1$, then, transfer function set

$$\mathcal{G} = \left\{ g(z) \mid g(z) = \mathcal{F}_l(F(z), \Delta(z)), \max_{|z| \leq 1} \bar{\sigma}(\Delta(z)) \leq 1 \right\}$$

exhausts all of the transfer functions that have \mathcal{H}^∞ -norm not greater than 1 and match the possible plant input-output pairs that are derived from the measured plant input-output data $(u_i, y_i) \mid_{i=0}^n$ which are contaminated by a magnitude bounded noise series v_i , $v_i \in \mathcal{R}$, $|v_i| \leq \kappa$, $0 \leq i \leq n$ in y_i in additive form, and vice versa. Here, the matrices U , Y are the same as those defined in Theorem 2, and the matrices E , Λ are defined by (43) and (57), respectively.

Proof: From Theorem 2 and Theorem 3, it is obvious that transfer function set

$$\bar{\mathcal{G}} = \{g(z) \mid g(z) = \mathcal{H}\mathcal{M}(\mathcal{F}_l(W(z), \Lambda), \epsilon(z)),$$

$$b_i \in \mathcal{R}, \bar{\sigma}(\Lambda) \leq 1, \epsilon(z) \in \mathcal{B}\mathcal{H}^\infty\} \quad (65)$$

Fig. 1. Identification experiment.

equals the transfer function set which includes all of the transfer functions that do not contradict the plant available information.

Note that every transfer function in $\bar{\mathcal{G}}$ has a structure like that depicted in Fig. 2.

The internal relations of Fig. 2 are

$$\begin{bmatrix} y(z) \\ u(z) \\ w_2(z) \end{bmatrix} = \begin{bmatrix} q_{11}(z) & q_{12}(z) & q_{13}(z) \\ q_{21}(z) & q_{22}(z) & q_{23}(z) \\ q_{31}(z) & q_{32}(z) & q_{33}(z) \end{bmatrix} \begin{bmatrix} v_1(z) \\ w_1(z) \\ v_2(z) \end{bmatrix}, \quad (66)$$

$$v_1(z) = \epsilon(z)w_1(z), \quad (67)$$

$$v_2(z) = \Lambda w_2(z). \quad (68)$$

Note that

$$q_{22}(z) = W_{11}^{22}(z) = \bar{p}' Z_2 \quad (69)$$

which is invertible on the closed unit disk $D = \{z \mid |z| \leq 1\}$.

On the other hand, the relation in (66) can be rewritten as

$$\begin{bmatrix} 1 & -q_{12}(z) & 0 \\ 0 & -q_{22}(z) & 0 \\ 0 & -q_{32}(z) & I \end{bmatrix} \begin{bmatrix} y(z) \\ w_1(z) \\ w_2(z) \end{bmatrix} = \begin{bmatrix} 0 & q_{11}(z) & q_{13}(z) \\ -1 & q_{21}(z) & q_{23}(z) \\ 0 & q_{31}(z) & q_{33}(z) \end{bmatrix} \begin{bmatrix} u(z) \\ v_1(z) \\ v_2(z) \end{bmatrix}. \quad (70)$$

Since

$$\begin{bmatrix} 1 & -q_{12}(z) & 0 \\ 0 & -q_{22}(z) & 0 \\ 0 & -q_{32}(z) & I \end{bmatrix}$$

is invertible if and only if $q_{22}(z)$ is invertible. (70) equals (71) (found at the bottom of the next page) which implies that

$$\mathcal{G} = \bar{\mathcal{G}}. \quad (72)$$

$$Q(z) = \begin{bmatrix} q_{11}(z) & q_{12}(z) & q_{13}(z) \\ q_{21}(z) & q_{22}(z) & q_{23}(z) \\ q_{31}(z) & q_{32}(z) & q_{33}(z) \end{bmatrix} = \begin{bmatrix} W_{11}^{11}(z) & W_{11}^{12}(z) & W_{11}^{13} \\ W_{11}^{21}(z) & W_{11}^{22}(z) & W_{11}^{23} \\ W_{21}^{11}(z) & W_{21}^{12}(z) & W_{22} \end{bmatrix},$$

$$F(z) = \begin{bmatrix} q_{12}(z)q_{22}^{-1}(z) & q_{11}(z) - q_{12}(z)q_{22}^{-1}(z)q_{21}(z) & q_{13}(z) - q_{12}(z)q_{22}^{-1}(z)q_{23}(z) \\ q_{22}^{-1}(z) & -q_{22}^{-1}(z)q_{21}(z) & -q_{22}^{-1}(z)q_{23}(z) \\ q_{32}(z)q_{22}^{-1}(z) & q_{31}(z) - q_{32}(z)q_{22}^{-1}(z)q_{21}(z) & q_{33}(z) - q_{32}(z)q_{22}^{-1}(z)q_{23}(z) \end{bmatrix},$$

$$\Delta(z) = \begin{bmatrix} \epsilon(z) & 0 \\ 0 & \Lambda \end{bmatrix}.$$

Fig. 2 Structure of transfer function belonging to $\bar{\mathcal{G}}$ 

Fig. 3 Structure of plant possible transfer function

This completes the proof. ■

From Theorem 4 we see that the transfer function set which includes all of the plant possible transfer functions can be parameterized by a linear fractional transformation of a fixed transfer function matrix and a structure fixed norm bounded, free transfer function matrix.

The structure of the possible plant transfer function is illustrated in Fig. 3.

The results of Theorem 4 can be extended to the case when $\max_{|z| \leq \kappa} \bar{\sigma}[(I + E)U^{-1}] \leq 1$. In this situation all the plant possible transfer functions can also be parameterized as \mathcal{G} in Theorem 4. The idea behind the proof of this conclusion is to firstly parameterize all the possible transfer functions for the plant whose transfer function's \mathcal{H}^∞ norm is not greater than $1 + \alpha$ for arbitrary $\alpha > 0$ and whose input-output pairs can be deduced from the measured input-output data $(u_i, y_i) |_{i=0}^n$, represent it as $\mathcal{G}(1 + \alpha)$ and then, take the limit of the transfer function set $\mathcal{G}(1 + \alpha)$ as α tends to 0 from the positive side. Based on the relations that $\mathcal{G}(1 + \alpha) \supset \mathcal{G}$ for any $\alpha > 0$, and $\lim_{\alpha \rightarrow 0^+} \mathcal{G}(1 + \alpha) = \mathcal{G}$ we obtain the transfer function set with the desirable properties. The proof is elementary but tedious, and is therefore omitted here. The details of the proof can be found in [41].

When the noise magnitude bound κ does not satisfy the condition mentioned above, i.e., $\max_{|z| \leq \kappa} \bar{\sigma}[(I + E)U^{-1}] \leq 1$, let

$$\nabla = \begin{bmatrix} \delta_0 & 0 & 0 \\ \delta_1 & \delta_0 & 0 \\ \vdots & \vdots & \vdots \\ \delta_n & \delta_{n-1} & \delta_0 \end{bmatrix}$$

For those $\delta_0, \delta_1, \dots, \delta_n$, such that $(\frac{1}{\kappa}Y + \nabla)^t (\frac{1}{\kappa}Y + \nabla) > \frac{1}{\kappa}U^t U$, or $(Y + \kappa \nabla)^t (Y + \kappa \nabla) > U^t U$, and $\delta_i \in \mathcal{R}$, $|\delta_i| \leq 1$, the plant under investigation cannot have a response $(y_i + \kappa \delta_i) |_{i=0}^n$ when the input series $u_i |_{i=0}^n$ is applied to it, since according to the input-output extrapolation-minimization theorem [28], [36]–[37], every transfer function that can match these input-output pairs, i.e., $(u_i, y_i + \kappa \delta_i) |_{i=0}^n$, will have a \mathcal{H}^∞ -norm greater than 1. Videlicet, these noise series $(-\kappa \delta_i) |_{i=0}^n$ are impossible according to the plant assumptions. Therefore, they should be excluded from the noise set $\mathcal{V} = \{v_i |_{i=0}^n | v_i \in \mathcal{R}, |v_i| \leq \kappa\}$. From the above discussion, it is apparent that in this case the transfer function set that contains all of the plant possible transfer functions equals transfer function set

$$\mathcal{G} = \{g(\cdot) | g(\cdot) = \mathcal{F}_l(F(\cdot), \Delta(\cdot))\}$$

$$\max_{|\delta_i| \leq 1} \bar{\sigma}(\Delta(\cdot)) \leq 1 \quad (\delta_0, \delta_1, \dots, \delta_n) \in D_\delta$$

Here $D_\delta = \{(\delta_0, \delta_1, \dots, \delta_n) | (\frac{1}{\kappa}Y + \nabla)^t (\frac{1}{\kappa}Y + \nabla) \leq \frac{1}{\kappa}U^t U, \delta_i \in \mathcal{R}, |\delta_i| \leq 1\}$, and the other matrices or transfer function matrices have the same definitions as those in Theorem 4.

IV APPLICATION TO IDENTIFICATION FOR ROBUST CONTROL

In Section III we showed that when the magnitude bounded additive noise existent in the measure plant output is not too significant the transfer function set that consists of all plant possible transfer functions can be parameterized as a linear fractional transformation of a fixed transfer function matrix and a structure fixed norm bounded, free transfer function matrix. The importance of linear fractional transformation has been widely recognized in control community in recent years, as well as homographic transformation [5], [11], [20], [27]. Note that all of the transfer function set descriptions widely used in robust control theory, such as nominal model

$$\begin{aligned} \begin{bmatrix} y(z) \\ w_1(z) \\ w_2(z) \end{bmatrix} &= \begin{bmatrix} 1 & -q_{12}(z) & 0 \\ 0 & -q_{22}(z) & 0 \\ 0 & -q_{32}(z) & 1 \end{bmatrix}^{-1} \begin{bmatrix} 0 & q_{11}(z) & q_{13}(z) \\ -1 & q_{21}(z) & q_{23}(z) \\ 0 & q_{31}(z) & q_{33}(z) \end{bmatrix} \begin{bmatrix} u(z) \\ v_1(z) \\ v_2(z) \end{bmatrix} \\ &= \begin{bmatrix} q_{12}(z)q_{22}^{-1}(z) & q_{11}(z) - q_{12}(z)q_{22}^{-1}(z)q_{21}(z) & q_{13}(z) - q_{12}(z)q_{22}^{-1}(z)q_{23}(z) \\ q_{22}^{-1}(z) & -q_{22}^{-1}(z)q_{21}(z) & -q_{22}^{-1}(z)q_{23}(z) \\ q_{32}(z)q_{22}^{-1}(z) & q_{31}(z) - q_{32}(z)q_{22}^{-1}(z)q_{21}(z) & q_{33}(z) - q_{32}(z)q_{22}^{-1}(z)q_{23}(z) \end{bmatrix} \begin{bmatrix} u(z) \\ v_1(z) \\ v_2(z) \end{bmatrix} \\ &= F(z) \begin{bmatrix} u(z) \\ v_1(z) \\ v_2(z) \end{bmatrix} \end{aligned} \quad (71)$$

with parametric uncertainty bound, nominal model with additive unstructured uncertainty bound, nominal model with multiplicative unstructured uncertainty bound, nominal model with coprime factor unstructured uncertainty bound, etc., can be easily transformed into a linear fractional transformation representation, which conversely implies that linear fractional transformation with structure fixed, norm bounded, uncertain transfer function matrix is in fact one of the most general descriptions of plant model with intended application as robust controller design. Moreover, a transfer function set, which is parameterized by linear fractional transformation of a fixed transfer function matrix and a norm bounded, structure fixed, uncertain transfer function matrix, can be directly used in robust controller design, because such a parameterization just fits the framework of structured singular value theory or μ , although this robust controller design theory is still not complete and more powerful design algorithms are needed to be developed [4], [8], [27].

In controller design, however, the direct utilization of the transfer function set given in Section III suffers from several drawbacks. For instance, the plant nominal model generally has a high degree and the number of the uncertain parameters is large. In fact, they generally equal to the identification experiment data length and the identification experiment data length + 1, respectively. Here, by nominal model, we mean the transfer function corresponding to $\Delta(z) = 0$. Moreover, the dimension of the matrices used in the parameterization is extremely large, e.g., the dimension of the uncertain transfer function matrix is $4(n+1)^4 + 1$, in which n stands for the identification experiment data length. But in controller design, it is preferable to use low complexity nominal model and a simple description of the nominal model error uncertainty bound, because such a plant model will represent the dominant characteristics of the plant dynamics which is more convenient in control system analysis and synthesis, and will lead to a low complexity controller which is highly appreciated in realization. Furthermore, we note that in the plant possible transfer function parameterization, there are both dynamic uncertainty and real perturbation. The dynamic uncertainty is due to the plant unmeasured output, while the real perturbation is due to the effect of noise. If this parameterization is directly applied to robust controller design, it will lead to a mixed μ -synthesis problem, which is well known as NP hard [8], [27].

In this section, we would like to briefly discuss the problem of obtaining the desirable fixed complexity plant nominal model and its error uncertainty bound from the aforementioned plant available information.

First, we introduce some notations that will be used in this section.

For a given matrix structure \mathcal{X} , let \mathcal{BX} represent the unit ball defined as $\mathcal{BX} = \{\Delta \mid \Delta \in \mathcal{X}, \bar{\sigma}(\Delta) \leq 1\}$. When $\mathcal{X}(z)$ is a transfer function matrix structure, we define $\mathcal{BX}(z)$ as $\mathcal{BX}(z) = \{\Delta(z) \mid \Delta(z) \in \mathcal{X}(z), \max_{|z| \leq 1} \bar{\sigma}(\Delta(z)) \leq 1\}$. Moreover, for a given matrix structure \mathcal{X} and a transfer function matrix $H(z)$ which belongs to \mathcal{H}^∞ and has suitable dimension, with a little abuse of notation, we define $\mu_{\mathcal{X}}(H)$ as the maximal structured singular value of $H(z)$ according

to \mathcal{X} over the closed unit disk $\mathcal{D} = \{z \mid |z| \leq 1\}$, i.e., $\mu_{\mathcal{X}}(H) := \max_{|z| \leq 1} \mu_{\mathcal{X}}(H(z))$.

Note that for a transfer function matrix $H(z') = D + C(z'I - A)^{-1}B$ which is analytic on the complement of the open unit disk, i.e., $\mathcal{D}_{open}^c = \{z' \mid |z'| \geq 1\}$ ² let $z = 1/z'$, then, $H(z')$ can be rewritten as $H(z) = \mathcal{F}_l\left(\begin{bmatrix} D & C \\ B & A \end{bmatrix}, zI\right)$. It is obvious that $H(z) \in \mathcal{H}^\infty$ and from the main loop theorem that plays an important role in μ -analysis and μ -synthesis [27], it can be proved that $\mu_{\mathcal{X}}(H) \leq \beta$ for a positive real number β if and only if $\mu_{\overline{\mathcal{X}}}(M) \leq 1$. Here, $M = \begin{bmatrix} D/\beta & C/\sqrt{\beta} \\ B/\sqrt{\beta} & A \end{bmatrix}$, and $\overline{\mathcal{X}}$ is a matrix structure defined as $\overline{\mathcal{X}} = \{\overline{\Delta} \mid \overline{\Delta} = \text{diag}\{\Delta, \epsilon I\}, \Delta \in \mathcal{X}, \epsilon \in \mathcal{C}\}$. Especially, when $\mu_{\mathcal{X}}(H) = 1$, it can be shown that $\mu_{\overline{\mathcal{X}}}(M) = 1$, also. To express the results in this section more concisely, we adopt the notation $\mu_{\mathcal{X}}(H)$ for a transfer function matrix $H(z) \in \mathcal{H}^\infty$ and a compatible matrix structure \mathcal{X} .

Using a similar argument as that in the proof of the main loop theorem, we can obtain the following lemma.

Lemma 1: For a $(m+p) \times (m+p)$ transfer function matrix $H(z) = \begin{bmatrix} H_{11}(z) & H_{12}(z) \\ H_{21}(z) & H_{22}(z) \end{bmatrix} \in \mathcal{H}^\infty$, a matrix structure \mathcal{X}_1 with dimension $m \times m$, and a matrix structure \mathcal{X}_2 with dimension $p \times p$, define a new matrix structure \mathcal{X}' as $\mathcal{X}' = \left\{ \Delta = \begin{bmatrix} \Delta_1 & \Delta_2 \end{bmatrix} \mid \Delta_1 \in \mathcal{X}_1, \Delta_2 \in \mathcal{X}_2 \right\}$. If $\mu_{\mathcal{X}_2}(H_{22}) < 1$, then, $\mu_{\mathcal{X}'}(H) \leq 1$, if and only if $\max_{\Delta_2 \in \mathcal{BX}_2} \mu_{\mathcal{X}_1}(\mathcal{F}_l(H, \Delta_2)) \leq 1$.

Proof: Since $\mu_{\mathcal{X}_2}(H_{22}) < 1$, we have eliminate at every $z \in \mathcal{D} = \{z \mid |z| \leq 1\}$

$$\det(I_p - H_{22}(z)\Delta_2) \neq 0 \quad (73)$$

if $\Delta_2 \in \mathcal{BX}_2$. Therefore, for every $z \in \mathcal{D}$, $\Delta_1 \in \mathcal{X}_1$, $\Delta_2 \in \mathcal{BX}_2$, a simple computation will show

$$\begin{aligned} \det\left(I_{m+p} - \begin{bmatrix} H_{11}(z) & H_{12}(z) \\ H_{21}(z) & H_{22}(z) \end{bmatrix} \begin{bmatrix} \Delta_1 \\ \Delta_2 \end{bmatrix}\right) \\ = \det(I_p - H_{22}(z)\Delta_2) \cdot \det(I_m - \mathcal{F}_l(H(z), \Delta_2)\Delta_1). \end{aligned} \quad (74)$$

Hence, $\mu_{\mathcal{X}'}(H) < 1$ if and only if $\max_{\Delta_2 \in \mathcal{BX}_2} \mu_{\mathcal{X}_1}(\mathcal{F}_l(H, \Delta_2)) < 1$.

If $\max_{\Delta_2 \in \mathcal{BX}_2} \mu_{\mathcal{X}_1}(\mathcal{F}_l(H, \Delta_2)) = 1$, then, there exist at least one $z_0 \in \mathcal{D}$, one $\Delta_2 \in \mathcal{BX}_2$, and one $\Delta_1 \in \mathcal{X}_1$, such that $\bar{\sigma}(\Delta_1) = 1$, and

$$\det(I_m - \mathcal{F}_l(H(z_0), \Delta_2)\Delta_1) = 0 \quad (75)$$

which implies that

$$\det\left(I_{m+p} - \begin{bmatrix} H_{11}(z_0) & H_{12}(z_0) \\ H_{21}(z_0) & H_{22}(z_0) \end{bmatrix} \begin{bmatrix} \Delta_1 \\ \Delta_2 \end{bmatrix}\right) = 0. \quad (76)$$

Since

$$\bar{\sigma}\left[\begin{bmatrix} \Delta_1 \\ \Delta_2 \end{bmatrix}\right] = \max\{\bar{\sigma}(\Delta_1), \bar{\sigma}(\Delta_2)\} = 1 \quad (77)$$

²The analyticity of a transfer function matrix on \mathcal{D}_{open}^c equals the commonly utilized concept of stability of a transfer function matrix in control engineering.

we have

$$\mu_1(H) \leq 1 \quad (78)$$

If $\mu_1(H) = 1$, then, for arbitrary $\alpha > 0$, $\mu_1(H) < 1 + \alpha$. According to the definition of structured singular value, we have that for any $z \in \mathcal{D}$, $\Delta_1 \in \mathcal{X}_1$, $\bar{\sigma}(\Delta_1) \leq \frac{1}{1+\alpha}$, $\Delta_2 \in \mathcal{X}_2$, $\bar{\sigma}(\Delta_2) \leq \frac{1}{1+\alpha}$

$$\det \left(I_{m+p} - \begin{bmatrix} H_{11}(z) & H_{12}(z) \\ H_{21}(z) & H_{22}(z) \end{bmatrix} \begin{bmatrix} \Delta_1 & \\ & \Delta_2 \end{bmatrix} \right) \neq 0 \quad (79)$$

which implies that

$$\max_{\Delta_1 \in \mathcal{X}_1, \Delta_2 \in \mathcal{X}_2} \mu_1(\mathcal{F}_l(H, \Delta_2)) < 1 + \alpha \quad (80)$$

Since α is an arbitrary positive number, we claim that

$$\max_{\Delta_1 \in \mathcal{X}_1, \Delta_2 \in \mathcal{X}_2} \mu_1(\mathcal{F}_l(H, \Delta_2)) \leq 1 \quad (81)$$

This completes the proof. ■

At first we investigate the problem that concerns under what condition a transfer function set described by a nominal model and an additive unstructured uncertainty bound can include all the possible plant transfer functions when an upper bound of the plant transfer function's \mathcal{H}^∞ -norm and a series of the plant's weakly corrupted time domain input-output pairs have been provided.

Partition the transfer function matrix $F(z)$ defined in Theorem 4 as $F(z) = \begin{bmatrix} F_{11}(z) & F_{12}(z) \\ F_{21}(z) & F_{22}(z) \end{bmatrix}$ where $F_{11}(z)$ has a dimension $l \times l$ and the other transfer function matrices have compatible dimensions.

Define transfer function matrix structure $\mathcal{V}(z)$ and matrix structures $\mathcal{X} = \bar{\mathcal{X}}$ as

$$\mathcal{X}(\cdot) = \{ \Delta(\cdot) \mid \Delta(\cdot) = \text{diag} \{ \epsilon(\cdot) \delta_0 I, \delta_1 I, \dots, \delta_n I \} \\ \epsilon(\cdot) \in \mathcal{H}^\infty, \delta_i \in \mathcal{R}, 0 \leq i \leq n \}$$

$$\bar{\mathcal{X}} = \{ \underline{\Delta} \mid \underline{\Delta} = \text{diag} \{ \epsilon \delta_0 I, \delta_1 I, \dots, \delta_n I \} \\ \epsilon \in \mathcal{C}, \delta_i \in \mathcal{R}, 0 \leq i \leq n \}$$

$$\mathcal{V} = \left\{ \bar{\Delta} \mid \bar{\Delta} = \begin{bmatrix} \Delta_1 & \\ & \Delta_2 \end{bmatrix}, \Delta_1 \in \mathcal{C}, \Delta_2 \in \mathcal{V} \right\}$$

Then, according to Theorem 4, when the plant transfer function is derived from an upper bound of its \mathcal{H}^∞ -norm and a series of weakly corrupted time domain input-output data, the transfer function set \mathcal{G} which consists of all the plant possible transfer functions can be parameterized as

$$\mathcal{G} = \{ q(z) \mid q(z) = \mathcal{F}_l(F(z), \Delta(z)), \Delta(z) \in \mathcal{BX}(z) \}$$

Theorem 5 For a given transfer function $q_0(z) \in \mathcal{H}^\infty$ and a unimodular transfer function of \mathcal{H}^∞ , $W_a(z)$, define a transfer function set

$$\mathcal{G}_a = \{ g(z) \mid g(z) = q_0(z) + W_a(z) \Delta_a(z), \Delta_a(z) \in \mathcal{BH}^\infty \} +$$

Then, $\mathcal{G}_a \supseteq \mathcal{G}$ if and only if

$$\mu_{\bar{\mathcal{V}}} \begin{bmatrix} W_a^{-1}(F_{11} - q_0) & W_a^{-1}F_{12} \\ I_{21} & I_{22} \end{bmatrix} \leq 1$$

Proof First, we note that since $\mathcal{G} \subset \mathcal{H}^\infty$, it is necessary that at every $z \in \mathcal{D}$, $(I - F_{22}(z)\Delta(z))$ are invertible, for arbitrary $\Delta(z) \in \mathcal{V}(z)$.

Assume that there exists a $z_0 \in \mathcal{D}$ and a $\underline{\Delta} = \text{diag} \{ \alpha \delta_0 I, \delta_1 I, \dots, \delta_n I \} \in \mathcal{BX}$, such that

$$\det(I - F_{22}(z_0)\underline{\Delta}) = 0 \quad (82)$$

If $|z_0| < 1$ from $|\alpha| \leq 1$ and the Nevanlinna-Pick interpolation theorem [22], we conclude that there exists an $\epsilon(\cdot) \in \mathcal{BH}^\infty$ that satisfies $\epsilon(z_0) = \alpha$. Let $\Delta(z) = \text{diag} \{ \epsilon(z) \delta_0 I, \delta_1 I, \dots, \delta_n I \}$ then, it is obvious that $\Delta(z) \in \mathcal{BX}(\cdot)$ and $\det(I - F_{22}(z_0)\Delta(z_0)) = 0$ which is a contradiction.

If $|z_0| = 1$, let $z'_0 = \beta z_0$ for arbitrary $|\beta| < 1$, then, using a similar argument, it can be proved that, there exists a $\Delta(\cdot) \in \mathcal{BX}(\cdot)$ that meets the condition $\Delta(\beta z_0) = \underline{\Delta}$. From $\Delta(\cdot) \in \mathcal{BX}(\cdot)$, we have

$$\Delta(z_0) = \lim_{\eta \rightarrow 1} \Delta(\eta z_0) \quad (83)$$

Since β is arbitrary except that $|\beta| < 1$, we conclude that there exists a $\Delta(\cdot) \in \mathcal{BX}(\cdot)$ such that

$$\det(I - F_{22}(z_0)\Delta(z_0)) = 0 \quad (84)$$

which is also a contradiction.

Therefore, for every z $|z| \leq 1$, $\det(I - F_{22}(z)\underline{\Delta}) \neq 0$ whenever $\underline{\Delta} \in \mathcal{BX}$ which implies that

$$\mu_{\bar{\mathcal{V}}}(F_{22}) < 1 \quad (85)$$

If $\mathcal{G}_a \supseteq \mathcal{G}$ then for arbitrary transfer function $q(z) \in \mathcal{G}$, there exists a $\Delta_a(z) \in \mathcal{BH}^\infty$ such that

$$q(z) = q_0(z) + W_a(z)\Delta_a(z) \quad (86)$$

That is, there exists at least one $\Delta_a(z) \in \mathcal{BH}^\infty$ which satisfies

$$F_{11}(z) + F_{12}(z)\Delta(z)[I - F_{22}(z)\Delta(z)]^{-1}F_{21}(z) \\ = q_0(z) + W_a(z)\Delta_a(z) \quad (87)$$

for arbitrary $\Delta(z) \in \mathcal{BX}(z)$.

Hence

$$\Delta_a(z) = W_a^{-1}(z)[F_{11}(z) - q_0(z) + F_{12}(z)\Delta(z) \\ (I - F_{22}(z)\Delta(z))^{-1}F_{21}(z)] \\ = \mathcal{F}_l \left[\begin{pmatrix} W_a^{-1}(z)(F_{11}(z) - q_0(z)) & W_a^{-1}(z)F_{12}(z) \\ F_{21}(z) & F_{22}(z) \end{pmatrix} \right. \\ \left. \Delta(z) \right] \quad (88)$$

which implies that

$$\max_{\Delta(z) \in \mathcal{B}\mathcal{X}(z)} \left\| \mathcal{F}_l \left[\begin{pmatrix} W_a^{-1}(z)(F_{11}(z) - g_0(z)) & W_a^{-1}(z)F_{12}(z) \\ F_{21}(z) & F_{22}(z) \end{pmatrix}, \Delta(z) \right] \right\|_{\infty} \leq 1 \quad (89)$$

because $\Delta_a(z) \in \mathcal{B}\mathcal{H}^{\infty}$.

Therefore, using similar arguments as in the proof of $\mu_{\mathcal{X}}(F_{22}) < 1$, we conclude that

$$\max_{\Delta \in \mathcal{B}\mathcal{X}} \mu_c \left(\mathcal{F}_l \left[\begin{pmatrix} W_a^{-1}(F_{11} - g_0) & W_a^{-1}F_{12} \\ F_{21} & F_{22} \end{pmatrix}, \Delta \right] \right) \leq 1. \quad (90)$$

From Lemma 1 and (85) and (90), we have

$$\mu_{\overline{\mathcal{X}}} \left(\begin{pmatrix} W_a^{-1}(F_{11} - g_0) & W_a^{-1}F_{12} \\ F_{21} & F_{22} \end{pmatrix} \right) \leq 1. \quad (91)$$

On the other hand, if

$$\mu_{\overline{\mathcal{X}}} \left(\begin{pmatrix} W_a^{-1}(F_{11} - g_0) & W_a^{-1}F_{12} \\ F_{21} & F_{22} \end{pmatrix} \right) \leq 1$$

then, according to Lemma 1, we have

$$\max_{\Delta \in \mathcal{B}\mathcal{X}} \max_{|z| \leq 1} \left\| \mathcal{F}_l \left[\begin{pmatrix} W_a^{-1}(z)(F_{11}(z) - g_0(z)) & W_a^{-1}(z)F_{12}(z) \\ F_{21}(z) & F_{22}(z) \end{pmatrix}, \Delta \right] \right\|_{\infty} \leq 1. \quad (92)$$

Assume that there is a transfer function $g(z) \in \mathcal{G}$, but $g(z) \notin \mathcal{G}_a$. Since $g(z) \in \mathcal{G}$, there exists a $\Delta(z) \in \mathcal{B}\mathcal{X}(z)$, such that

$$g(z) = F_{11}(z) + F_{12}(z)\Delta(z)(I - F_{22}(z)\Delta(z))^{-1}F_{21}(z). \quad (93)$$

Let $\Delta_a(z) = W_a^{-1}(z)(g(z) - g_0(z))$; then, it is obvious that $\Delta_a(z) \in \mathcal{H}^{\infty}$ and

$$\|\Delta_a(z)\|_{\infty} > 1 \quad (94)$$

which implies that there exists at least one $z_0 \in \mathcal{D}$, at which

$$|\Delta_a(z_0)| > 1. \quad (95)$$

Let $\underline{\Delta} = \Delta(z_0)$, then, it is apparent that

$$\underline{\Delta} \in \mathcal{B}\mathcal{X}. \quad (96)$$

Note that

$$\begin{aligned} \Delta_a(z_0) &= \mathcal{F}_l \left[\begin{pmatrix} W_a^{-1}(z_0)(F_{11}(z_0) - g_0(z_0)) & W_a^{-1}(z_0)F_{12}(z_0) \\ F_{21}(z_0) & F_{22}(z_0) \end{pmatrix}, \underline{\Delta} \right] \\ &\quad \cdot \underline{\Delta} \end{aligned} \quad (97)$$

we conclude that $\|\Delta_a(z)\|_{\infty} > 1$ contradicts with (92).

Therefore, there is no transfer function that belongs to \mathcal{G} but does not belong to \mathcal{G}_a .

This completes the proof. \blacksquare

Noting that unimodular transfer functions of \mathcal{H}^{∞} are capable of representing all the kinds of frequency-magnitude characteristics, the assumption that $W_a(z)$ is a unimodular function of \mathcal{H}^{∞} does not sacrifice any generality concerned with the application of the results in Theorem 5.

From Theorem 5, we see that for a weakly corrupted plant, the problem of checking whether a transfer function set, which is defined by a nominal model and an additive nominal model error uncertainty bound, includes all of the possible plant transfer functions that are deduced from an upper bound of the plant transfer function's \mathcal{H}^{∞} -norm and measured time domain input-output data, is equal to a μ -analysis problem [4], [27]. Here, by weakly corrupted plant, we mean that the normalized measured plant input-output satisfies the condition $\max_{|v_i| \leq \kappa} \overline{\sigma}((Y + E)U^{-1}) \leq 1$.

Finally, we discuss the problem of obtaining the smallest transfer function set which is parameterized by a fixed complexity nominal model with an additive nominal model error uncertainty bound, and includes all the plant possible transfer functions that do not contradict the aforementioned available plant information.

Mathematically, this identification problem can be formulated as finding out the fixed complexity nominal model $g_0(z) \in \mathcal{H}^{\infty}$, such that for a given frequency weight function $W_{ai}(z)$ (which can be chosen as a unimodular transfer function of \mathcal{H}^{∞}) and the unfalsified transfer function set, i.e., \mathcal{G} , the cost function

$$J(g_0(z)) = \max_{g(z) \in \mathcal{G}} \|W_{ai}(z)[g(z) - g_0(z)]\|_{\infty} \quad (98)$$

is minimized. For control engineering background of this problem formulation, refer to [7], [9], [24], and [38].

Let \mathcal{H}_m^{∞} denote the transfer function set that includes all transfer functions which belong to \mathcal{H}^{∞} and have degree not greater than m . Moreover, assume that

$$\alpha = \min_{g_0(z) \in \mathcal{H}_m^{\infty}} \max_{g(z) \in \mathcal{G}} \|W_{ai}(z)[g(z) - g_0(z)]\|_{\infty}, \quad (99)$$

$$g_0^*(z) = \arg \min_{g_0(z) \in \mathcal{H}_m^{\infty}} \max_{g(z) \in \mathcal{G}} \|W_{ai}(z)[g(z) - g_0(z)]\|_{\infty} \quad (100)$$

then, the desirable transfer function set \mathcal{G}_{opt} will be given as

$$\mathcal{G}_{opt} = \{g(z) \mid g(z) = g_0^*(z) + \alpha W_{ai}^{-1}(z)\Delta_a(z), \|\Delta_a(z)\|_{\infty} \leq 1\}. \quad (101)$$

On the other hand, when an upper bound of the \mathcal{H}^{∞} -norm of the plant transfer function and a series of the plant weakly corrupted time domain input-output data have been supplied, transfer function set \mathcal{G} can be parameterized as a linear fractional transformation and the cost function defined in (98) can be rewritten as

$$\begin{aligned} J(g_0(z)) &= \max_{g(z) \in \mathcal{G}} \|W_{ai}(z)[g(z) - g_0(z)]\|_{\infty} \\ &= \max_{\Delta(z) \in \mathcal{B}\mathcal{X}(z)} \|W_{ai}(z)\{F_{11}(z) + F_{12}(z)\Delta(z) \\ &\quad \cdot [I - F_{22}(z)\Delta(z)]^{-1}F_{21}(z) - g_0(z)\}\|_{\infty} \end{aligned}$$

$$\begin{aligned}
 &= \max_{\Delta(z) \in \mathcal{B}\mathcal{X}(z)} \left\| \mathcal{F}_l \left[\begin{pmatrix} W_{a1}(z)(F_{11}(z) - g_0(z)) & W_{a1}(z)F_{12}(z) \\ F_{21}(z) & F_{22}(z) \end{pmatrix} \right. \right. \\
 &\quad \left. \left. \cdot \Delta(z) \right] \right\|_{\infty}. \quad (102)
 \end{aligned}$$

Theorem 6: Assume that

$$\begin{aligned}
 &\min_{g_0(z) \in \mathcal{H}_m^{\infty}} \max_{\Delta(z) \in \mathcal{B}\mathcal{X}(z)} \left\| \mathcal{F}_l \left[\begin{pmatrix} W_{a1}(z)(F_{11}(z) - g_0(z)) & W_{a1}(z)F_{12}(z) \\ F_{21}(z) & F_{22}(z) \end{pmatrix} \right. \right. \\
 &\quad \left. \left. \cdot \Delta(z) \right] \right\|_{\infty} = \alpha
 \end{aligned}$$

and $g_0^*(z)$ is the solution of this minimization problem. Then

$$\mu_{\overline{\mathcal{X}}} \left[\begin{pmatrix} \frac{1}{\alpha} W_{a1}(F_{11} - g_0^*) & \frac{1}{\sqrt{\alpha}} W_{a1} F_{12} \\ \frac{1}{\sqrt{\alpha}} F_{21} & F_{22} \end{pmatrix} \right] = 1.$$

Proof: Since $\alpha = 0$ is a trivial case, we assume without loss of generality that $\alpha > 0$. From

$$\begin{aligned}
 &\min_{g_0(z) \in \mathcal{H}_m^{\infty}} \max_{\Delta(z) \in \mathcal{B}\mathcal{X}(z)} \left\| \mathcal{F}_l \left[\begin{pmatrix} W_{a1}(z)(F_{11}(z) - g_0(z)) & W_{a1}(z)F_{12}(z) \\ F_{21}(z) & F_{22}(z) \end{pmatrix} \right. \right. \\
 &\quad \left. \left. \cdot \Delta(z) \right] \right\|_{\infty} = \alpha \quad (103)
 \end{aligned}$$

and at $g_0^*(z)$ the cost function achieves its minimal value, we have

$$\begin{aligned}
 &\max_{\Delta(z) \in \mathcal{B}\mathcal{X}(z)} \left\| \mathcal{F}_l \left[\begin{pmatrix} \frac{1}{\alpha} W_{a1}(z)(F_{11}(z) - g_0^*(z)) & \frac{1}{\sqrt{\alpha}} W_{a1}(z)F_{12}(z) \\ \frac{1}{\sqrt{\alpha}} F_{21}(z) & F_{22}(z) \end{pmatrix} \right. \right. \\
 &\quad \left. \left. \cdot \Delta(z) \right] \right\|_{\infty} = 1. \quad (104)
 \end{aligned}$$

Since $\mu_{\underline{\mathcal{X}}}(F_{22}) < 1$ according to the proof of Theorem 5, from Lemma 1, we have

$$\mu_{\overline{\mathcal{X}}} \left[\begin{pmatrix} \frac{1}{\alpha} W_{a1}(F_{11} - g_0^*) & \frac{1}{\sqrt{\alpha}} W_{a1} F_{12} \\ \frac{1}{\sqrt{\alpha}} F_{21} & F_{22} \end{pmatrix} \right] = 1. \quad (105)$$

This completes the proof. ■

For the given transfer function matrix $F(z)$ and the frequency weight function $W_{a1}(z)$, define a scalar function $\overline{J}(\beta, g_0(z))$ as

$$\overline{J}(\beta, g_0(z)) = \mu_{\overline{\mathcal{V}}} \left[\begin{pmatrix} \frac{1}{\beta} W_{a1}(F_{11} - g_0) & \frac{1}{\sqrt{\beta}} W_{a1} F_{12} \\ \frac{1}{\sqrt{\beta}} F_{21} & F_{22} \end{pmatrix} \right] \quad (106)$$

for $\beta > 0$ and $g_0(z) \in \mathcal{H}_m^{\infty}$.

Note that since $\mu_{\underline{\mathcal{X}}}(F_{22}) < 1$, we have

$$\det \left(I - \begin{bmatrix} \frac{1}{\beta} W_{a1}(z)(F_{11}(z) - g_0(z)) & \frac{1}{\sqrt{\beta}} W_{a1}(z)F_{12}(z) \\ \frac{1}{\sqrt{\beta}} F_{21}(z) & F_{22}(z) \end{bmatrix} \cdot \begin{bmatrix} \Delta_1 \\ \Delta_2 \end{bmatrix} \right)$$

$$\begin{aligned}
 &= \det(I - F_{22}(z)\Delta_2) \\
 &\quad \times \det \left(I - W_{a1}(z)[F_{11}(z) - g_0(z) \right. \\
 &\quad \left. + F_{12}(z)\Delta_2(I - F_{22}(z)\Delta_2)^{-1}F_{21}(z)] \left(\frac{1}{\beta} \Delta_1 \right) \right) \quad (107)
 \end{aligned}$$

at every $z \in \mathcal{D}$, for all $\Delta_1 \in \mathcal{C}$ and $\Delta_2 \in \mathcal{B}\mathcal{X}$. It is obvious that if $\beta_1 > \beta_2 > 0$, then

$$\overline{J}(\beta_1, g_0(z)) \leq \overline{J}(\beta_2, g_0(z)). \quad (108)$$

Therefore, when $\beta_1 > \beta_2 > 0$, we have

$$\min_{g_0(z) \in \mathcal{H}_m^{\infty}} \overline{J}(\beta_1, g_0(z)) \leq \min_{g_0(z) \in \mathcal{H}_m^{\infty}} \overline{J}(\beta_2, g_0(z)). \quad (109)$$

From the above discussion, it is apparent that the problem of obtaining the smallest transfer function set, which is determined by a fixed complexity nominal model and its additive error uncertainty bound, and includes all of the plant possible transfer functions deduced from the aforementioned plant information, can be transformed into a μ -synthesis problem, with combination of one free parameter search, i.e., to find the smallest β such that at this point the minimal structured singular value (with respect to $g_0(z) \in \mathcal{H}_m^{\infty}$) of the transfer function matrix

$$\begin{bmatrix} \frac{1}{\beta} W_{a1}(z)(F_{11}(z) - g_0(z)) & \frac{1}{\sqrt{\beta}} W_{a1}(z)F_{12}(z) \\ \frac{1}{\sqrt{\beta}} F_{21}(z) & F_{22}(z) \end{bmatrix}$$

according to the matrix structure $\overline{\mathcal{X}}$ is equal to 1. From the properties of the cost function $\overline{J}(\beta, g_0(z))$ defined in (106), i.e., $\overline{J}(\beta, g_0(z))$ will not increase with the increment of β , the algorithm for the search of the desirable β can be easily developed. A candidate procedure for this search may be as following.

Assume that two initial values of β , $0 < \beta_s^0 < \beta_l^0$ have been given which satisfy

$$\min_{g_0(z) \in \mathcal{H}_m^{\infty}} \overline{J}(\beta_s^0, g_0(z)) > 1, \quad \min_{g_0(z) \in \mathcal{H}_m^{\infty}} \overline{J}(\beta_l^0, g_0(z)) < 1.$$

In the N th iteration, let $\beta = \beta_s^{N-1} + (1 - \rho_N)\beta_l^{N-1}$. If $\min_{g_0(z) \in \mathcal{H}_m^{\infty}} \overline{J}(\beta, g_0(z)) > 1$, let $\beta_s^N = \beta$, $\beta_l^N = \beta_l^{N-1}$; otherwise, let $\beta_s^N = \beta_s^{N-1}$, $\beta_l^N = \beta$. If $0 < \rho_N < 1$ for all the iterations, it can be proved that this algorithm will converge to the desirable β . For detail, refer to [39].

In summary, we claim that the difficulty in developing the optimization algorithm for obtaining $g_0^*(z)$ and α that describe the desirable transfer function set \mathcal{G}_{opt} lies on μ -synthesis problem and the large dimension of the transfer function matrix $F(z)$.

V. CONCLUSION

In this paper, we investigated the structure of a transfer function set which includes all the possible plant transfer functions, under the situation that an upper bound of the \mathcal{H}^{∞} -norm of the plant transfer function is prescribed and the plant time domain input-output data are only weakly corrupted

in its output. Results show that such a transfer function set has an elegant structure, i.e., all of its element can be parameterized by a linear fractional transformation of a fixed transfer function matrix and a structure fixed, norm bounded, free transfer function matrix. The fixed transfer function matrix is completely determined by the plant measured input-output data, the noise level and the upper bound of the \mathcal{H}^∞ -norm of the plant transfer function. Moreover, it has been shown that the problem of obtaining the smallest transfer function set, which is defined by a fixed complexity nominal model and its additive error uncertainty bound and includes all of the plant possible transfer functions, can be transformed into a series of μ -synthesis problems.

While in this situation, the plant possible transfer function can be compactly expressed, the results in the last section suggest that it may be futile to pursue the analytic solution for the problem of searching the transfer function that belongs to \mathcal{H}^∞ , has a fixed complexity, and approximates all the plant possible transfer functions in the smallest additive error measured by a frequency weighted \mathcal{H}^∞ -norm. Moreover, although this problem can be converted to a series of μ -synthesis problems, it is still computationally difficult, due to the large dimension of the parameterization of the plant possible transfer function and the difficulties met in μ -synthesis problem itself. From these points, further research in developing computationally tractable approximation methods is still needed.

ACKNOWLEDGMENT

The authors would like to express their grateful acknowledgement to the anonymous referees for their suggestive comments and valuable criticisms.

Tong Zhou was born in Hunan Province, China, in 1964. He received the B.A. degree in control engineering from Chengdu Institute of Telecommunications Engineering in 1984, the M.S. degree in automatic control theory and application from the University of Electronic Science and Technology of China in 1988, the M.S. degree in electrical and computer engineering from Kanazawa University in 1991, and the Ph.D. degree in mechanical engineering for industrial machinery and systems from Osaka University in 1994.

From 1984 to 1986, he was a Research and Teaching Assistant at Chengdu Institute of Telecommunications Engineering. He joined the Department of Automation, University of Electronic Science and Technology of China in 1994, where he is presently an Associate Professor. His research interests include robust control theory, identification theory, adaptive control theory and their application to real world control engineering problems.

Hidenori Kimura (F'90) received the Bachelor, Master, and Doctor of Engineering degrees from the University of Tokyo in 1965, 1967, and 1970, respectively.

In 1970, he joined the Department of Control Engineering, Osaka University, where he was engaged in research and education of control engineering until 1987, when he moved to the Department of Mechanical Engineering for Computer-Controlled Machinery, Osaka University. In 1994, he joined the Department of Systems Engineering, Osaka University.

He is currently a Professor of Control Engineering at the Department of Mathematical Engineering and Information Physics, The University of Tokyo. His current research interests lie in H^∞ control, robust control, modeling for robust control and study of complex systems.

In 1972, 1983, and 1993, Dr. Kimura received the Paper Award from the SICE (the Society of Instrumentation and Control Engineers). Also, he was a recipient of the Paper Prize Award from IFAC in 1984 and 1990 and of the Outstanding Paper Award from the IEEE Control Systems Society in 1985. In 1990, he was awarded the Fellow of IELE. Since 1991, he has been a member of the Board of Governors of the IEEE Control Systems Society. He is the General Chair of the 35th CDC to be held in Japan in 1996.

Explicit Formulas for Optimally Robust Controllers for Delay Systems

Harry Dym, Tryphon T. Georgiou, and Malcolm C. Smith, *Member, IEEE*

Abstract—This paper considers single-input/single-output systems whose transfer functions take the form of a strictly proper rational function times a delay. A closed-form expression is presented for the controller which is optimally robust with respect to perturbations measured in the gap metric. The formula allows the \mathcal{H}_∞ loop-shaping procedure of Glover–McFarlane to be carried out explicitly for this class of systems without the need to first find a rational approximation of the plant. The form of the controller involves a certain algebra of “pseudo-derivation” operators. These operators, and their matrix generalizations, play a central role in the derivation of the controller. A discussion of the main properties of these operators will be given. An example will be presented of a controller design to achieve disturbance attenuation and robust set-point following for a plant with two lightly damped poles and a nontrivial time delay. The performance is compared, and shown to be superior, to that of a Smith predictor.

NOTATION

\mathbb{R} and \mathbb{C} denote the real and complex fields. $\mathcal{H}_2, \mathcal{H}_\infty$ denote the standard Hardy spaces in the right-half plane (RHP). \mathcal{L}_p denotes the standard Lebesgue space and $\|\cdot\|_p$ its norm. The inner product in \mathcal{L}_2 is denoted by $\langle \cdot, \cdot \rangle$. For $x \in \mathcal{L}_2(-\infty, \infty)$ we denote the Laplace transform of x by \hat{x} . If $G(s)$ is a matrix function of s , $G^*(s) := \overline{G(-\bar{s})}^T$ is the conjugate of $G(s)$. If $G(s)$ is real rational, $G^*(s) = G(-s)^T$. $\mathcal{H}_2^n, \mathcal{L}_2^n$, etc. denote corresponding spaces of vector-valued functions. $(\mathcal{H}_2^n)^\perp$ denotes the orthogonal complement of \mathcal{H}_2^n in $\mathcal{L}_2^n(-j\infty, j\infty)$. We denote by Π_+ (respectively, Π_-) the orthogonal projection from $\mathcal{L}_2^n(-j\infty, j\infty)$ onto \mathcal{H}_2^n (respectively, $(\mathcal{H}_2^n)^\perp$). Dimensions will be suppressed if they can be inferred from the context. The symbol $\text{spec}(A)$ designates the eigenvalues of A .

I. INTRODUCTION

IN this paper we consider the class of single-input/single-output delay systems of the form $P(s) = e^{-s\tau} P_0(s)$, where $P_0(s)$ is a strictly proper rational function and $\tau > 0$ is a time-delay. We present a closed form formula for controllers which are optimally robust with respect to gap/normalized coprime

factor uncertainty. This formula is a generalization of one given in [19] (see also [18]) for the case of a first-order $P_0(s)$. The approach also builds on the work of [24] which developed state-space formulas for computing optimal H_∞ -performance for such systems.

The derivation of the controllers is based on a synthesis of state-space techniques, associated with the rational part $P_0(s)$, along with the use of a certain commutative algebra of operators. These operators are defined as follows

$$\partial_\alpha f := \frac{f(s) - f(\alpha)}{s - \alpha}$$

(for $\alpha \in \mathbb{C}$ and $f(s)$ any meromorphic function which is analytic at α), and they represent an analog of the “backward shift” operator in the continuous-time setup. Some early use of these operators ([2] and [3]) was in the context of reproducing kernel Hilbert spaces and scattering theory—see [7] and [8] for more recent accounts, numerous references, and applications to interpolation theory. The formula for the optimal controllers contains infinite-dimensional “distributed delays” resulting from the action of the ∂_α ’s (or a suitable matrix generalization ∂_H) on the delay element $e^{-s\tau}$.

The controller formula derived in this paper allows the \mathcal{H}_∞ loop shaping design procedure of Glover–McFarlane to be carried out explicitly for the delay systems considered without the need to first find a rational approximation of the plant. We illustrate this fact by designing a controller to achieve disturbance attenuation and robust set-point following for a plant with two lightly damped poles and a nontrivial delay. This type of system is a suitable nominal model in a number of process control applications. We will show that our design has significantly better performance than a Smith predictor.

Research on the subject of \mathcal{H}_∞ control for distributed parameter systems has been on-going since the mid 1980’s. One of the objectives of this research has been to develop explicit formulas which provide insight into the limitations on performance imposed by infinite-dimensional elements such as delays. An additional goal has been to understand the effect of such elements on the structure of the controller, thereby giving an alternative design approach to finite-dimensional approximation of the plant. Early work was concerned with computing the optimal performance for problems such as weighted sensitivity minimization [10], [13]. Subsequent efforts focused mainly on developing computational methodologies for increasingly general situations [14], [22], [28], [29], [34] and for explicitly computing the controllers. The computation of the optimal performance involves finding the

IEEE Log Number 9408279

maximum singular value (norm) of a certain generalized Hankel or Sarason operator. The construction of the optimal controller requires computing the associated singular vectors. Extra care is needed in case the infimum is not achieved in the optimization problem [11] or in case the underlying operator is not compact. (We mention incidentally that neither of these two cases arises in the problem treated here.) The computation of singular values and vectors usually exploits special structures in the family of systems considered, such as the presence of general \mathcal{H}_∞ inner factors multiplied by rational functions. In the case of delay systems, the computations were originally cast in the form of a certain two-point boundary value problem in the time domain [13], [24], [35] which in turn led to a solution in the form of a transcendental equation. Analogous computations can be carried out in the s -domain, or in the z -domain after a bilinear transformation, as in the skew-Toeplitz approach in [1] and [22]. The general methodology has been shown to apply to quite a general class of distributed parameter systems and provides a framework for obtaining a numerical solution [12], [23]. An alternative viewpoint for \mathcal{H}_∞ control of distributed parameter systems, based on an infinite dimensional state space approach, has been considered in [5] and [6] and the references therein.

The current work is part of a continuing effort to realize the original goals of the above research program. A formula for an \mathcal{H}_∞ controller is derived which takes a particularly simple form and is easily programmable. Moreover, the controller minimizes a certain cost functional which has proved to be especially convenient for design. We would like to mention that, in some recent work [30], an algorithm has been outlined for the computation of suboptimal controllers of delay systems for robustness in the gap. At the moment, it is an interesting open problem to seek an explicit formula of the type given in this paper for the suboptimal case.

The paper is organized as follows. In Section II some background material is reviewed on the properties and computation of gap/normalized coprime factor optimally robust controllers. In Section III the singular value/vector equations of Partington–Glover, and the procedure to find the gap optimal controller from them, are summarized. In Section IV the (scalar) operator ∂_α is introduced, and the main properties of the operator, which will be used in the controller derivation, will be described. In Section V the general procedure for the computation of the optimal controller will be carried out for the case where $P(s) = e^{-s\tau}/(s - \sigma)$. The purpose of this section is to motivate the computational steps that are necessary in the higher order case. In Section VI a generalization of the ∂_α operator to the matrix case will be presented together with its properties. In Section VII the general controller formula is derived and, in Section VIII, an illustrative example is presented.

II. BACKGROUND

We consider the feedback configuration of Fig. 1, denoted by $[P, K]$, where P and K are the transfer functions of the plant and the controller, respectively (and are ratios of \mathcal{H}_∞ -functions). We say that $[P, K]$ is stable if the closed-loop

Fig. 1 Standard feedback configuration.

transfer functions, mapping d_i to e_j ($i, j = 1, 2$), belong to \mathcal{H}_∞ . If $[P, K]$ is stable then the following quantity can be defined

$$b_{P,K} := (I + KP)^{-1}(I, K)$$

which is the gap metric robustness radius for the feedback system. That is, $b_{P,K}$ is the radius of the largest ball of uncertainty about P , measured in the gap metric, which is stabilized by K . For the definition of the gap metric, connections with normalized coprime factorizations, and associated results on robust stabilization the reader is referred to [16] and [19].

It appears that $b_{P,K}$ is a useful quantity to maximize for a feedback system, especially if it is weighted appropriately. In fact, the maximization of $b_{WP,K}$, for some weighting function W chosen by the designer, is the basis of the Glover–McFarlane \mathcal{H}_∞ loop shaping method [21]. This problem is also the same as the optimal robustness problem in the weighted gap metric (see [4] and [15]). From the point of view of computations, it is sufficient to consider the unweighted case only. This will be our point of view until the example in the last section.

We now summarize some background results on the optimization of $b_{P,K}$. Let $P = N/M$, where $M, N \in \mathcal{H}_\infty$, is a normalized coprime factorization of P (i.e., $NN^* + MM^* = 1$) and let $F = (-N, M)$. We define the optimal robustness radius

$$b_{\text{opt}}(P) := \sup_{K \text{ stabiliz}} b_{P,K}. \quad (1)$$

It can be shown that the following formula holds

$$b_{\text{opt}}(P) = (1 - \|F\|^2)^{1/2} \quad (2)$$

where F is the Hankel operator defined by $F = H_- F^*|_{\mathcal{H}_2}$ (see [19] and [16]).

If F is continuous on the compactified right-half plane then it follows (from Hartman's Theorem) that the operator F is compact and hence that it achieves its norm $\|F\|$, which is equal to the maximal singular value of the operator. Moreover if $0 < \lambda = \|F\| < 1$ then there is a unique optimally robust controller which can be determined from λ and any corresponding singular vector. Specifically, let $\hat{x} \in \mathcal{H}_2$, $\hat{y} = (\hat{y}_1, \hat{y}_2) \in \mathcal{H}_2^{1 \times 2}$ satisfy

$$F\hat{x} = \lambda\hat{y}^*, \quad (3)$$

$$F^*\hat{y}^* = \lambda\hat{x} \quad (4)$$

and define $\hat{u} = H_+ F^* \lambda \hat{x}$. Then the optimal compensator has a transfer function $K = -\hat{u}_1/\hat{u}_2$. See [18] for a more detailed explanation of these facts and further references.

III. COMPUTATION OF SINGULAR VALUES AND VECTORS

In this section we consider a single-input/single-output system with transfer function of the form $P(s) = e^{-s\tau} P_0(s)$ where $P_0(s)$ is a strictly proper rational function and τ is a time-delay. Since $e^{-s\tau}$ is inner we can find the normalized coprime factors of $P(s)$ by finding the normalized coprime factors of $P_0(s)$ using the state-space construction of [20] and [31] and then multiplying the numerator by $e^{-s\tau}$. Let $P_0(s) = C(sI - A_0)^{-1}B$ be a minimal realization with state dimension n . We define R to be the stabilizing solution of the Riccati equation

$$A_0 R + R A_0 - R C^* C R + B B^* = 0 \quad (5)$$

and set $A = A_0 + EC$ where $E = -RC^*$. Then $\text{spec}(A)$ is in the open left-half plane, and

$$F = (-N, M) = (0, I) + C(sI - A)^{-1}(-B e^{-s\tau}, E). \quad (6)$$

We assume that $P(s) \not\equiv 0$ which implies that $\|F\| > 0$. Since $F(s)$ is right invertible over \mathcal{H}_∞ , which is equivalent to P being stabilizable, $\|F\| < 1$ (see [16, Sections III and VII]). Finally we note that, since $F(s)$ is continuous on the compactified right-half plane, the optimal controller for $P(s)$ can be found from the singular values and vectors of F .

We now summarize the formulas of Partington and Glover [24] for the computation of the singular values of F . The idea is to give a time-domain realization of (3) and (4). These are the equations

$$\begin{aligned} w(\tau) &= \int_{\tau}^{\infty} e^{A^*(u-\tau)} C^* x(u) du, \\ \dot{w}(t) &= -A^* w(t) - C^* x(t) \quad \text{for } 0 \leq t \leq \tau, \\ \lambda y_1(t) &= -B^* w(\tau - t) \quad \text{for } 0 \leq t \leq \tau, \\ \lambda \begin{bmatrix} y_1(t + \tau) \\ y_2(t) \end{bmatrix} &= \begin{bmatrix} -B^* \\ E^* \end{bmatrix} e^{A^* t} w(0) \quad \text{for } t > 0 \end{aligned} \quad (7)$$

and

$$v(0) = \int_0^{\infty} e^{A u} (-B y_1(u + \tau) + E y_2(u)) du, \quad (8)$$

$$\begin{aligned} \dot{v}(t) &= A v(t) - B y_1(\tau - t) \quad \text{for } 0 \leq t \leq \tau, \\ \lambda x(t) &= \begin{cases} C v(t) & \text{for } 0 \leq t \leq \tau \\ C e^{A(t-\tau)} v(\tau) & \text{for } t \geq \tau \end{cases} \end{aligned} \quad (9)$$

These equations can be solved by considering a two-point boundary value problem on the interval $[0, \tau]$. On this interval the differential equations become

$$\frac{d}{dt} \begin{bmatrix} v \\ w \end{bmatrix} = H \begin{bmatrix} v \\ w \end{bmatrix} \quad (10)$$

where

$$H = \begin{bmatrix} A & \lambda^{-1} B B^* \\ -\lambda^{-1} C^* C & -A^* \end{bmatrix}. \quad (11)$$

Thus

$$\begin{bmatrix} v(t) \\ w(t) \end{bmatrix} = e^{Ht} \begin{bmatrix} v(0) \\ w(0) \end{bmatrix}. \quad (12)$$

Next, by substituting for x and y in (8) and (7), we obtain the relations

$$v(0) = \lambda^{-1} R w(0). \quad (13)$$

$$w(\tau) = \lambda^{-1} S v(\tau) \quad (14)$$

where S is the unique solution of the Lyapunov equation

$$A^* S + S A + C^* C = 0. \quad (15)$$

(Incidentally, observe that R satisfies the Lyapunov equation $AR + RA^* + BB^* + EE^* = 0$.) This leads to the equation

$$0 = L(\lambda) w(0)$$

where

$$L(\lambda) := \left\{ \begin{bmatrix} -S & \lambda I \end{bmatrix} \exp(H\tau) \begin{bmatrix} R \\ \lambda I \end{bmatrix} \right\}. \quad (16)$$

Proposition 1 [24]: A necessary and sufficient condition for λ to be a singular value of $F = \Pi F^*|_{\mathcal{H}_2}$ is that $\det L(\lambda) = 0$. \square

It follows that, to find the optimal controller for $P(s)$, we can use the following procedure:

- P1) Find the largest λ in $[0, 1]$ such that $\det L(\lambda) = 0$ and then find a nonzero vector w_0 such that $L(\lambda)w_0 = 0$. (By the assumptions on $P(s)$, $\lambda \neq 0, 1$.) Then find $v_0 = \lambda^{-1} R w_0$ and solve for $v(t)$ on $[0, \tau]$ using (12) with $v(0) = v_0$ and $w(0) = w_0$.
- P2) Calculate $\lambda x(t)$ on $[0, \infty)$ from (9).
- P3) Find $u = \Pi_+ K^* \lambda \hat{x}$, whence $K(s) = -u_1/\hat{u}_2$ [18].

IV. THE OPERATOR ∂_α

Let $f(s)$ be analytic in $\Omega \subset \mathbb{C}$, and define

$$(\partial_\alpha f)(s) := \frac{f(s) - f(\alpha)}{s - \alpha}$$

for $\alpha \in \Omega$. Then ∂_α defines a linear operator and has a number of interesting properties (see, e.g., [7] and [8]). Several of these properties will be exploited in this paper and we list these below. Note that ∂_α resembles a derivative, but without a limiting process. With $\alpha = 0$ the operator is the adjoint of the shift operator on \mathcal{H}_2 of the disc. Thus, ∂_α can be thought of as a generalized backward shift. It is readily verified that it satisfies the resolvent identity

$$\partial_\alpha - \partial_\beta = (\alpha - \beta) \partial_\alpha \partial_\beta \quad (17)$$

for any pair of points $\alpha, \beta \in \mathbb{C}$ which are points of analyticity for the class of functions acted upon. A direct consequence is that $\partial_\alpha \partial_\beta = \partial_\beta \partial_\alpha$. The following pseudo-derivation identities take the place of a product rule

$$(\partial_\alpha f g)(s) = (\partial_\alpha f)(s) g(s) + f(\alpha) (\partial_\alpha g)(s), \quad (18)$$

$$(\partial_\alpha f g)(s) = f(s) (\partial_\alpha g)(s) + (\partial_\alpha f)(s) g(\alpha). \quad (19)$$

(They differ from the usual product rule of differentiation by the fact that one of the two terms involves evaluation of one of the functions at the point α .) If $\alpha + \gamma \neq 0$ then

$$\partial_\alpha \frac{1}{s + \gamma} = \frac{-1/(\alpha + \gamma)}{(s + \gamma)}. \quad (20)$$

If $\alpha + \gamma \neq 0$ and g is analytic at α , then (18), (19), and (20) give the following two identities

$$\partial_\alpha \frac{g}{s + \gamma} = \frac{1}{s + \gamma} \left(\partial_\alpha g - \frac{1}{\alpha + \gamma} g(\alpha) \right), \quad (21)$$

$$\partial_\alpha \frac{g}{s + \gamma} = \frac{1}{\alpha + \gamma} \left(\partial_\alpha - \frac{1}{s + \gamma} \right) g. \quad (22)$$

If $\operatorname{Re}(\gamma) > 0$, and $g \in \mathcal{H}_2$ then

$$\Pi_+ \frac{1}{s - \gamma} g = \partial_\gamma g. \quad (23)$$

Finally we present the following result which will be needed in the controller derivations of Sections V and VII.

Proposition 2: Let $\operatorname{Re}(\gamma) > 0$ and $\alpha + \gamma \neq 0$. Suppose $F \in \mathcal{H}_\infty$ admits a representation of the form $F(s) = c + \int_0^\infty e^{-st} f(t) dt$ with c constant and $f(t) \in \mathcal{L}_1[0, \infty)$. Then $\Pi_+ F^* \partial_\alpha e^{-s\tau} / (s + \gamma)^k$ is analytic in $\mathbb{C} \setminus \{-\gamma\}$, and

$$\Pi_+ F^* \partial_\alpha \frac{1}{(s + \gamma)^k} = \partial_\alpha \Pi_+ F^* \frac{1}{(s + \gamma)^k} \quad (24)$$

for $k = 1, 2, \dots$.

Proof: We consider first the case $k = 1$. Under the given assumptions it is readily checked that

$$\begin{aligned} \Pi_+ F^* \partial_\alpha \frac{1}{s + \gamma} &= -\frac{1}{\alpha + \gamma} \Pi_+ F^* \frac{1}{s + \gamma} \\ &\quad - \frac{F^*(-\gamma)}{\alpha + \gamma} \frac{1}{s + \gamma} \end{aligned} \quad (25)$$

$$\begin{aligned} &= \partial_\alpha \frac{F^*(-\gamma)}{s + \gamma} \\ &= \partial_\alpha \Pi_+ F^* \frac{1}{s + \gamma}. \end{aligned} \quad (26)$$

Equation (25) shows that $\Pi_+ F^* \partial_\alpha 1 / (s + \gamma)$ is analytic in $\mathbb{C} \setminus \{-\gamma\}$. The proof now proceeds in two steps. We first introduce the natural projection operator, in the Wiener algebra on the line, defined as follows

$$P : \int_{-\infty}^\infty e^{-st} g(t) dt \rightarrow \int_0^\infty e^{-st} g(t) dt$$

with $g \in \mathcal{L}_1(\mathbb{R})$ and $s \in j\mathbb{R}$.

Step 1: Let $F_1(s) = F(s) - c = \int_0^\infty e^{-st} f(t) dt$. Then $PF_1^* e^{-s\tau}$ is an entire function and

$$PF_1^* \partial_\alpha e^{-s\tau} = \partial_\alpha PF_1^* e^{-s\tau}$$

for every choice of $\alpha \in \mathbb{C}$.

Proof of Step 1: The proof is an adaptation of [9, Lemma 4.4]. Observe that

$$\begin{aligned} PF_1^* e^{-s\tau} &= P \int_{-\infty}^0 e^{-st} f^*(t) dt \cdot e^{-s\tau} \\ &= P \int_{-\infty}^\tau e^{-su} f^*(u - \tau) du \\ &= \int_0^\tau e^{-su} f^*(u - \tau) du \end{aligned}$$

and hence $PF_1^* e^{-s\tau}$ is entire since it is the Laplace transform of a function with support on the interval $[0, \tau]$. Further

$$\begin{aligned} \partial_\alpha PF_1^* e^{-s\tau} &= \int_0^\tau (\partial_\alpha e^{-su}) f^*(u - \tau) du \\ &= \int_0^\tau \int_0^u e^{-(s-\alpha)v} dv (-e^{\alpha u}) f^*(u - \tau) du \\ &= - \int_0^\tau \int_0^\tau e^{\alpha(v-u)} f^*(u - \tau) du dv \\ &= - \int_0^\tau \int_v^\tau e^{\alpha(x-\tau)} f^*(v - x) dx dv. \end{aligned} \quad (27)$$

On the other hand

$$\begin{aligned} PF_1^* \partial_\alpha e^{-s\tau} &= P \int_0^\tau e^{-sx} (-e^{\alpha(x-\tau)}) dx \int_{-\infty}^0 e^{-st} f^*(t) dt \\ &= P \int_0^\tau (-e^{\alpha(x-\tau)}) \int_{-\infty}^x e^{-sv} f^*(v - x) dv dx \end{aligned}$$

which turns into expression (27) after interchanging the order of integration and then taking the projection. ∇

Step 2: The function $\Pi_+ F^* \partial_{-\gamma} e^{-s\tau}$ is an entire function, and

$$\Pi_+ F^* \partial_\alpha \partial_{-\gamma} e^{-s\tau} = \partial_\alpha \Pi_+ F^* \partial_{-\gamma} e^{-s\tau}$$

for every complex number α such that $\alpha + \gamma \neq 0$.

Proof of Step 2: It follows using Step 1 that $\Pi_+ F_1^* \partial_{-\gamma} e^{-s\tau}$ is entire. Clearly $\Pi_+ c^* \partial_{-\gamma} e^{-s\tau} = c^* \partial_{-\gamma} e^{-s\tau}$ is also entire. We now verify the formula for each of the components of $F(s) = c + F_1(s)$ separately. The first is easy

$$\Pi_+ c^* \partial_\alpha \partial_{-\gamma} e^{-s\tau} = c^* \partial_\alpha \partial_{-\gamma} e^{-s\tau} = \partial_\alpha \Pi_+ c^* \partial_{-\gamma} e^{-s\tau}.$$

Next, for $\alpha \neq -\gamma$ we have

$$\begin{aligned} \Pi_+ F_1^* \partial_\alpha \partial_{-\gamma} e^{-s\tau} &= \Pi_+ F_1^* \frac{\partial_\alpha - \partial_{-\gamma}}{\alpha + \gamma} e^{-s\tau} \\ &= PF_1^* \frac{\partial_\alpha - \partial_{-\gamma}}{\alpha + \gamma} e^{-s\tau} \\ &= \frac{\partial_\alpha - \partial_{-\gamma}}{\alpha + \gamma} PF_1^* e^{-s\tau} \\ &= \partial_\alpha \partial_{-\gamma} PF_1^* e^{-s\tau} \\ &= \partial_\alpha PF_1^* \partial_{-\gamma} e^{-s\tau} \\ &= \partial_\alpha \Pi_+ F_1^* \partial_{-\gamma} e^{-s\tau} \end{aligned}$$

using Step 1. The operator P is needed here because $F_1^* e^{-s\tau}$ may not belong to $\mathcal{L}_2(j\mathbb{R})$ and hence Π_+ cannot always be applied to it directly. ∇

With the help of the preceding analysis, we can now prove the proposition for the case $k = 1$. For $\alpha \neq -\gamma$

$$\begin{aligned} \Pi_+ F^* \partial_\alpha \frac{e^{-s\tau}}{s + \gamma} &= \Pi_+ F^* \partial_\alpha \left\{ \partial_{-\gamma} e^{-s\tau} + \frac{e^{\gamma\tau}}{s + \gamma} \right\} \\ &= \partial_\alpha \Pi_+ F^* \left\{ \partial_{-\gamma} e^{-s\tau} + \frac{e^{\gamma\tau}}{s + \gamma} \right\} \end{aligned}$$

using (26) and Step 2. This establishes the required equality.

To complete the proof we note that the result for the case of $k = 1$ can be applied to

$$g_n(s) = \frac{1}{(s + \gamma) \left(s + \gamma + \frac{1}{n}\right) \cdots \left(s + \gamma + \frac{k-1}{n}\right)}$$

for n sufficiently large, to give

$$\Pi_+ F^* \partial_\alpha e^{-s\tau} g_n(s) = \partial_\alpha \Pi_+ F^* e^{-s\tau} g_n(s).$$

By letting $n \rightarrow \infty$ we can check in turn that

$$g_n(s) \rightarrow g(s) = \frac{1}{(s + \gamma)^k} \text{ in } \mathcal{L}_2(j\mathbb{R}),$$

$$\partial_\alpha g_n(s) \rightarrow \partial_\alpha g(s) \text{ in } \mathcal{L}_2(j\mathbb{R}), \text{ and}$$

$$\Pi_+ F^* e^{-s\tau} g_n(s) \rightarrow \Pi_+ F^* e^{-s\tau} g(s)$$

pointwise in $\mathbb{C} \setminus \{-\gamma\}$. Thus

$$\begin{aligned} \Pi_+ F^* \partial_\alpha e^{-s\tau} g(s) &= \lim_{n \rightarrow \infty} \Pi_+ F^* \partial_\alpha e^{-s\tau} g_n(s) \\ &= \lim_{n \rightarrow \infty} \partial_\alpha \Pi_+ F^* e^{-s\tau} g_n(s) \\ &= \partial_\alpha \Pi_+ F^* e^{-s\tau} g(s). \end{aligned} \quad \square$$

V. FIRST-ORDER CASE

In the present section we consider the simplest example of a plant having transfer function of the form "time-delay \times rational function." $P(s) = e^{-s\tau}/(s - \sigma)$. An expression for the optimal controller was derived in [18]. A simplified formula involving the operator ∂_α was given in [19]. Below we present a new derivation of the optimal controller making explicit use of certain properties of the operator ∂_α . The computations illustrate several key steps which motivate analogous steps in the general case.

Proposition 3: Let $P(s) = e^{-s\tau}/(s - \sigma)$ where σ is any real constant and $\tau > 0$.

- a) The optimal robustness radius for gap ball uncertainty is given by

$$b_{\text{opt}}(P) = (1 - \lambda_{\max}^2)^{1/2} \quad (28)$$

where λ_{\max} is the largest solution of the following transcendental equation

$$e^{2\mu\tau} = \frac{\sigma + \mu}{\sigma - \mu} \left(\frac{\gamma - \mu}{\gamma + \mu} \right)^2 \quad (29)$$

where $\mu = \mu(\lambda) = \sqrt{\gamma^2 - \lambda^{-2}}$ and $\gamma = \sqrt{1 + \sigma^2}$.

- b) The transfer function of the optimal controller is given by

$$K_{\text{opt}}(s) = \frac{1}{\sqrt{\sigma^2 - \mu^2} - \frac{\gamma^2 - \mu^2}{2\mu} ((\sigma + \mu)\partial_\mu - (\sigma - \mu)\partial_{-\mu}) e^{-s\tau}} \quad (30)$$

where $\mu = \sqrt{\gamma^2 - \lambda_{\max}^{-2}}$, in the case $\mu \neq 0$. (A general formula covering also the case $\mu = 0$ is given in Theorem 1.)

Proof: Setting $B = C = 1$, $A_0 = \sigma$ gives $A = -\gamma$, $R = \sigma + \gamma$ and $S = 1/2\gamma$, whence

$$F(s) = \left(-\frac{e^{-s\tau}}{s + \gamma}, \frac{s - \sigma}{s + \gamma} \right).$$

Then

$$H = \begin{pmatrix} -\gamma & \lambda^{-1} \\ -\lambda^{-1} & \gamma \end{pmatrix}$$

with eigenvalues $\pm\mu$ where $\mu = \sqrt{\gamma^2 - \lambda^{-2}}$. Note that μ can be complex but $\pm\mu \neq \gamma$. An eigenvalue-eigenvector decomposition of H leads to

$$\begin{aligned} e^{Ht} &= \begin{pmatrix} \lambda^{-1} & \lambda^{-1} \\ \gamma + \mu & \gamma - \mu \end{pmatrix} \begin{pmatrix} e^{\mu t} & 0 \\ 0 & e^{-\mu t} \end{pmatrix} \\ &\quad \cdot \begin{pmatrix} \gamma - \mu & -\lambda^{-1} \\ -(\gamma + \mu) & \lambda^{-1} \end{pmatrix} \frac{-\lambda}{2\mu}. \end{aligned}$$

By substituting into (16) it follows that

$$\begin{aligned} L(\lambda) &= 0 \Leftrightarrow e^{2\mu\tau} \\ &= \frac{-\lambda^{-2} + 2\gamma(\gamma - \mu)}{-\lambda^{-2} + 2\gamma(\gamma + \mu)} \cdot \frac{(\sigma + \gamma)(\gamma + \mu) - 1}{(\sigma + \gamma)(\gamma - \mu) - 1} \\ &= \frac{(\gamma - \mu)^2}{(\gamma + \mu)^2} \cdot \frac{(\sigma + \gamma)(\sigma + \mu)}{(\sigma + \gamma)(\sigma - \mu)}. \end{aligned}$$

This gives (29). Also (28) follows from (2). Setting $w_0 = 1$ gives $v_0 = \lambda^{-1}R$, which leads to

$$\begin{aligned} v(t) &= (1 \ 0) e^{Ht} \begin{pmatrix} \lambda^{-1} R \\ 1 \end{pmatrix} \\ &= \alpha e^{\mu t} + \beta e^{-\mu t} \end{aligned}$$

on $[0, \tau]$, where

$$\begin{aligned} \alpha &= \frac{-(\sigma + \gamma)(\sigma - \mu)}{2\mu\lambda}, \\ \beta &= \frac{(\sigma + \gamma)(\sigma + \mu)}{2\mu\lambda}. \end{aligned}$$

(The calculation of α and β is eased by judicious use of the fact that $1 = \gamma^2 - \sigma^2$.) Thus

$$\lambda r(t) = \begin{cases} \alpha e^{\mu t} + \beta e^{-\mu t} & \text{on } [0, \tau] \\ e^{-\gamma(t-\tau)} (\alpha e^{\mu\tau} + \beta e^{-\mu\tau}) & \text{on } [\tau, \infty). \end{cases}$$

Hence

$$\begin{aligned} \lambda \dot{r} &= \int_0^\infty \lambda r(t) e^{-st} dt \\ &= -\alpha e^{\mu\tau} \left(\partial_\mu - \frac{1}{s + \gamma} \right) e^{-s\tau} \\ &\quad - \beta e^{-\mu\tau} \left(\partial_{-\mu} - \frac{1}{s + \gamma} \right) e^{-s\tau} \\ &= (-\alpha(\gamma + \mu) e^{\mu\tau} \partial_\mu - \beta(\gamma - \mu) e^{-\mu\tau} \partial_{-\mu}) \frac{e^{-s\tau}}{s + \gamma} \end{aligned}$$

where the first step uses direct integration and the second step follows from (22). Next

$$\begin{aligned}\Pi_+ F^* \lambda \hat{x} &= \Pi_+ \left(\frac{e^{s\tau}/(s-\gamma)}{(s+\sigma)/(s-\gamma)} \right) \lambda x \\ &= (-\alpha(\gamma+\mu)e^{\mu\tau}\partial_\mu - \beta(\gamma-\mu)e^{-\mu\tau}\partial_{-\mu}) \\ &\quad \cdot \Pi_+ \left(\frac{e^{s\tau}/(s-\gamma)}{(s+\sigma)/(s-\gamma)} \right) \frac{e^{-s\tau}}{s+\gamma} \\ &= (-\alpha(\gamma+\mu)e^{\mu\tau}\partial_\mu - \beta(\gamma-\mu)e^{-\mu\tau}\partial_{-\mu}) \\ &\quad \cdot \left(\frac{-1/2\gamma(s+\gamma)}{(1+(\sigma+\gamma)\partial_\gamma)e^{-s\tau}/(s+\gamma)} \right),\end{aligned}$$

where we have used Proposition 2 in the first step (which is applicable because $\pm\mu + \gamma \neq 0$), and (20) and (23) in the second step. Using (20), the first element of $\Pi_+ F^* \lambda \hat{x}$ becomes

$$\frac{-1}{2\gamma(s+\gamma)}(\alpha e^{\mu\tau} + \beta e^{-\mu\tau}) = \frac{-(\sigma+\gamma)\sqrt{\sigma^2}}{\lambda(\gamma^2 - \mu^2)(s+\gamma)}$$

where the equality follows by substituting for α, β and $e^{\mu\tau} = \sqrt{(\sigma+\mu)/(\sigma-\mu)(\gamma-\mu)/(\gamma+\mu)}$. The second element of $\Pi_+ F^* \lambda \hat{x}$ is equal to

$$\begin{aligned}&\left\{ (-\alpha(\gamma+\mu)e^{\mu\tau}) \left(1 + \frac{\sigma+\gamma}{\mu-\gamma} \right) \partial_\mu \right. \\ &\quad + (-\beta(\gamma-\mu)e^{-\mu\tau}) \left(1 + \frac{\sigma+\gamma}{-\mu-\gamma} \right) \partial_{-\mu} + (\sigma+\gamma) \\ &\quad \left. \frac{\alpha(\gamma+\mu)}{\mu-\gamma} e^{\mu\tau} + \frac{\beta(\gamma-\mu)}{-\mu-\gamma} e^{-\mu\tau} \right\} \partial_\gamma \frac{e^{-s\tau}}{s+\gamma}\end{aligned}$$

after using (17). In fact, by substituting for α, β and $e^{\mu\tau}$, the coefficient of ∂_γ in Δ is easily seen to be zero. Next, using similar substitutions, we get

$$\begin{aligned}\Delta &= \frac{2\mu\lambda}{(\sigma+\gamma)\sqrt{\sigma^2 - \mu^2}} \{ -(\sigma+\mu)\partial_\mu + (\sigma-\mu)\partial_{-\mu} \} s + \gamma \\ &\quad \frac{2\mu\lambda(s+\gamma)}{(\sigma+\gamma)\sqrt{\sigma^2 - \mu^2}} \{ -(\sigma+\mu)\partial_\mu + (\sigma-\mu)\partial_{-\mu} \} e^{-s\tau} \\ &\quad + \frac{(\sigma+\gamma)\sqrt{\sigma^2 - \mu^2}}{2\mu\lambda(s+\gamma)} \frac{\sqrt{\sigma^2}}{\gamma^2 - \mu^2} 2\mu\end{aligned}$$

where the second step uses (21). Taking the quotient of (31) and the above expression for Δ gives the required result. \square

VI. THE MATRIX ∂ -OPERATOR

To facilitate the controller computations in higher order cases we will need a matrix generalization of the operator ∂_α and its properties.

Let $A \in \mathbb{C}^{n \times n}$ and let $F(s)$ be an $n \times r$ matrix whose elements are analytic in an open simply connected region $\Omega \subset \mathbb{C}$ for which $\text{spec}(A) \subset \Omega$. Then we define

$$(\partial_A F)(s) = \frac{1}{2\pi j} \int_{\gamma_1} \frac{1}{z-s} (zI - A)^{-1} F(z) dz \quad (32)$$

for s inside γ_1 , where γ_1 is any simple closed curve (with positive orientation) inside Ω which encloses $\text{spec}(A)$. We also define $(\partial_A F)(s)$ by the same formula if either A or $F(s)$ is scalar. The above definition (32) is independent of the choice

of γ_1 and can be evaluated explicitly in terms of the Jordan decomposition of A and the values of F and its derivatives at the points of the spectrum of A , as in (39) below. The present contour integral formulation is, however, often easier to work with. In particular, it follows from Cauchy's theorem that (32) yields

$$(\partial_\alpha F)(s) = \frac{F(s) - F(\alpha)}{s - \alpha}$$

for $s, \alpha \in \Omega$, when $A = \alpha$ is a scalar. This is consistent with the definition given in Section IV. On the other hand, if F is equal to a scalar function f and A is either a matrix or a scalar, it is standard to define

$$f(A) = \frac{1}{2\pi j} \int_{\gamma_1} (zI - A)^{-1} f(z) dz$$

where γ_1 is any simple closed curve inside Ω which encloses $\text{spec}(A)$ (see e.g., [26, Chapter VI.3]). Using the identity

$$(zI - sI)^{-1} - (zI - A)^{-1} = (zI - A)^{-1} (sI - A) (zI - sI)^{-1}$$

we see that

$$\begin{aligned}(\partial_A f)(s) &= (sI - A)^{-1} \left\{ \frac{1}{2\pi j} \int_{\gamma_1} \frac{1}{z-s} f(z) dz I \right. \\ &\quad \left. - \frac{1}{2\pi j} \int_{\gamma_1} (zI - A)^{-1} f(z) dz \right\} \\ &= (sI - A)^{-1} (f(s)I - f(A)).\end{aligned}$$

Let $A \in \mathbb{C}^{n \times n}$ and let $F(s)$ be an $n \times r$ matrix whose elements are analytic in an open simply connected region $\Omega \subset \mathbb{C}$. Take $\alpha \in \Omega$ with $\alpha \notin \text{spec}(A)$. Then we can show that the following generalizations of (20)–(22) hold

$$\begin{aligned}\partial_\alpha (sI - A)^{-1} &= -(sI - A)^{-1} (\alpha I - A)^{-1} \\ &= -(\alpha I - A)^{-1} (sI - A)^{-1}, \quad (33)\end{aligned}$$

$$\begin{aligned}\partial_\alpha ((sI - A)^{-1} F(s)) &= (\alpha I - A)^{-1} (\partial_\alpha F(s)) \\ &\quad - (sI - A)^{-1} F(s), \quad (34)\end{aligned}$$

$$\begin{aligned}\partial_\alpha ((sI - A)^{-1} F(s)) &= (sI - A)^{-1} (\partial_\alpha F(s)) \\ &\quad - (\alpha I - A)^{-1} F(\alpha). \quad (35)\end{aligned}$$

For the matrix ∂ operator, a version of the resolvent identity still holds. Let $A, B \in \mathbb{C}^{n \times n}$ with $AB = BA$ then

$$\partial_A - \partial_B = (A - B) \partial_A \partial_B \quad (36)$$

where the operators act on a matrix $F(s)$ whose elements are analytic in an open simply connected region $\Omega \subset \mathbb{C}$ containing $\text{spec}(A) \cup \text{spec}(B)$. To see this, take two simple closed curves γ_1, γ_2 inside Ω , both containing $\text{spec}(A) \cup \text{spec}(B)$, and with

γ_1 strictly inside γ_2 . Then, for s inside γ_1

$$\begin{aligned} (\partial_A \partial_B F)(s) &= \frac{-1}{4\pi^2} \int_{\gamma_1} \frac{1}{z-s} (zI - A)^{-1} \\ &\quad \int_{\gamma_2} \frac{1}{w-z} (wI - B)^{-1} F(w) dw dz \\ &= \frac{-1}{4\pi^2} \int_{\gamma_2} \left\{ \int_{\gamma_1} \frac{1}{w-z} \cdot \frac{1}{z-s} (zI - A)^{-1} dz \right\} \\ &\quad \cdot (wI - B)^{-1} F(w) dw \\ &= \frac{1}{2\pi j} \int_{\gamma_2} \frac{1}{w-s} \\ &\quad \cdot (wI - A)^{-1} (wI - B)^{-1} F(w) dw \end{aligned}$$

where the last step uses the fact that w is outside of γ_1 . The required result now follows from the identity

$$(A - B)(wI - A)^{-1}(wI - B)^{-1} = (wI - A)^{-1} - (wI - B)^{-1}.$$

Let $f = f_+ + f_- \in \mathcal{L}_2(-j\infty, j\infty)$, where $f_+ \in \mathcal{H}_2$ and $f_- \in \mathcal{H}_2^\perp$. Then

$$f_+(s) = \left\langle f_+(jt), \frac{1}{2\pi(jt + s^*)} \right\rangle = \left\langle f(jt), \frac{1}{2\pi(jt + s^*)} \right\rangle$$

for $\mathcal{R}e(s) > 0$. Now consider $L \in \mathbb{C}^{n \times n}$ where $\text{spec}(L)$ is in the open right-half plane and let $g \in \mathcal{H}_2^n$. Then

$$\begin{aligned} \Pi_+(sI - L)^{-1}g(s) &= \int_{-\infty}^{\infty} \frac{1}{2\pi(jt + s^*)} (jtI - L)^{-1}g(jt) dt \\ &= \frac{-1}{2\pi j} \int_{-j\infty}^{j\infty} \frac{1}{z-s} (zI - L)^{-1}g(z) dz \\ &= (\partial_L g)(s). \end{aligned} \quad (37)$$

Let $L = PJP^{-1}$ be a Jordan decomposition with k Jordan blocks of size n_i and corresponding eigenvalues μ_i , and accordingly let

$$P = (V_1, \dots, V_k) \quad \text{and} \quad P^{-1} = \begin{pmatrix} U_1^* \\ \vdots \\ U_k^* \end{pmatrix}.$$

Then

$$(sI - L)^{-1} = \sum_{i=1}^k V_i \left\{ \sum_{\ell=1}^{n_i} \frac{1}{(s - \mu_i)^\ell} Z_{n_i}^{\ell-1} \right\} U_i^* \quad (38)$$

where Z_m is an $m \times m$ matrix with ones on the first superdiagonal and zeros elsewhere. If γ_1 is a simple closed curve containing s and μ , and γ_R is a circle of radius R about zero, then

$$\begin{aligned} \frac{1}{2\pi j} \int_{\gamma_1} \frac{1}{(z-s)} \frac{1}{(z-\mu)^\ell} dz \\ = \lim_{R \rightarrow \infty} \frac{1}{2\pi j} \int_{\gamma_R} \frac{1}{(z-s)} \frac{1}{(z-\mu)^\ell} dz = 0 \end{aligned}$$

for $\ell \geq 1$. Thus

$$\begin{aligned} \frac{1}{2\pi j} \int_{\gamma_1} \frac{1}{(z-s)} \frac{1}{(z-\mu)^\ell} f(z) dz \\ = \frac{1}{2\pi j} \int_{\gamma_1} \frac{1}{(z-s)} \frac{1}{(z-\mu)^{\ell-1}} (\partial_\mu f)(z) dz \\ = \frac{1}{2\pi j} \int_{\gamma_1} \frac{1}{(z-s)} \frac{1}{(z-\mu)} (\partial_\mu^{\ell-1} f)(z) dz \\ = (\partial_\mu^\ell f)(s). \end{aligned}$$

Hence, from (38)

$$(\partial_L F)(s) = \sum_{i=1}^k \sum_{\ell=1}^{n_i} V_i Z_{n_i}^{\ell-1} U_i^* (\partial_\mu^\ell F)(s). \quad (39)$$

VII. GENERAL CONTROLLER FORMULA

In this section we will generalize the formula of Proposition 3 to the case where $P(s) = e^{-s\tau} P_0(s)$, and $P_0(s) = C(sI - A_0)^{-1}B$ is (a minimal realization) of degree n . We recall the notation of Section III, namely $A = A_0 + EC$, $E = -R C^*$, with R, S, H defined as in (5), (15), (11).

To carry out the derivations of this section, a mild genericity assumption will be needed on $P_0(s)$, namely that the reflections of the zeros of $P_0(s)$ about the imaginary axis are disjoint from the poles of $P_0(s)$. As shown in the lemma below, this is equivalent to the spectrum of H and A being disjoint, which is the assumption we will need in the computations below. A discussion on the validity of the formula when the assumption fails is given in Remark 2.

Lemma 1: Let A, B, C , and $P_0(s)$ be defined as above, and let H be defined as in (11). Let $\{\zeta_i : i = 1, \dots, k\}$ be the zeros of $P_0(s)$ and let $\{\pi_i : i = 1, \dots, \ell\}$ be the poles of $P_0(s)$ (since $P_0(s)$ is a scalar function these two sets are disjoint). Then the following statements are equivalent:

- a) $\{\zeta_i : i = 1, \dots, k\} \cap \{-\bar{\pi}_i : i = 1, \dots, \ell\} = \emptyset$.
- b) (A, B) and (A, E) are controllable.
- c) $\text{spec}(H) \cap \text{spec}(A) = \emptyset$.

Proof: Define $\{\zeta_i^+ : i = 1, \dots, k^+\}$ and $\{\zeta_i^- : i = 1, \dots, k^-\}$ to be the set of zeros of $P_0(s)$ in $\mathcal{R}e(s) > 0$ and $\mathcal{R}e(s) < 0$ respectively. Similarly, $\{\pi_i^+ : i = 1, \dots, \ell^+\}$ and $\{\pi_i^- : i = 1, \dots, \ell^-\}$ define the set of poles of $P_0(s)$ in the same regions. We now introduce the following subsidiary statements:

- a₁) $\{\zeta_i^- : i = 1, \dots, k^-\} \cap \{-\bar{\pi}_i^+ : i = 1, \dots, \ell^+\} = \emptyset$.
- a₂) $\{\zeta_i^+ : i = 1, \dots, k^+\} \cap \{-\bar{\pi}_i^- : i = 1, \dots, \ell^-\} = \emptyset$.
- b₁) (A, B) is controllable.
- b₂) (A, E) is controllable.
- b₂') $C(-\bar{\alpha}I - A)^{-1}B \neq 0$ for all $\alpha \in \text{spec}(A)$.

It is clear that a) \Leftrightarrow a₁) and a₂), since imaginary axis poles or zeros of $P_0(s)$ can only belong to one of the sets in a). The lemma will be proved by establishing the following equivalences: a₁) \Leftrightarrow b₁); a₂) \Leftrightarrow b₂) \Leftrightarrow b₂') b₁), b₂') \Leftrightarrow c).

Let $P_0(s) = p(s)/q(s)$ where $p(s), q(s)$ are coprime polynomials and $q(s)$ is monic. Let $p(s)/r(s), q(s)/r(s)$ be normalized coprime factors of $P_0(s)$ over \mathcal{H}_∞ (so $r(s)$ is a monic polynomial of degree n).

$a_1) \Leftrightarrow b_1)$. Assume that (A, B) is not controllable. Then for some α ($\mathcal{R}e(\alpha) < 0$), $r(\alpha) = p(\alpha) = 0$. Since $p^*p + q^*q = r^*r$ then $q^*(\alpha)q(\alpha) = 0$. Therefore $q^*(\alpha) = \overline{q(-\bar{\alpha})} = 0$ since $p(s)$ and $q(s)$ are coprime. Thus $a_1)$ fails. Conversely, if $a_1)$ fails then for some α ($\mathcal{R}e(\alpha) < 0$), $p(\alpha) = q(-\bar{\alpha}) = 0$. This means that $r^*(\alpha)r(\alpha) = 0$ which implies $r(\alpha) = 0$, since $r(s)$ is Hurwitz. Therefore, $p(s)$ and $r(s)$ have a common factor. Since (C, A_0) is observable, so is (C, A) , which means that (A, B) is not controllable.

$a_2) \Leftrightarrow b_2)$. The proof is the same as for $a_1) \Leftrightarrow b_1)$ but with p and q interchanged and B and E interchanged.

$a_2) \Leftrightarrow b_2')$. Suppose $b_2')$ fails. It follows that there exists an α ($\mathcal{R}e(\alpha) < 0$) such that $r(\alpha) = p(-\bar{\alpha}) = 0$. Since $p^*p + q^*q = r^*r$, it follows that $q^*(\alpha)q(\alpha) = 0$ and hence, since $p(s)$ and $q(s)$ are coprime, that $q^*(\alpha) \neq 0$ and $q(\alpha) = 0$. Thus $a_2)$ fails. Conversely, if $a_2)$ fails, then we can write $P_0(s) = (s - \bar{\alpha})/(s + \alpha)P_1(s)$ where $\bar{\alpha}$ is a zero of $p(s)$, α is a zero of $q(s)$, and hence $P_1(s)$ has degree $n - 1$. We now find a normalized coprime factorization $P_1(s) = N_1(s)M_1(s)^{-1}$ over \mathcal{H}_∞ . Then $P_0(s) = ((s - \bar{\alpha})/(s + \alpha)N_1(s))M_1(s)^{-1}$ is a normalized coprime factorization. Therefore, since the degree of $((s - \bar{\alpha})/(s + \alpha)N_1(s), M_1(s))$ must be n , $-\alpha$ is in the spectrum of the matrix A . Finally, since normalized coprime factorizations are unique modulo a unitary constant then $b_2')$ fails.

$b_1), b_2') \Leftrightarrow c)$. Let $\alpha \in \text{spec}(A)$. Then $\alpha I + A^*$ is nonsingular since A is Hurwitz. Thus

$$\begin{aligned} \det(\alpha I - H) &= \det \begin{pmatrix} \alpha I - A & -\lambda^{-1}BB^* \\ \lambda^{-1}C^*C & \alpha I + A^* \end{pmatrix} \\ &= \det(\alpha I - A + \lambda^{-2}BB^*(\alpha I + A^*)^{-1}C^*C) \\ &\quad \cdot \det(\alpha I + A^*). \end{aligned} \quad (40)$$

Clearly

$$\begin{aligned} \det(\alpha I - H) \neq 0 &\Rightarrow B^*(\alpha I + A^*)^{-1}C^* \neq 0 \\ &\Leftrightarrow C^*(-\bar{\alpha}I - A)^{-1}B \neq 0. \end{aligned}$$

Thus $c) \Rightarrow b_2')$. Also, if (A, B) is not controllable, then there exists an $\alpha \in \text{spec}(A)$ such that $v^T(\alpha I - A) = 0$, $v^T B = 0$ for some $v \neq 0$. This implies by (40) that $\alpha \in \text{spec}(H)$. Thus $c) \Rightarrow b_1)$. Conversely, let $b_1), b_2')$ hold. Take $\alpha \in \text{spec}(A)$ and note that $\beta := \lambda^2 B^*(\alpha I + A^*)^{-1}C^* \neq 0$. We now claim that $\alpha I - A + \beta BC^*$ is nonsingular. To see this, note that $C^*(sI - A)^{-1}B = p(s)/q(s) = p(s)/\det(sI - A)$ (since $q(s)$ is monic) and that $p(s)$ and $\det(sI - A)$ have no common factor (since (A, B) is controllable and (C, A) is observable). Since

$$\begin{aligned} \det(1 + \beta C^*(sI - A)^{-1}B) \\ = \det(sI - A)^{-1} \det(sI - A + \beta BC^*) \end{aligned}$$

it follows that $\det(sI - A + \beta BC^*) = \det(sI - A) + \beta p(s)$, and hence that $\det(\alpha I - A + \beta BC^*) = \beta p(\alpha) \neq 0$. Therefore, $\alpha \notin \text{spec}(H)$ using (40). This proves $c)$. \square

We now follow the steps P1)–P3) outlined in Section III. Let λ be the largest solution of $\det L(\lambda) = 0$ in $[0, 1]$ and let $w_0 \neq 0$ solve $L(\lambda)w_0 = 0$. Then

$$v(t) = (I, 0)e^{Ht} \begin{pmatrix} \lambda^{-1}R \\ I \end{pmatrix} w_0$$

on $[0, \tau]$. This gives

$$\lambda x(t) = \begin{pmatrix} (C', 0)e^{Ht} & -\lambda^{-1}R \\ I & I \end{pmatrix} w_0 \quad \text{on } [0, \tau],$$

$$C'e^{A(t-\tau)}(I, 0)e^{H\tau} \begin{pmatrix} \lambda^{-1}R \\ I \end{pmatrix} w_0 \quad \text{on } [\tau, \infty)$$

by (9). Direct calculation shows that

$$\int_0^\tau e^{-st} e^{Ht} dt = -\partial_H(e^{-s\tau})e^{H\tau}$$

and

$$\int_\tau^\infty e^{-st} e^{A(t-\tau)} dt = e^{-s\tau}(sI - A)^{-1}.$$

Thus

$$\begin{aligned} \lambda \hat{x} &= C'(e^{-s\tau}(sI - A)^{-1}(I, 0) - (I, 0)\partial_H(e^{-s\tau})) \\ &\quad \cdot H\tau \begin{pmatrix} \lambda^{-1}R \\ I \end{pmatrix} w_0. \end{aligned} \quad (41)$$

We now assume that H is diagonalizable, for simplicity, and write $H = \sum_i w_i v_i^* \mu_i$. (In the proof of Theorem 1, we show that the result also holds without the assumption.) Thus, the term in parentheses in (41) can be written as

$$\sum_i ((sI - A)^{-1}e^{-s\tau}(I, 0) - \partial_{\mu_i}(e^{-s\tau})(I, 0))w_i v_i^*.$$

From (34) we see that

$$\begin{aligned} \partial_{\mu_i}((sI - A)^{-1}e^{-s\tau}) \\ = (\mu_i I - A)^{-1}(\partial_{\mu_i}(e^{-s\tau})I - (sI - A)^{-1}e^{-s\tau}) \end{aligned}$$

which gives

$$\lambda \hat{x} = -C' \left(\sum_i (\mu_i I - A) \partial_{\mu_i}((sI - A)^{-1}e^{-s\tau} X_i) \right)$$

where

$$X_i := (I, 0)w_i v_i^* e^{H\tau} \begin{pmatrix} \lambda^{-1}R \\ I \end{pmatrix} w_0.$$

We will now calculate $u = H_+ F^* \lambda x$. Then

$$\begin{aligned} u_1 &= -H_+ e^{s\tau} B^*(sI + A^*)^{-1} C^* C \\ &\quad \cdot \sum_i (\mu_i I - A) \partial_{\mu_i}((sI - A)^{-1}e^{-s\tau} X_i) \\ &= -\sum_i \partial_{\mu_i}(H_+ B^*(sI + A^*)^{-1} \\ &\quad \cdot C^* C(sI - A)^{-1}(\mu_i I - A)X_i) \end{aligned}$$

by Proposition 2. (Note that, with the aid of a partial fraction expansion, the proposition can be applied elementwise.) Using (15) we have

$$(sI + A^*)^{-1} C^* C(sI - A)^{-1} = -S(sI - A)^{-1} + (sI + A^*)^{-1} S.$$

Thus

$$\begin{aligned} \hat{u}_1 &= \sum_i \partial_{\mu_i}(B^* S(sI - A)^{-1}(\mu_i I - A)X_i) \\ &= -\sum_i B^* S(sI - A)^{-1} X_i \\ &= -B^* S(sI - A)^{-1} v(\tau). \end{aligned} \quad (42)$$

Now define

$$g_i(s) := C(\mu_i I - A)(sI - A)^{-1} e^{-s\tau} X_i.$$

Then

$$\begin{aligned} -\hat{u}_2 &= H_+(1 - E^*(sI + A^*)^{-1}C^*) \sum_i \partial_{\mu_i}(g_i(s)) \\ &= \sum_i \partial_{\mu_i}(g_i(s) - E^*H_+(sI + A^*)^{-1}C^*g_i(s)) \\ &= \sum_i \partial_{\mu_i}(g_i(s) - E^*\partial_{-A^*}C^*g_i(s)) \\ &= \sum_i (\partial_{\mu_i}g_i(s) - E^*(\mu_i I + A^*)^{-1} \\ &\quad \cdot (\partial_{\mu_i} - \partial_{-A^*})(C^*g_i(s))) \\ &= \sum_i ((1 - E^*(\mu_i I + A^*)^{-1}C^*)\partial_{\mu_i}(g_i(s))) \\ &\quad + E^*\partial_{-A^*} \left(\sum_i (\mu_i I + A^*)^{-1}C^*g_i(s) \right) \end{aligned} \quad (43)$$

Proposition 4: The following identity holds

$$\sum_i (\mu_i I + A^*)^{-1}C^*g_i(s) = 0.$$

In the proof of the proposition we will make use of the following fact.

Lemma 2: Let $X, Y \in \mathbb{C}^{n \times n}$ be such that

$$\text{rank}(X) + \text{rank}(Y) = n$$

and $X + Y$ be nonsingular. Then

$$Y(X + Y)^{-1}X = 0.$$

Proof: We assume that $0 < r := \text{rank}(X) < n$, otherwise the statement is trivial. We now write $X = X_1X_2$ and $Y = Y_1Y_2$, where $X_1 \in \mathbb{C}^{n \times r}$, $X_2 \in \mathbb{C}^{r \times n}$, $Y_1 \in \mathbb{C}^{n \times (n-r)}$ and $Y_2 \in \mathbb{C}^{(n-r) \times n}$. Thus

$$\begin{aligned} Y(X + Y)^{-1}X &= Y_1Y_2 \left((X_1, Y_1) \begin{pmatrix} X_2 \\ Y_2 \end{pmatrix} \right)^{-1} X_1X_2 \\ &= Y_1Y_2 \begin{pmatrix} X_2 \\ Y_2 \end{pmatrix}^{-1} (X_1, Y_1)^{-1} X_1X_2 \\ &= Y_1(0_{(n-r) \times r}, I_{(n-r) \times (n-r)}) \begin{pmatrix} I_{r \times r} \\ 0_{(n-r) \times r} \end{pmatrix} X_2 \\ &= 0. \end{aligned} \quad \square$$

Proof of Proposition 4 It is sufficient to show that

$$\sum_i U_i T V_i = 0 \quad (44)$$

for an arbitrary constant matrix T , where

$$\begin{aligned} U_i &= (\mu_i I + A^*)^{-1}, \\ V_i &= (\mu_i I - A)(I, 0)w_i v_i^* e^{H\tau} \begin{pmatrix} \lambda^{-1}R \\ I \end{pmatrix} w_0. \end{aligned}$$

In fact it is sufficient to prove (44) for an arbitrary T of rank one, since the general fact then follows by linear superposition.

We first take $T = z_j y^*$, where z_j is an eigenvector of A^* , i.e., $A^* z_j = \bar{\gamma}_j z_j$, and y^* is an arbitrary row vector. Observe that

$$e^{H\tau} \begin{pmatrix} \lambda^{-1}R \\ I \end{pmatrix} w_0 = \begin{pmatrix} v(\tau) \\ w(\tau) \end{pmatrix} = \begin{pmatrix} I \\ \lambda^{-1}S \end{pmatrix} v(\tau) \quad (45)$$

from (12)–(14). Thus

$$\begin{aligned} \sum_i U_i T V_i &= z_j y^* \left(\sum_i \frac{1}{\mu_i + \bar{\gamma}_j} (\mu_i I - A)(I, 0)w_i v_i^* \right) \\ &\quad \cdot \begin{pmatrix} I \\ \lambda^{-1}S \end{pmatrix} v(\tau) \\ &= z_j y^* \left((I, 0) \sum_i \frac{\mu_i}{\mu_i + \bar{\gamma}_j} w_i v_i^* - (A, 0) \right. \\ &\quad \cdot \left. \sum_i \frac{1}{\mu_i + \bar{\gamma}_j} w_i v_i^* \right) \begin{pmatrix} I \\ \lambda^{-1}S \end{pmatrix} v(\tau) \\ &= z_j y^* ((I, 0)H(H + \bar{\gamma}_j I)^{-1} \\ &\quad - (A, 0)(H + \bar{\gamma}_j I)^{-1}) \begin{pmatrix} I \\ \lambda^{-1}S \end{pmatrix} v(\tau) \\ &= z_j y^* ((0, \lambda^{-1}BB^*)(H + \bar{\gamma}_j I)^{-1} \\ &\quad \cdot \begin{pmatrix} I \\ \lambda^{-1}S \end{pmatrix} v(\tau)) \end{aligned} \quad (46)$$

Since, by assumption, $-\bar{\gamma}_j$ is distinct from the eigenvalues of H , we have

$$\begin{aligned} (H + \bar{\gamma}_j I)^{-1} &= \begin{pmatrix} A + \bar{\gamma}_j I & \lambda^{-1}BB^* \\ -\lambda^{-1}C^*C & -A^* + \bar{\gamma}_j I \end{pmatrix}^{-1} \\ &= \begin{pmatrix} \Delta^{-1} \lambda^{-1}C^*C^* (A + \bar{\gamma}_j I)^{-1} & \Delta^{-1} \end{pmatrix} \end{aligned}$$

where $\Delta = (-A^* + \bar{\gamma}_j I) + \lambda^{-2}C^*C(A + \bar{\gamma}_j I)^{-1}BB^*$. Note that Δ is nonsingular since $\det(H + \bar{\gamma}_j I) \neq 0$. Thus

$$\begin{aligned} (0, \lambda^{-1}BB^*)(H + \bar{\gamma}_j I)^{-1} \begin{pmatrix} I \\ \lambda^{-1}S \end{pmatrix} &= \lambda^{-2}BB^*\Delta^{-1}(C^*C + S(A + \bar{\gamma}_j I))(A + \bar{\gamma}_j I)^{-1} \\ &= \lambda^{-2}BB^*\Delta^{-1}(-A^* + \bar{\gamma}_j I)S(A + \bar{\gamma}_j I)^{-1}. \end{aligned}$$

We now claim that $B^*\Delta^{-1}(-A^* + \bar{\gamma}_j I) = 0$. It suffices to show that

$$\lambda^{-2}C^*C(A + \bar{\gamma}_j I)^{-1}BB^*\Delta^{-1}(-A^* + \bar{\gamma}_j I) = 0 \quad (47)$$

since $C(A + \bar{\gamma}_j I)^{-1}B \neq 0$ by Lemma 1 and C^* is a nonzero column vector. To show (47) let $Y = \lambda^{-2}C^*C(A + \bar{\gamma}_j I)^{-1}BB^*$ and $X = (-A^* + \bar{\gamma}_j I)$. Observe that $\Delta = X + Y$ is nonsingular and $\text{rank}(X) + \text{rank}(Y) = \text{rank}(\Delta)$. This follows since X is rank deficient and Y has rank at most one (B, C are vectors). Thus the conditions of Lemma 2 are satisfied and so $Y(X + Y)^{-1}X = 0$. This shows that (47) and hence (46) is zero. Since y^* is arbitrary in (46) and z_j is any eigenvector of A^* this proves that (44) holds for any $n \times n$ matrix T having range the span of the eigenvectors of A^* . This completes the proof if A is diagonalizable.

The same conclusion holds in the nondiagonalizable case as well. To see this consider a sequence of matrices A_k ($k = 1, 2, \dots$) tending to A , each of which is diagonalizable, and

let $P_k(s)$ ($k = 1, 2, \dots$) denote the corresponding perturbed transfer functions. It can be easily seen that $P_k(s) \rightarrow P(s)$ in the gap metric (this follows because the graph symbol F depends continuously on A ; see [16] for the definition and expressions for the gap metric). Further, due to the metric property of the gap (see, e.g. [16]) the optimal robustness radius $b_{\text{opt}}(P)$ depends continuously on $P(s)$. Since the largest root of $\det(L(\lambda)) = 0$ is $\lambda = \sqrt{1 - b_{\text{opt}}^2(P)}$, λ depends continuously on A as well. Clearly R and S depend continuously on A , hence so does $L(\lambda)$. Note that $L(\lambda)$ remains singular as A varies. Now suppose that $w_{0,k}$ are unit vectors satisfying $L_k(\lambda_k)w_{0,k} = 0$, $k = 1, 2, \dots$ (where L_k is defined via (16) for the case of each $P_k(s)$, respectively). Without loss of generality we can take $w_{0,k}$ to be a convergent sequence (otherwise we select an appropriate subsequence), and let the limit point be w_0 . Then $L(\lambda)w_0 = 0$, so this limit point can be taken as the definition of w_0 . Since H is assumed diagonalizable and since it depends continuously on A , we can assume that, in each case, H_k is also diagonalizable (possibly for k sufficiently large). Further, we can select eigenvectors for H_k tending to corresponding ones for H . Compiling the above, it is seen that Σ, U, TV_z depends continuously on the perturbations of A . By the earlier part of the proof this expression is identically zero in the case of each A_k . Thus in the limit it is also zero for the given $P(s)$ and A . This completes the proof. \square

Proposition 4 and (43) show that

$$u_2 = - \sum_i (1 - E^*(\mu_i I + A^*)^{-1} C^*) \partial_{\mu_i}(g_i(s)) \quad (48)$$

$$= - \sum_i M^*(\mu_i) \partial_{\mu_i}(g_i(s)). \quad (49)$$

We now expand $\partial_{\mu_i}(g_i(s))$ using (35) so that the ∂ -operator acts only on the infinite-dimensional element $e^{-s\tau}$

$$\begin{aligned} \partial_{\mu_i}(g_i(s)) &= C(\mu_i I - A) \partial_{\mu_i}((sI - A)^{-1} e^{-s\tau} X_i) \\ &= C(\mu_i I - A)(sI - A)^{-1} (\partial_{\mu_i}(e^{-s\tau}) I \\ &\quad - (\mu_i I - A)^{-1} e^{-\mu_i \tau} X_i) \\ &= C(sI - A)^{-1} (\mu_i I - A) X_i \partial_{\mu_i}(e^{-s\tau}) \\ &\quad - C(sI - A)^{-1} X_i e^{-\mu_i \tau}. \end{aligned}$$

Using the following equalities

$$\begin{aligned} &\sum \mu_i M^*(\mu_i) \partial_{\mu_i}(e^{-s\tau}) X_i \\ &= (I, 0) H M^*(H) \partial_H(e^{-s\tau}) e^{H\tau} \begin{pmatrix} \lambda^{-1} R \\ I \end{pmatrix} w_0, \\ &\sum A M^*(\mu_i) \partial_{\mu_i}(e^{-s\tau}) X_i \\ &= (A, 0) M^*(H) \partial_H(e^{-s\tau}) e^{H\tau} \begin{pmatrix} \lambda^{-1} R \\ I \end{pmatrix} w_0, \\ &\sum M^*(\mu_i) X_i e^{-\mu_i \tau} \\ &= (I, 0) M^*(H) \begin{pmatrix} \lambda^{-1} R \\ I \end{pmatrix} w_0 \end{aligned}$$

and (49) we obtain

$$\begin{aligned} \hat{u}_2 &= C(sI - A)^{-1} (I, 0) M^*(H) \begin{pmatrix} \lambda^{-1} R \\ I \end{pmatrix} w_0 \\ &\quad - C(sI - A)^{-1} B(0, \lambda^{-1} B^*) M^*(H) \partial_H(e^{-s\tau}) \\ &\quad \cdot \begin{pmatrix} I \\ \lambda^{-1} S \end{pmatrix} v(\tau). \end{aligned} \quad (50)$$

We are now ready to state the form of the optimal compensator.

Theorem 1: Let $P(s) = e^{-s\tau} P_0(s)$ be a single-input/single-output plant with $P_0(s) = C(sI - A_0)^{-1} B$ a minimal realization and $\tau > 0$. Suppose that $P_0(s)$ satisfies condition a) of Lemma 1. Then the optimal robustness radius for gap ball uncertainty is given by the formula

$$b_{\text{opt}}(P) = (1 - \lambda_{\text{max}}^2)^{1/2}$$

where λ_{max} is the largest solution of the transcendental equation $\det L(\lambda) = 0$ on $[0, 1]$ (which is defined by (16)). The transfer function of the optimal controller is given by

$$K_{\text{opt}}(s) = \frac{B^* S(sI - A)^{-1} B_1}{C(sI - A)^{-1} B_2 - C(sI - A)^{-1} B h(\tau, s)} \quad (51)$$

where $L(\lambda)w_0 = 0$

$$w_1 = \begin{pmatrix} \lambda^{-1} R \\ I \end{pmatrix} w_0,$$

$$B_1 = (I, 0) e^{H\tau} w_1,$$

$$B_2 = (I, 0) M^*(H) w_1,$$

$$h(\tau, s) = (0, \lambda^{-1} B^*) M^*(H) \partial_H(e^{-s\tau}) e^{H\tau} w_1$$

with R, S, H defined as in (5), (15), (11), and $\lambda = \lambda_{\text{max}}$ throughout.

Before proving the theorem we will establish the following result.

Lemma 3: Consider any (nonzero) strictly proper rational function $P_0(s)$. Then $b_{\text{opt}}(e^{-s\tau} P_0(s))$ is a strictly decreasing, continuous function of τ .

Proof: Let $P_0 = N_0/M_0$ be a normalized coprime factorization over \mathcal{H}_∞ . Then $(e^{-s\tau} N, M)$ varies continuously with τ in the \mathcal{H}_∞ norm. Thus $\| \Pi_- \begin{pmatrix} e^{-s\tau} N_0^* \\ M_0^* \end{pmatrix} \|_{\mathcal{H}_2}$ varies continuously with τ , and the same is true for $b_{\text{opt}}(e^{-s\tau} P_0(s))$ using (2). Thus, the statement of the lemma requires proof of the following fact

$$\Pi_- \begin{pmatrix} -e^{-s\tau_2} N_0^* \\ M_0^* \end{pmatrix}_{\mathcal{H}_2} > \Pi_- \begin{pmatrix} -e^{-s\tau_1} N_0^* \\ M_0^* \end{pmatrix}_{\mathcal{H}_2} \quad (52)$$

for $\tau_2 > \tau_1$ (cf. (2)). We will prove a slightly more general fact than (52). Let $F \in \mathcal{H}_\infty^{1 \times 2}$ be continuous (and non-constant) on the compactified right-half plane, co-inner and right invertible over \mathcal{H}_∞ . Let $\Phi(s) \in \mathcal{H}_\infty^{2 \times 2}$ be unitary ($\Phi^* \Phi = \Phi \Phi^* = I$) with $\det \Phi(s)$ not a constant. We will show that $\| \Pi_- \Phi^* F^* \|_{\mathcal{H}_2} > \| \Pi_- F^* \|_{\mathcal{H}_2}$. First note that, for any $\hat{x} \in \mathcal{H}_2$

$$\begin{aligned} \| \Pi_- \Phi^* F^* \hat{x} \|_2^2 &= \| \Pi_- \Phi^* \Pi_- F^* \hat{x} + \Pi_- \Phi^* \Pi_+ F^* \hat{x} \|_2^2 \\ &= \| \Pi_- \Phi^* \Pi_- F^* \hat{x} \|_2^2 + \| \Pi_- \Phi^* \Pi_+ F^* \hat{x} \|_2^2 \\ &= \| \Pi_- F^* \hat{x} \|_2^2 + \| \Pi_- \Phi^* \Pi_+ F^* \hat{x} \|_2^2. \end{aligned} \quad (53)$$

The second equality follows since the inner product

$$\langle \Pi_- \Phi^* \Pi_- F^* \hat{x}, \Pi_- \Phi^* \Pi_+ F^* \hat{x} \rangle = 0.$$

We now take \hat{x} to be the maximal vector for $\Pi_- F^*|_{\mathcal{H}_2}$ and write $\hat{v} = \Pi_+ F^* \hat{x}$. Let us suppose that $\Pi_- \Phi^* \hat{v} = 0$, i.e., the second term in (53) vanishes. This means that $\hat{v} = \Phi \hat{w}$ for some $\hat{w} \in \mathcal{H}_2$, so \hat{v} has a nontrivial inner factor. But this contradicts the fact that \hat{x} is outer and \hat{v}/\hat{x} is left invertible over \mathcal{H}_∞ for the assumed conditions on F [19]. This establishes the required result. \square

Proof of Theorem 1: Under the assumption that $H = H_\lambda$ is diagonalizable the result follows from Proposition 1, (2), and steps P1)–P3). It follows that $K_{\text{opt}}(s) = -\hat{u}_1/\hat{u}_2$, where \hat{u}_1 and \hat{u}_2 are given in (42) and (50). To show that the formula is also valid when H is not diagonalizable we use a perturbation argument. We break the reasoning into two steps.

Step 1: We claim that H_λ has distinct eigenvalues for almost all λ if the conditions of Lemma 1 hold. To see this we write $C(sI - A)^{-1}B = p(s)/r(s)$ where $p(s)$ and $r(s)$ are coprime and $r(s)$ has degree n (this is possible since (A, B) is controllable). We note that p^*p and r^*r are coprime (this follows as in the proof of $a_1 \leftrightarrow b_1$) in Lemma 1). Thus $\lambda^2 r^*r - p^*p$ has distinct roots for almost all λ (this follows by taking derivatives with respect to s , eliminating λ^2 to give a nonzero polynomial in s , and verifying that these root locations can only be achieved by finitely many λ). The claim now follows by noting that the eigenvalues of H_λ coincide with the zeros of the expression

$$1 - \lambda^{-2} C(sI - A)^{-1} B B^* (-sI - A^*)^{-1} C^*$$

which are the same as the zeros of $\lambda^2 r^*r - p^*p$.

Step 2: Suppose for some τ and $\lambda = \lambda_{\max}(\tau)$ that H_λ has repeated roots. Take a sequence τ_i ($i = 1, 2, \dots$) with $\tau_i < \tau$ and $\tau_i \rightarrow \tau$. By Lemma 3, $\lambda_i = \lambda_{\max}(\tau_i) < \lambda$ and $\lambda_i \rightarrow \lambda$. Using Step 1 we can assume, without loss of generality, that H_{λ_i} has distinct eigenvalues. Now suppose that w_i are unit vectors satisfying $L(\lambda_i)w_i$. Without loss of generality we can take w_i to be a convergent sequence (otherwise we select an appropriate subsequence), and let the limit point be w_0 . Then $L(\lambda)w_0 = 0$. Let \hat{x} be defined as in (41) with $H = H_\lambda$, and let \hat{x}_i be defined by the same equation but with w_0 replaced by w_i , τ replaced by τ_i and H by H_{λ_i} . We note that $\hat{x}_i \rightarrow \hat{x}$. Define $\hat{u} = \Pi_+ F^* \lambda \hat{x}$ and let $(\hat{u})_i$ be defined similarly but with \hat{x} replaced by \hat{x}_i and τ replaced by τ_i in F . Then $(\hat{u})_i \rightarrow \hat{u}$. The proof is now completed by noting that, with the first and second components of \hat{u} defined through (42) and (50), we also have $(\hat{u})_i \rightarrow \hat{u}$ by virtue of the fact that $M^*(H)$ and $\partial_H(e^{-s\tau})$ are continuous functions of H . Thus (42) and (50) are correct expressions even when H is not diagonalizable. \square

Remark 1: The form of $K_{\text{opt}}(s)$ given in (51) is the ratio of two \mathcal{H}_2 functions. Consequently, it is not a coprime factorization over \mathcal{H}_∞ since there will be a common zero at infinity. In fact it was proved in [19] that $(s+1)\hat{x}$ is a unit in \mathcal{H}_∞ and that \hat{u}/\hat{x} belongs to \mathcal{H}_∞ and is left invertible. Thus (51) becomes a coprime factorization over \mathcal{H}_∞ on multiplication of the numerator and denominator by $(s+1)$.

Remark 2: (On the failure of conditions of Lemma 1.) If the poles and zeros of $P_0(s)$ do not satisfy the genericity assumption a) of Lemma 1 then $M^*(H)$ may not be defined. Examples where such a situation arises are: $P_0(s) = (s-1)/(s(s+1))$ and $P_0(s) = (s+1)/(s(s-1))$. It seems to be the case in such situations, however, that $(I, 0)M^*(H)w_1$, as well as the second term in (50), is bounded in the limit as $P_0(s)$ is approached. If a well-defined limit can be proved to exist then the controller formula of Theorem 1 would also be valid in this sense when Lemma 1 fails, by virtue of known results about the continuity of \hat{u}/\hat{x} (see [25]).

Remark 3: It should be observed that the infinite dimensionality of $K_{\text{opt}}(s)$ is confined to the term $h(\tau, s)$, and more specifically to $\partial_H(e^{-s\tau})$. It is possible to approximate $\partial_H(e^{-s\tau})$ uniformly in the \mathcal{H}_∞ norm, which then implies that the corresponding finite dimensional controller converges to $K_{\text{opt}}(s)$ in the gap metric. (This follows since the corresponding coprime factors then converge in the \mathcal{H}_∞ norm, cf. Remark 1.) To approximate $\partial_H(e^{-s\tau})$ uniformly, it suffices to find a sequence of functions $f_k(s)$, with uniformly bounded \mathcal{H}_∞ norm, such that $e^{-s\tau}$ is approximated uniformly on any finite interval of the imaginary axis. If H has an eigenvalue of multiplicity r on the imaginary axis, however, then it is also necessary to have the first r derivatives of $f_k(s)$ tending to those of $e^{-s\tau}$ at that point. Possible choices satisfying these conditions are: $f_k(s) = 1/(1 + s\tau/k)^k$, $f_k(s) = (1 - 0.5s\tau/k)^k/(1 + 0.5s\tau/k)^k$ or general Padé approximants. An alternative approach to finite dimensional controller design for the \mathcal{H}_∞ design problem of this paper has been given in [19] which explores approximation of the time-domain vector $\iota(t)$.

Remark 4: An alternative approach to the design technique presented in this paper is to first approximate the plant $e^{-s\tau}P_0(s)$, or simply the delay element $e^{-s\tau}$, by a rational transfer function, and then design an optimal controller using finite-dimensional techniques. It is well known and an easy consequence of the metric property of the gap that the robustness radius $b_{\text{opt}}(\cdot)$ is a continuous function of the data (i.e., the system transfer function). Therefore, any controller designed using a finite-dimensional approximation of the plant model, which is close to the plant in the gap metric, will qualify as a suboptimal controller for the nominal model. The performance degradation will be reflected in a reduced value for $b_{P,K}$ and, accordingly, in an increased value for the \mathcal{H}_∞ -norm of $(\begin{smallmatrix} I \\ J \end{smallmatrix})(I + KP)^{-1}(I, K)$. In general, however, controllers obtained in this way may not be close in the gap to the optimal one. One such case where this occurs is when the maximal singular value of the operator Γ has multiplicity greater than one. Such an example is $P(s) = s/(s^2 + 1)$ (given in [17] and discussed in [32]). At the moment, sufficient conditions which guarantee the convergence of suboptimal controllers to the optimal one are not known.

VIII. DESIGN EXAMPLE

In this section we will use the formula in Theorem 1 to design a controller to achieve disturbance attenuation and robust set-point following for a delay system. We will take a plant with two lightly damped poles and a nontrivial delay.

Fig. 2. Scheme for optimal robustness controller.

Fig. 3. Smith predictor control system.

 Fig. 4. Bode plots of optimal robustness and Smith predictor compensators: K and K_s .

This type of system is a suitable nominal model in a number of process control applications. We will show that our design has significantly better performance than a Smith predictor.

The plant we will consider is

$$P(s) = e^{-1.5s} \frac{1}{s^2 + 0.2s + 1}.$$

We will demand increased damping of the oscillations in response to disturbances at the plant input, together with robust asymptotic tracking of constant reference inputs. To achieve these goals, we follow the H_∞ loop shaping (optimal robustness) design procedure of Glover-McFarlane [21]. We select an appropriate weighting function $W(s)$ and compute the optimal controller $K_W(s)$ for $W(s)P(s)$. The final controller for $P(s)$ is then given by $K(s) = K_W(s)W(s)$.

Since an integral term is required in the controller for robust tracking, a proportional-plus-integral weighting function $W(s) = k_p + k_i/s$ was selected. The values $k_p = 1.4$ and $k_i = 0.4$ were found to give an acceptable loop shape and a sufficiently large robustness margin of $b_{opt} = 0.3296$. (Increasing k_p and k_i gives larger loop gain but causes b_{opt}

 Fig. 7. Response of y to a unit step at r with optimal robustness and Smith predictor compensators.

to decrease.) The final $K(s)$ obtained is stable (except for the pole at $s = 0$) and is nonminimum phase as evidenced by the lagging phase characteristic between 0.3 and 1.0 rad/sec (see Fig. 4). A suitable implementation of the controller is shown

in Fig. 2, where $k_0 = K_W(0)$. (Note that the specifications are also met with $K(s)$ in the forward path and unity negative feedback. The arrangement of Fig. 2, however, ensures that the response from r to y is not adversely affected by the nonminimum phaseness of $K_W(s)$. Moreover, any admissible command response—a stable system with at least second order roll-off in series with a time delay of τ seconds—can be achieved in this setup using an additional stable filter outside the loop. In particular, the command response could be made the same as the Smith predictor below.)

The idea of the Smith predictor [27] is that a precompensator K_0 is designed for P_0 to give a desired command response from r to y in the delay-free situation. The precompensator

$$K_s = \frac{K_0}{1 + (1 - e^{-s\tau})P_0K_0}$$

stabilizes the plant $e^{-s\tau}P_0$, if P_0 is stable and gives the same command response but with a delay of τ seconds (see Fig. 3). For this example, K_0 was designed using the H_∞ loop shaping (optimal robustness) procedure using the same weighting function as above: $W(s) = 1.4 + 0.4/s$. This gives

$$K_0(s) = \frac{(2.302s^2 + 0.470s + 0.612)(s + 0.286)}{s(s^2 + 2.693s + 0.719)}.$$

The Bode plots for both compensators K and K_s are shown for comparison in Fig. 4. The Nyquist plots of the return ratio transfer functions PK and PK_s are shown in Fig. 5. Although there are some broad similarities in the forms of these plots, it should be pointed out that a basic property of the Smith predictor is that open loop poles of P_0 are cancelled by the zeros of the compensator K_s . Thus, the open-loop lightly damped poles in P are not shifted by feedback in Fig. 3, in contrast to the situation in Fig. 2. The adverse effects of this cancellation become evident if the response at the plant output y is compared to step disturbances d at the plant input (see Fig. 6). We remark that the bad properties of the Smith predictor in case the plant has poles near the imaginary axis, have already been noted in the literature, and this has led to modifications of the scheme being proposed [33].

Finally, a comparison of the command response to step inputs at r is shown in Fig. 7. Note that in Figs. 4–7 the solid line denotes the optimal robustness compensator and the broken line the Smith predictor.

He received the Ph.D. degree in mathematics from Massachusetts Institute of Technology, Cambridge, in 1965.

In 1960, Dr. Dym worked in the Communications Department of the MITRE Corp. Since 1970, he has been associated with the Department of Theoretical Mathematics of the Weizmann Institute of Science, Rehovot, Israel. His current research interests include the intersection of operator theory and complex analysis and their applications to problems of interpolation and approximation.

Tryphon T. Georgiou was born in Athens, Greece, on October 18, 1956. He received the Diploma in mechanical and electrical engineering from the National Technical University of Athens, Greece, in 1979 and the Ph.D. degree from the University of Florida, Gainesville, in 1983.

He served in the faculty of Florida Atlantic University from 1983–1986 and on the faculty of Iowa State University from 1986–1989. Since 1989, he has been with the University of Minnesota where he is currently a Professor of Electrical Engineering.

His research interests include control theory, signal processing, and applied mathematics.

Dr. Georgiou is a corecipient (with M. C. Smith) of the 1992 George Axelby Best Paper Award. He was an Associate Editor for IEEE TRANSACTIONS ON AUTOMATIC CONTROL from 1991–1992 and is currently an Associate Editor for the *SIAM Journal on Control and Optimization*.

Malcolm C. Smith (M'90) was born in Bolton, England, on June 12, 1957. He received the B.A. degree in mathematics in 1978, the M.Phil. degree in control engineering and operational research in 1979, and the Ph.D. degree in control engineering in 1982, all from Cambridge University, England.

He was subsequently a Research Fellow at the Institute for Flight Systems Dynamics, DLR, Germany, a Visiting Assistant Professor and Research Fellow with the Department of Electrical Engineering at McGill University, Canada, and an Assistant Professor with the Department of Electrical Engineering at Ohio State University, Columbus. Since 1990, he has been a lecturer in engineering at the University of Cambridge, England. His current research interests include the theory and practice of control engineering.

Dr. Smith is a corecipient (with T. T. Georgiou) of the 1992 George Axelby Best Paper Award. He is currently an Associate Editor for the *SIAM Journal on Control and Optimization*.

Stochastic System Identification with Noisy Input–Output Measurements Using Polyspectra

Jitendra K. Tugnait, *Fellow, IEEE*, and Yisong Ye, *Member, IEEE*

Abstract—Two new classes of parametric, frequency domain approaches are proposed for estimation of the parameters of scalar, linear “errors-in-variables” models, i.e., linear systems where measurements of both input and output of the system are noise contaminated. One of the proposed classes of approaches consists of linear estimators where using the bispectrum or the integrated polyspectrum (bispectrum or trispectrum) of the input and the cross-bispectrum or the integrated cross-polyspectrum (respectively, of the input–output), the system transfer function is first estimated at a number of frequencies exceeding one-half the number of unknown parameters. The estimated transfer function is then used to estimate the unknown parameters using an overdetermined linear system of equations. In the second class of approaches, quadratic transfer function matching criteria are optimized by using the results of the linear estimators as initial guesses. Both classes of the parameter estimators are shown to be consistent in any measurement noise that has symmetric probability density function when the bispectral approaches are used. The proposed parameter estimators are shown to be consistent in Gaussian measurement noise when trispectral approaches are used. The input to the system need not be a linear process but must have nonvanishing bispectrum or trispectrum. Computer simulation results are presented in support of the proposed approaches. Performance comparisons with several existing approaches based upon computer simulations are also provided.

I. INTRODUCTION

PARAMETER estimation and system identification for stochastic linear systems have been a topic of active research for over three decades now [7], [19], [20], [37], [45]. It is often assumed that the measurements of the system output are noisy but the measurements of the input to the system are perfect. The problem considered in this paper is that of identification of stochastic linear systems when the input as well as the output measurements are noisy. An interesting example of system identification with noisy input may be found in [38] where the problem of (off-line) estimation of certain parameters associated with the dynamics of a submerged undersea vehicle is studied. The various control inputs and the corresponding motion variables can only be remotely sensed and, hence, are contaminated with sensor noises. In multivariate time series problems where one is interested in exploring the relationship (transfer function) between two groups of variables, it is more logical to “symmetrically” model the system by allowing all

measured variables to be noisy [29]. Such models are called errors-in-variables models in the econometrics literature [6].

In this paper we consider a specific class of systems where the input process is non-Gaussian and the measurement noise at the input as well as the output is Gaussian if the input process has symmetric probability density function (PDF). The noise processes are allowed to be non-Gaussian with symmetric PDF if the input process has asymmetric PDF. Clearly, this model may not be always appropriate but there are several situations of practical interest where such assumptions are valid. For instance, a pseudo-random binary sequence is often used to probe a control system for identification purposes [7], [19], [20]; such sequences are clearly non-Gaussian with nonvanishing trispectrum. The problem of differential time delay estimation given measurements at two spatially separated sensors can also be cast in the framework of this paper [10]–[12], [26], [28].

Past approaches to the problem of stochastic linear system identification for errors-in-variables models may be divided into two classes: those that exploit only the second-order statistics and those that use higher (higher than second) order cumulant statistics. A good survey of the work done prior to about 1980 is given in [2]. For later work, see [3]–[9], [16]–[18], [29], and [32]. Higher order statistics have been exploited in [5], [6], [12]–[14], [31], [33]–[35], [39], [40], and [44]. Söderström [1], [2] allows only white additive noise at the input, and furthermore, the input and the output noises are assumed to be mutually uncorrelated. Most of the early work in this area has been done in econometrics. When only second-order statistics are exploited, it is known that, in general, there does not exist a unique solution [3]–[6], [9]. Therefore, attention has been focused on characterization of the class of transfer functions which fit the data.

The use of higher order cumulant statistics [23], [24] can, in principle, yield consistent parameter estimates. Deistler [5] (also [14]) has shown how to estimate the transfer function of a single-input/single-output (SISO) system in the frequency domain by use of the higher order cumulant spectrum of the output and the higher order cumulant cross-spectrum of the input–output record. Cross-cumulants between input–output have been exploited for FIR (finite impulse response) filter identification in [12] and [44]. Instrumental variable type approaches have been considered in [31] and [35] where the consistency results have been proven only for i.i.d. (independent and identically distributed) inputs. In [34] a novel cost function involving the third-order cumulants of the input–output data has been proposed, and it has been shown to

be proportional to a conventional mean-square error criterion based upon noiseless data. Consistency of the approach of [34] has been established under several restrictive conditions such as the system input is a linear process. Also [34] requires that the noise processes, if non-Gaussian with symmetric PDF, should be linear processes. In this paper we do not require any such constraints. It should be noted that unlike the second-order statistics case, one can not, in general, model a stationary random process with a given higher order cumulant spectrum as having been generated by driving a linear system with an i.i.d. sequence [27]. In [40] several linear/iterative approaches using the auto- and/or cross- third-order cumulants of the input-output processes have been presented. Conditions under which the proposed approaches will yield consistent parameter estimators have not been provided in [40].

In [28] and [39] the square root of the magnitude of the fourth cumulant of a generalized error signal is proposed as a performance criterion for parameter estimation. Both single-input single-output and multiple-input multiple-output models have been considered in [39]. Strong consistency of the proposed parameter estimator has been established for linear inputs in [39] for Gaussian noise processes. The approach of [28] and [39] results in a nonlinear estimator that requires a good initial guess for convergence; unfortunately, no method for reliable initialization was provided in [39].

In this paper two new classes of parametric frequency domain approaches are proposed for estimation of the parameters of scalar, linear errors-in-variables models. One of the proposed approaches is a linear estimator where using the bispectrum of the input and the cross-bispectrum of the input-output, the system transfer function is first estimated at a number of frequencies exceeding one-half the number of unknown parameters. The estimated transfer function is used to estimate the unknown parameters using an overdetermined linear system of equations. In the second approach a quadratic transfer function matching criterion is optimized by using the linear estimator as an initial guess. Both the parameter estimators are shown to be consistent in any measurement noise that has symmetric PDF. The input to the system need not be a linear process but must have nonvanishing bispectrum. These two classes of approaches can be modified to exploit integrated polyspectrum, either bispectrum or trispectrum. The integrated polyspectrum is defined as a cross-spectrum between the process and a nonlinear function of the process; see Section II for further details. As discussed in Section II, integrated polyspectrum (bispectrum or trispectrum) is computed as a cross-spectrum; hence, it is computationally cheaper than the corresponding polyspectrum particularly in the case of the fourth-order cumulant spectrum. If the non-Gaussian input to the linear system has a symmetric PDF, its bispectrum and the integrated bispectrum will vanish whereas its trispectrum and the integrated trispectrum will not, provided that the fourth cumulant of the input γ_{4u} is nonzero. Extension of the bispectrum-based approaches to trispectrum-based approaches is computationally complex, and the resulting estimators are likely to have poor statistical performance because of the high variance of the trispectrum estimators [24]. Herein lies the significance of the integrated polyspectrum-based approaches

which apply with almost equal computational and programming ease to both cases, those involving integrated bispectrum as well as those concerned with integrated trispectrum.

The paper is organized as follows. In Section II, a more precise statement of parameter estimation problem under consideration is provided along with a definition and some analysis of the integrated polyspectrum of interest in this paper. The bispectrum-based approaches are described in Section III. The integrated polyspectrum (bispectrum and trispectrum) based approaches are described in Section IV. Consistency of the proposed parameter estimators is established in Section V under some mild sufficient conditions. Finally, two simulation examples are presented in Section VI to illustrate the proposed approaches and to compare them with several existing approaches. Certain technical details may be found in the Appendix.

II. MODEL ASSUMPTIONS AND CUMULANT SPECTRA

Let $u(t)$ and $s(t)$ denote the "true" input and output, respectively, at (discrete) time t , related via a finite-dimensional ARMA(n_a, n_b) model

$$s(t) + \sum_{i=1}^{n_b} a_i s(t-i) = \sum_{i=1}^{n_a} b_i u(t-i). \quad (2-1)$$

As in [1] and [7], we have assumed for convenience only that no term $b_0 u(t)$ is present, i.e., there is at least one delay in the system. The processes $\{u(t)\}$ and $\{s(t)\}$ are not available for measurement. But we can measure noise-contaminated input and output

$$x(t) = u(t) + v_i(t) \quad (2-2)$$

$$y(t) = s(t) + v_o(t). \quad (2-3)$$

The model (2-1) is assumed to be exponentially stable and minimal, i.e., the following condition is assumed to be true.

H1) $A(z) = 1 + \sum_{i=1}^{n_b} a_i z^{-i} \neq 0$ for $|z| \geq 1$ where z is a complex variable. Moreover, $A(z)$ and $B(z) = \sum_{i=1}^{n_a} b_i z^{-i}$ are coprime (they have no common factors).

It is also assumed that all of the processes involved (i.e., $x(t)$, $y(t)$, $v_i(t)$, and $v_o(t)$) are zero-mean and jointly stationary. Furthermore, the noise sequences $\{v_i(t)\}$ and $\{v_o(t)\}$ are independent of $\{u(t)\}$, hence of $\{s(t)\}$.

Define the vector of the unknown parameters in the system model as

$$\theta(n_a, n_b) := (a_1, a_2, \dots, a_{n_b}, b_1, b_2, \dots, b_{n_a}). \quad (2-4)$$

Let θ_0 , n_{a0} and n_{b0} denote the true values of the respective vector/parameters. Also define the following set

$$\Theta(n_a, n_b) := \{\theta(n_a, n_b) | A(z; \theta(n_a, n_b)) \neq 0 \text{ for } |z| \geq 1\}$$

where $A(z; \theta(n_a, n_b))$ denotes $A(z)$ explicitly parameterized by $\theta(n_a, n_b)$. Where there is no risk of confusion, we will suppress explicit dependence upon the model orders, e.g., we will denote $\theta(n_a, n_b)$ by θ , $\Theta(n_a, n_b)$ by Θ , etc. The objective is to estimate the transfer function $B(z)/A(z)$ (equivalently, θ) given a data record $\{x(i), y(i), 1 \leq i \leq N\}$.

Consider the third-order cumulant function $C_{xy}(i, k)$ defined as

$$C_{xy}(i, k) := E\{x(t+i)x(t+k)y(t)\}. \quad (2-5)$$

Denote the cross-bispectrum of input/output by $B_{xy}(\omega_1, \omega_2)$, given by

$$B_{xy}(\omega_1, \omega_2) = \sum_{i=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} C_{xy}(i, k) \cdot \exp\{-j(\omega_1 i + \omega_2 k)\}. \quad (2-6)$$

Similarly, let $B_{xxx}(\omega_1, \omega_2)$ and $B_{sss}(\omega_1, \omega_2)$ denote the bispectra of the processes $\{x(t)\}$ and $\{s(t)\}$, respectively. From the above definitions it is easy to see that

$$C_{ssx}(i, k) = \frac{1}{(2\pi)^2} \int_{-\pi}^{\pi} \int_{-\pi}^{\pi} B_{ssx}(\omega_1, \omega_2) \cdot \exp\{j(\omega_1 i + \omega_2 k)\} d\omega_1 d\omega_2. \quad (2-7)$$

Define

$$w(t) := s^2(t) - E\{s^2(t)\} \quad \text{and} \quad v(t) := s^2(t). \quad (2-8)$$

Then both the cross-spectrum between the process $\{w(t)\}$ and $\{s(t)\}$ and the cross-spectrum between the process $\{w(t)\}$ and $\{s(t)\}$ are given by

$$\begin{aligned} S_{ws}(\omega) &:= \sum_{k=-\infty}^{\infty} E\{w(t+k)s(t)\} \exp\{-j\omega k\} \\ &= \sum_{k=-\infty}^{\infty} C_{ws}(k, k) \exp\{-j\omega k\} \\ &= S_{ws}(\omega) \end{aligned} \quad (2-9)$$

It then follows that

$$\begin{aligned} C_{ws}(k, k) &= \frac{1}{2\pi} \int_{-\pi}^{\pi} S_{ws}(\omega) \exp\{j\omega k\} d\omega \\ &= C_{ss}(0, -k) = C_{ss}^*(0, -k) \end{aligned} \quad (2-10)$$

where $*$ denotes complex conjugation. Compare (2-7) with (2-10) to deduce that

$$\begin{aligned} S_{ws}^*(\omega) &= \frac{1}{2\pi} \int_{-\pi}^{\pi} B_{ws}(\omega, \omega_2) d\omega_2 \\ &= \frac{1}{2\pi} \int_{-\pi}^{\pi} B_{ss}(\omega_1, \omega) d\omega_1 \\ &= S_{ss}^*(\omega). \end{aligned} \quad (2-11)$$

Notice that the cross-spectrum between the signal $s(t)$ and its square can be interpreted as an integrated bispectrum of $s(t)$. This integrated bispectrum will form a basis (along with the integrated trispectrum, to be defined later) for unknown parameter estimation. It is easy to see that since bispectrum of a Gaussian process is identically zero, so is its integrated bispectrum. Therefore, the integrated bispectrum of $\{y(t)\}$ equals the integrated bispectrum of $\{s(t)\}$. In the sequel it will be easier to work with the centered (zero-mean) $s^2(t)$, i.e., $w(t)$.

Turning to the trispectrum, it is defined as ([23] and [24])

$$T_{ssss}(\omega_1, \omega_2, \omega_3) := \sum_{i=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} C_{ssss}(i, k, l) \cdot \exp\{-j(\omega_1 i + \omega_2 k + \omega_3 l)\} \quad (2-12)$$

where

$$\begin{aligned} C_{ssss}(i, k, l) &:= E\{s(t)s(t+i)s(t+k)s(t+l)\} \\ &\quad - E\{s(t)s(t+i)\}E\{s(t+k)s(t+l)\} \\ &\quad - E\{s(t)s(t+k)\}E\{s(t+l)s(t+i)\} \\ &\quad - E\{s(t)s(t+l)\}E\{s(t+k)s(t+i)\} \\ &\quad + E\{s(t)s(t+k)s(t+i)\}E\{s(t+l)\} \end{aligned} \quad (2-13)$$

is the fourth-order cumulant function of the process $\{s(t)\}$. It then follows that

$$\begin{aligned} C_{ssss}(i, k, l) &= \frac{1}{(2\pi)^3} \int_{-\pi}^{\pi} \int_{-\pi}^{\pi} \int_{-\pi}^{\pi} T_{ssss}(\omega_1, \omega_2, \omega_3) \\ &\quad \cdot \exp\{j(\omega_1 i + \omega_2 k + \omega_3 l)\} \\ &\quad \cdot d\omega_1 d\omega_2 d\omega_3. \end{aligned} \quad (2-14)$$

Define

$$\tilde{r}(t) := s^3(t) - 3s(t)E\{s^2(t)\}$$

and

$$r(t) = \tilde{r}(t) - E\{\tilde{r}(t)\} \quad (2-15)$$

Then both the cross-spectrum between the process $\{r(t)\}$ and $\{s(t)\}$ and the cross-spectrum between the process $\{r(t)\}$ and $\{s(t)\}$ are given by

$$\begin{aligned} S_{rs}(\omega) &:= \sum_{k=-\infty}^{\infty} E\{r(t+k)s(t)\} \exp\{-j\omega k\} \\ &= \sum_{k=-\infty}^{\infty} C_{rs}(k, k) \exp\{-j\omega k\} \\ &= S_{rs}(\omega). \end{aligned} \quad (2-16)$$

It then follows that

$$\begin{aligned} C_{rs}(k, k, k) &= \frac{1}{2\pi} \int_{-\pi}^{\pi} S_{rs}(\omega) \exp\{j\omega k\} d\omega \\ &= C_{ssss}(0, 0, -k) \\ &= C_{ssss}^*(0, 0, -k). \end{aligned} \quad (2-17)$$

Compare (2-14) with (2-17) to deduce that

$$\begin{aligned} S_{rs}^*(\omega) &= \frac{1}{(2\pi)^2} \int_{-\pi}^{\pi} \int_{-\pi}^{\pi} T_{ssss}(\omega, \omega_2, \omega_3) d\omega_2 d\omega_3 \\ &= S_{rs}^*(\omega). \end{aligned} \quad (2-18)$$

Notice that the cross-spectrum between the signal $s(t)$ and a function of its cube can be interpreted as an integrated trispectrum of $s(t)$.

Given the above definitions we are now ready to state the remaining model assumptions.

Assumption Set I: Assume that the bispectra of the noise processes $\{v_i(t)\}$ and $\{v_o(t)\}$ are zero and that the noise processes are statistically independent of the process $\{u(t)\}$, hence of $\{s(t)\}$. It is also assumed that $B_{uuu}(\omega_1, \omega_2) \neq 0$ and that H1) holds. Assume that all moments of the various processes involved, viz., $s(t)$, $u(t)$ etc., exist. Also assume that the third and lower order cumulant/cross-cumulant sequences of the various processes involved, viz., $C_{sux}(\tau_1, \tau_2)$ etc., satisfy the following summability conditions

$$\sum_{\tau_1, \dots, \tau_{k-1} = -\infty}^{\infty} [1 + |\tau_j|] |C_{z_1 z_2 \dots z_k}(\tau_1, \dots, \tau_{k-1})| < \infty$$

for each $j = 2, \dots, k-1$ and each $k = 2, 3, \dots$ where $z_i(t) \in \{s(t), u(t), x(t), y(t), v_i(t), v_o(t)\}$. The above summability conditions are sufficient for the corresponding bispectrum to exist [24], [42], [43]. They are also sufficient for the asymptotic results concerning the bispectrum estimator discussed in Section III-A-1) and concerning the integrated bispectrum discussed in Section IV-A to hold. \square

Assumption Set II: In addition to those stated in Assumption Set I, assume that $\{u(t)\}$ is such that at least one of the following conditions hold true:

AS1) $E\{u^3(t)\} = \gamma_{3u} \neq 0$.

AS2) $\{u(t)\}$ is a finite-dimensional, linear non-Gaussian process generated by driving a bounded-input bounded-output linear filter by a zero-mean, i.i.d. sequence $\{\epsilon(t)\}$

$$u(t) = \sum g(i)\epsilon(t-i) \quad (2-19)$$

where $\{g(i), -\infty < i < \infty\}$ is the impulse response of the filter and $E\{\epsilon^3(t)\} \neq 0$. \square

Assumption Set III: Assume that the trispectra of the noise processes $\{v_i(t)\}$ and $\{v_o(t)\}$ are zero and that the noise processes are statistically independent of the process $\{u(t)\}$, hence of $\{s(t)\}$. Also assume that $T_{uuuu}(\omega_1, \omega_2, \omega_3) \neq 0$. It is assumed that H1) holds and that all moments of the various processes involved, viz., $s(t)$, $u(t)$ etc., exist. Also assume that the fourth and lower order cumulant/cross-cumulant sequences of the various processes involved, viz., $C_{suxy}(\tau_1, \tau_2, \tau_3)$ etc., satisfy the following summability conditions

$$[1 + |\tau_j|] |C_{z_1 z_2 \dots z_k}(\tau_1, \dots, \tau_{k-1})| < \infty$$

for each $j = 1, 2, \dots, k-1$ and each $k = 2, 3, \dots$ where $z_i(t) \in \{s(t), u(t), x(t), y(t), v_i(t), v_o(t)\}$. The above summability conditions are sufficient for the corresponding trispectrum (or cross-trispectrum) to exist [24], [42], [43]. They are also sufficient for the asymptotic results concerning the integrated trispectrum discussed in Section IV-A to hold. Assume also that $\{u(t)\}$ is such that at least one of the following conditions hold true:

AS3) $\gamma_{4u} := E\{u^4(t)\} - 3[E\{u^2(t)\}]^2 \neq 0$.

AS4) $\{u(t)\}$ is a finite-dimensional, linear non-Gaussian process as in AS2) except that now $\gamma_{4\epsilon} \neq 0$. \square

Suppose that Assumption AS1) is true. Then we can not have $S_{u^2u}(\omega) \equiv 0$ because then $\gamma_{3u} = 0$ contrary to the assumption. Suppose that Assumption AS2) is true. Then using (2-19) it can be shown that [23] and [24] $S_{u^2u}(\omega) = \gamma_{3\epsilon} G_2(-\omega)G(\omega)$, where $\gamma_{3\epsilon} = E\{\epsilon^3(t)\}$, $G(\omega) = \sum_{k=-\infty}^{\infty} g(k) \exp\{-j\omega k\}$ and $G_2(\omega) = \sum_{k=-\infty}^{\infty} g^2(k) e^{-j\omega k}$. It then follows that unless $G(\omega) \equiv 0$, we have $S_{u^2u}(\omega) \neq 0$. Thus, under either AS1) or AS2) (or both), the integrated bispectrum of $u(t)$ is nonvanishing. Turning to the integrated trispectrum, it follows that under Assumption AS3) (i.e., $\gamma_{4u} \neq 0$), we must have $S_{r_{uu}}(\omega) \neq 0$ (where $r_u(t) := u^3(t) - 3u(t)E\{u^2(t)\}$), else we have a contradiction. Under AS4), $\gamma_{4u} = \gamma_{4\epsilon} \sum_k g^4(k) \neq 0$ unless $G(\omega) \equiv 0$ or $\gamma_{4\epsilon} = 0$.

III. BISPECTRUM BASED APPROACHES

In this section two new parametric frequency domain approaches are proposed for estimation of the parameters of linear errors-in-variables models. One of the proposed approaches is a linear estimator where using the bispectrum of the input and the cross-bispectrum of the input-output, the system transfer function is first estimated at a number of frequencies exceeding one-half the number of unknown parameters. The estimated transfer function is used to estimate the unknown parameters using an overdetermined linear system of equations. In the second approach a quadratic transfer function matching criterion is optimized by using the linear estimator as an initial guess. The input to the system need not be a linear process but must have nonvanishing bispectrum. The estimators are later analyzed in Section V under Assumption Set I.

A. Linear Estimator

It follows from (2-1)–(2-3), (2-5), and (2-6) that

$$B_{xy}(\omega_1, \omega_2) = H^*(e^{j(\omega_1 + \omega_2)}) B_{xx}(\omega_1, \omega_2)$$

where $H(z) = \sum_{i=1}^n b_i z^{-i} / [1 + \sum_{i=1}^n a_i z^{-i}]$ and H^* is the complex conjugate of H . Therefore, if $B_{xx}(\omega_1, \omega_2) \neq 0$ then

$$H^*(e^{j(\omega_1 + \omega_2)}) = B_{xy}(\omega_1, \omega_2) / B_{xx}(\omega_1, \omega_2). \quad (3-1)$$

The above relation occurs in [5] and [41]. Our new linear approach is to first rewrite (3-1) as

$$H(e^{j\omega}) = B_{xy}^*(\omega_1, \omega - \omega_1) / B_{xx}^*(\omega_1, \omega - \omega_1). \quad (3-2)$$

Thus, for a given ω several estimates of $H(e^{j\omega})$ can be obtained from (3-2) by using different values of ω_1 . This, in turn, can be used to devise parametric estimators for the model coefficients; details are in Sections III-A-2), III-B, and III-C.

1) **Estimation of Bispectrum and Cross-Bispectrum:** We now discuss estimation of the bispectra given data $\{x(t), y(t), 1 \leq t \leq N\}$ and some large sample properties of the estimators. Of the various approaches available in [21], [22], [25], and [30], we will follow the approach of [22] and [30]. Suppose that the given sample sequence of length N is divided into K nonoverlapping segments each of size L_B samples so that $N = KL_B$. Let $X^{(i)}(\omega)$

denote the discrete Fourier transform (DFT) of the i th block $\{x(t + (i-1)L_B), 1 \leq t \leq L_B\}$ ($i = 1, 2, \dots, K$) given by

$$X^{(i)}(\omega_k) = \sum_{t=0}^{L_B-1} x(t + 1 + (i-1)L_B) \exp(-j\omega_k t) \quad (3-3)$$

where

$$\omega_k = \frac{2\pi}{L_B} k, \quad k = 0, 1, \dots, L_B - 1. \quad (3-4)$$

Similarly define $Y^{(i)}(\omega_k)$. Then the bispectrum estimate $\hat{B}_{xxx}(m, n)$ at bifrequency (ω_m, ω_n) is given by averaging the "biperiodograms" over K blocks and spatially smoothing over a rectangular window of size $M \times M$ where $M = 2\bar{M} + 1$ is an odd integer

$$\begin{aligned} \hat{B}_{xxx}(m, n) = & \frac{1}{M^2} \sum_{r=-\bar{M}}^{\bar{M}} \sum_{s=-\bar{M}}^{\bar{M}} \left[\frac{1}{K} \sum_{i=1}^K \right. \\ & \cdot \left(\frac{1}{L_B} X^{(i)}(\omega_{m+r}) X^{(i)}(\omega_{n+s}) \right. \\ & \cdot \left. [X^{(i)}(\omega_{m+r} + \omega_{n+s})]^* \right) \end{aligned} \quad (3-5)$$

and similarly we have

$$\begin{aligned} \hat{B}_{xxy}(m, n) = & \frac{1}{M^2} \sum_{r=-\bar{M}}^{\bar{M}} \sum_{s=-\bar{M}}^{\bar{M}} \left[\frac{1}{K} \sum_{i=1}^K \right. \\ & \cdot \left(\frac{1}{L_B} X^{(i)}(\omega_{m+r}) X^{(i)}(\omega_{n+s}) \right. \\ & \cdot \left. [Y^{(i)}(\omega_{m+r} + \omega_{n+s})]^* \right) \end{aligned} \quad (3-6)$$

The principal domain (nonredundant region) of $\hat{B}_{xxx}(m, n)$ is the triangular grid

$$\begin{aligned} D_{xxx} = & \{(m, n) | m = Mk - \bar{M}, n = Ml - \bar{M}, \\ & 1 \leq l \leq k \leq \frac{L_B}{2M} - l, (m, n) \in \bar{D}_{xxx}\} \end{aligned} \quad (3-7)$$

where $\bar{D}_{xxx} = \{(k, l) | 0 \leq k \leq L_B/2, 0 \leq l \leq k, 2k + l \leq L_B\}$. The principal domain of $\hat{B}_{xxy}(m, n)$ is a larger triangular grid [41]

$$D_{xxy} = D_{xxy}^{(1)} \cup D_{xxy}^{(2)} \quad (3-8)$$

where $D_{xxy}^{(1)} = \{(m, n) | m = Mk - \bar{M}, n = Ml - \bar{M}, 1 \leq l \leq k \leq L_B/2M, (m, n) \in \bar{D}_{xxy}, n \geq 0\}$, $D_{xxy}^{(2)} = \{(m, n) | (m, -n) \in D_{xxy}^{(1)}\}$ and $\bar{D}_{xxy} = \{(k, l) | 0 \leq k \leq L_B/2, -L_B/2 < l \leq L_B/2, k \geq |l|\}$.

Define $\Delta_N = M/L_B = MK/N$. The quantity Δ_N is a measure of the "bandwidth" of the bispectrum estimate. Under the cumulant summability condition stated in Assumption Set I, it follows from [24, Chapter VII], [42, Chapter 4], and [43] that

$$E\{\hat{B}_{xxx}(m, n)\} = B_{xxx}(\omega_m, \omega_n) + O(\Delta_N), \quad (3-9)$$

$$\begin{aligned} \text{var}\{\text{Re}\{\hat{B}_{xxx}(m, n)\}\} = & \frac{1}{2N\Delta_N^2} S_x(\omega_m) S_x(\omega_n) \\ & \cdot S_x(\omega_{m+n}) + O\left(\frac{1}{N\Delta_N}\right) \\ = & \text{var}\{\text{Im}\{\hat{B}_{xxx}(m, n)\}\} \end{aligned} \quad (3-10)$$

where $S_x(\omega_m)$ denotes the power spectral density of $\{x(t)\}$ at frequency $\omega_m = 2\pi m/L_B$. Note that $N\Delta_N^2 = KM^2/L_B$. Therefore, as $N \rightarrow \infty$ such that $\Delta_N \rightarrow 0$ and $N\Delta_N^2 \rightarrow \infty$, we obtain an unbiased and mean-square consistent estimator. Moreover, under the above asymptotic conditions, the estimate $\hat{B}_{xxx}(m, n)$ ($m, n \neq 0$), is complex Gaussian (with asymptotically independent real and imaginary parts), and independent of $\hat{B}_{xxx}(m', n')$ ($m', n' \neq 0$) if $m' \neq m$ and/or $n' \neq n$, such that both (m, n) and (m', n') are in the interior of D_{xxx} . (See [42, Section 4.2] for a definition of complex Gaussian random variables.) Similar results holds for cross-bispectrum estimates leading to

$$E\{\hat{B}_{xxy}(m, n)\} = B_{xxy}(\omega_m, \omega_n) + O(\Delta_N), \quad (3-11)$$

$$\begin{aligned} \text{var}\{\text{Re}\{\hat{B}_{xxy}(m, n)\}\} = & \frac{1}{2N\Delta_N^2} S_x(\omega_m) S_x(\omega_n) \\ & S_y(\omega_{m+n}) + O\left(\frac{1}{N\Delta_N}\right) \\ = & \text{var}\{\text{Im}\{\hat{B}_{xxy}(m, n)\}\}. \end{aligned} \quad (3-12)$$

The estimate $\hat{B}_{xxy}(m, n)$ ($m, n \neq 0$) is complex Gaussian (with asymptotically independent real and imaginary parts) and independent of $\hat{B}_{xxy}(m', n')$ ($m', n' \neq 0$) if $m' \neq m$ and/or $n' \neq n$, such that both (m, n) and (m', n') are in the interior of D_{xxy} . As noted before following (3-10), as $N \rightarrow \infty$ such that $\Delta_N \rightarrow 0$ and $N\Delta_N^2 \rightarrow \infty$, we obtain an unbiased and mean-square consistent estimator. One way to accomplish this is to choose $\Delta_N = N^{c-0.5}$ with $0 < c < 0.5$. In terms of K , M , and L_B , one may pick $K = 1$, $L_B = N$, and $M = N^{c+0.5}$ with $0 < c < 0.5$. Alternatively, one may choose $M = 1$, $L_B = N^{0.5-c}$, and $K = N^{0.5+c}$ with $0 < c < 0.5$. The smallest bias results with $c \rightarrow 0$ whereas the smallest variance occurs for $c \rightarrow 0.5$.

2) *Overdetermined Linear System of Equations:* Returning to (3-2) and using the estimates of the bispectrum and cross-bispectrum, we have

$$\begin{aligned} \hat{H}(\omega_n; \omega_m) := & \frac{\hat{B}_{xxy}(m, n-m)}{\hat{B}_{xxx}(m, n-m)} \quad \text{for } (m, n-m) \in D_{xxy} \\ \text{and} \end{aligned}$$

$$n = lM - \bar{M}, 1 \leq l \leq \frac{L_B}{2M} - 1.$$

Let $\hat{H}_B(e^{j\omega_n})$ denote the least-squares estimate of $H(e^{j\omega_n})$ given $\hat{H}(\omega_n; \omega_m)$ for a fixed n with m ranging over $(m, n-m) \in D_{xxy}$. Then we have

$$\begin{aligned} \hat{H}_B(e^{j\omega_n}) = & \frac{\hat{B}_{xxx}(m, n-m) \hat{B}_{xxy}^*}{\sum_{(m, n-m) \in D_{xxy}} |\hat{B}_{xxx}(m, n-m)|^2} \quad (3-13) \end{aligned}$$

for $n = lM - \bar{M}$, $1 \leq l \leq (L_B/(2M)) - 1$.

From the definition of $H(e^{j\omega})$ we have

$$-\sum_{i=1}^{n_a} a_i H(e^{j\omega_n}) e^{-j\omega_n i} + \sum_{i=1}^{n_b} b_i e^{-j\omega_n i} = H(e^{j\omega_n}) \quad (3-14)$$

for any ω_n . Noting that a_i 's and b_i 's are real and $H(e^{j\omega})$ is, in general, complex-valued, we rewrite (3-14) after replacing $H(e^{j\omega_n})$ with its least-square estimate $\hat{H}_B(e^{j\omega_n})$, as

$$-\sum_{i=1}^{n_a} a_i \operatorname{Re} \{ \hat{H}_B(e^{j\omega_n}) e^{-j\omega_n i} \} + \sum_{i=1}^{n_b} b_i \operatorname{Re} \{ e^{-j\omega_n i} \} = \operatorname{Re} \{ \hat{H}_B(e^{j\omega_n}) \} \quad (3-15)$$

and

$$-\sum_{i=1}^{n_a} a_i \operatorname{Im} \{ \hat{H}_B(e^{j\omega_n}) e^{-j\omega_n i} \} + \sum_{i=1}^{n_b} b_i \operatorname{Im} \{ e^{-j\omega_n i} \} = \operatorname{Im} \{ \hat{H}_B(e^{j\omega_n}) \}. \quad (3-16)$$

We solve (3-15) and (3-16) for a_i 's and b_i 's with $n = lM - \bar{M}$, $1 \leq l \leq L_B/2M - 1$ using an ordinary linear least-squares formulation.

B. Nonlinear Estimator

We follow a quadratic transfer function matching approach. Let $H(e^{j\omega}|\theta)$ denote the transfer function of (2-1) with the system parameters specified by the parameter vector θ as defined in (2-4). Define

$$H(e^{j(\omega_m + \omega_n)}) = \frac{B_{xy}^*(m, n)}{\hat{B}_{xx}^*(m, n)}. \quad (3-17)$$

The following result is from [24] and [43]. A proof of Lemma 1 also follows from the mean-square convergence implied by (3-9)–(3-12).

Lemma 1: Under the Assumption Set 1, we have $\lim_{N \rightarrow \infty} B_{xx}(m, n) = B_{xx}(\omega_m, \omega_n)$ i.p. (in probability), and $\lim_{N \rightarrow \infty} B_{xy}(m, n) = B_{xy}(\omega_m, \omega_n)$ i.p. •

Using Lemma 1 and the asymptotic distribution of the bispectrum estimators, the following useful result can be established.

Lemma 2: Under the Assumption Set 1 as $N \rightarrow \infty$, the following results are true for any fixed (ω_m, ω_n) and $(\omega_{m'}, \omega_{n'})$ in the interior of the set D_{xy} .

- A) $\Delta_N \sqrt{N} (H(e^{j(\omega_m + \omega_n)}) - H(e^{j(\omega_m + \omega_n)}|\theta_0))$ converges in distribution to the complex normal distribution $\mathcal{N}_c(0, \sigma_{mn}^2)$ where

$$\sigma_{mn}^2 = \frac{g(m, n) S_x(\omega_m) S_x(\omega_n) S_y(\omega_{m+n})}{|B_{xx}(\omega_m, \omega_n)|^2}.$$

$$g(m, n) = 1 + |\beta_{m, n}|^2 \frac{S_{xx}(\omega_{m+n})}{S_{yy}(\omega_{m+n})} - 2 \operatorname{Re} \left\{ \beta_{m, n} \frac{S_{xy}(\omega_{m+n})}{S_{yy}(\omega_{m+n})} \right\}$$

and $\beta_{m, n} = B_{xy}^*(\omega_m, \omega_n) / B_{xx}^*(\omega_m, \omega_n)$.

- B) $\hat{H}(e^{j(\omega_m + \omega_n)})$ and $\hat{H}(e^{j(\omega_{m'} + \omega_{n'})})$ are statistically independent for $(m, n) \neq (m', n')$. •

Sketch of Proof: It follows from the asymptotic results (3-7)–(3-12) discussed in Section III-A-1, Lemma 1, Slutsky's Theorem [36, Section 4.1], and [42, Theorem P5.2]. □

Lemma 2 motivates the following cost criterion which is the negative log-likelihood (up to some constants which do not depend upon θ) of the asymptotically complex Gaussian vector $\{\hat{H}(e^{j(\omega_m + \omega_n)})\}$, $(m, n) \in D_{xy}^0$ where D_{xy}^0 is the interior of D_{xy} . Choose θ to minimize the cost

$$\sum_{(m, n) \in D_{xy}^0} \frac{|\hat{B}_{xy}^*(m, n) - H(e^{j(\omega_m + \omega_n)}|\theta)|^2}{\sigma_{mn}^2} \quad (3-18)$$

In the above we have assumed that $\sigma_{mn}^2 \neq 0$. If this is not the case then we delete that particular value of (m, n) from the summation. In practice, $S_x(\omega_m)$ and $S_y(\omega_m)$ are unknown; therefore, we replace them by their consistent estimates obtained by block averaging and/or frequency-domain smoothing as in (3-5)–(3-5). Thus we have the following practical cost criterion

$$J_N^{(B)}(\theta) = \sum_{(m, n) \in D_{xy}^0} \frac{|\hat{B}_{xy}^*(m, n) - H(e^{j(\omega_m + \omega_n)}|\theta)|^2}{\hat{\sigma}_{mn}^2} \quad (3-19)$$

where

$$\hat{\sigma}_{mn}^2 = \hat{g}(m, n) \hat{S}_x(m) \hat{S}_x(n) \cdot S_y(m+n) / |\hat{B}_{xx}(m, n)|^2 \quad (3-20)$$

and $\hat{g}(m, n)$ follows similarly by replacing the variables in $g(m, n)$ with their consistent estimates. Mimicking Lemma 1 and using Slutsky's Theorem, it is easy to show that $\hat{\sigma}_{mn}^2$ tends to σ_{mn}^2 i.p. as $N \rightarrow \infty$ provided $B_{xx}(\omega_m, \omega_n) \neq 0$. Minimization of (3-19) w.r.t. θ is a nonlinear optimization problem that is initialized by the linear estimator obtained by solving (3-15) and (3-16).

C. Summary of Algorithms

Summarizing the above two algorithms, we fit an ARMA(n_a, n_b) model as follows.

- Given the record length N , select the block length L_B , number of blocks K , and the smoothing window size M . See the discussion in Section III-A-1 [following (3-12)] for possible choices.
- Estimate the required bispectra using (3-5) and (3-6), and the spectra \hat{S}_{xx} and \hat{S}_{yy} using similar equations.
- Estimate the model coefficients via an ordinary least-squares formulation using (3-13), (3-15)–(3-16). (Use all possible bifrequencies in (3-13) unless $|\hat{B}_{xx}(m, n - m)|$ is too small. Since the bispectrum estimates at distinct bifrequencies are approximately statistically independent, the estimates at distinct bifrequencies carry “new” information.) Stop if desired only linear estimators.

- iv) Using the estimate obtained in iii) as an initial guess, refine the model coefficient estimates by minimizing (3-19). Again, if possible, use all possible bifrequencies.

IV. INTEGRATED POLYSPECTRUM BASED APPROACHES

In this section, the frequency domain approaches presented in Section III are discussed using integrated polyspectra. As discussed in Section II, integrated polyspectrum (bispectrum or trispectrum) is computed as a cross-spectrum; hence, it is computationally cheaper than the corresponding polyspectrum particularly in the case of the fourth-order cumulant spectrum. If the non-Gaussian input to the linear system has a symmetric PDF, its bispectrum and the integrated bispectrum will vanish whereas its trispectrum and the integrated trispectrum will not, provided that the fourth cumulant of the input γ_{4u} is nonzero. Extension of the approaches of Section III to trispectrum-based approaches is computationally complex and the resulting estimators are likely to have poor statistical performance because of the high variance of the trispectrum estimators [24]. Herein lies the significance of the integrated polyspectrum-based approaches which apply with almost equal computational and programming ease to both cases, those involving integrated bispectrum as well as those concerned with integrated trispectrum.

A. Linear Estimator

Define

$$r_{2x}(t) = x^2(t) \quad (4-1)$$

and

$$r_{3x}(t) = x^3(t) - 3x(t)E\{x^2(t)\} - E\{x^3(t)\} \quad (4-2)$$

Replacing $x(t)$ with $u(t)$ in (4-2) yields $r_{3u}(t)$ which is identical to $r_{uu}(t)$ in Section II. In the following we will use the notation $r_{\tau}(t)$ to refer to both $r_{2x}(t)$ and $r_{3x}(t)$, meaning (4-1) when discussing integrated bispectrum and implying (4-2) when discussing integrated trispectrum.

Under the Assumption Set II (or III), we have

$$S_{r_{xx}}(\omega) = S_{r_{uu}}(\omega) = \sum_{k=-\infty}^{\infty} E\{r_x(t+k)y(t)\} \exp(-j\omega k).$$

It follows from (2-1)–(2-3) that under the Assumption Set II (or III)

$$S_{r_{xy}}(\omega) = H^*(e^{j\omega})S_{r_{xx}}(\omega)$$

where $H(z) = B(z)/A(z)$, $S_{r_{xx}}(\omega) = S_{r_{uu}}(\omega)$ and $S_{r_{xy}}(\omega) = S_{r_{yu}}(\omega)$. Therefore, if $S_{r_{xx}}(\omega) \neq 0$ then

$$H^*(e^{j\omega}) = S_{r_{xy}}(\omega)[S_{r_{xx}}(\omega)]^{-1}. \quad (4-3)$$

1) Estimation of Integrated Auto- and Cross-Polyspectrum:

We now discuss estimation of the integrated polyspectra given data $\{x(t), y(t), 1 \leq t \leq N\}$ and some large sample properties of the estimators. Suppose that the given sample sequence of length N is divided into K nonoverlapping segments each of size L_B samples so that $N = KL_B$. Let $X^{(i)}(\omega)$ denote the DFT of the i th block $\{x(t+(i-1)L_B), 1 \leq t \leq L_B\}$ ($i = 1, 2, \dots, K$) as in (3-3) and (3-4). Similarly let $R_x^{(i)}(\omega)$ denote the DFT of the i th block of $r_x(t)$ given by

$$R^{(i)}(\omega_k) = \sum_{t=0}^{L_B-1} [x^3(t+1+(i-1)L_B) - 3x(t+1+(i-1)L_B)\hat{\mu}_{2x}] \cdot \exp(-j\omega_k t), \quad (4-4)$$

$$\hat{\mu}_{2x} = \frac{1}{N} \sum_{t=1}^N x^2(t) \quad (4-5)$$

when $r_x(t) = r_{3x}(t)$ [see (4-2)], and by

$$R^{(i)}(\omega_k) = \sum_{t=0}^{L_B-1} x^2(t+1+(i-1)L_B) \exp(-j\omega_k t) \quad (4-6)$$

when $r_x(t) = r_{2x}(t)$ [see (4-1)]. To set the mean of $\{r_x(t)\}$ in the i th block to zero, simply set $R^{(i)}(0) = 0$. Then the estimate $\hat{S}_{r_x}(\omega_m)$ of $S_{r_x}(\omega_m)$ based upon the record $\{x(t), y(t), 1 \leq t \leq N\}$ is given by averaging the block periodograms over K blocks and spatially smoothing over a rectangular window of size M where $M = 2\bar{M} + 1$ is an odd integer

$$\hat{S}_{r_x}(\omega_m) = M^{-1} \sum_{l=-\bar{M}}^{\bar{M}} \left\{ \frac{1}{K} \sum_{i=1}^K \overline{R^{(i)}(\omega_{m+l})} \cdot R^{(i)}(\omega_{m+l}) \right\} \quad (4-7)$$

where $m = Ml - \bar{M}$, $1 \leq l \leq L_B/2M - 1$. The estimate $\hat{S}_{r_y}(\omega_m)$ is given similarly by

$$\hat{S}_{r_y}(\omega_m) = M^{-1} \sum_{l=-\bar{M}}^{\bar{M}} \left\{ \frac{1}{K} \sum_{i=1}^K \left[\frac{1}{L_B} R^{(i)}(\omega_{m+l}) \cdot [Y^{(i)}(\omega_{m+l})]^* \right] \right\} \quad (4-8)$$

where $m = Ml - \bar{M}$, $1 \leq l \leq L_B/2M - 1$.

Under the cumulant summability conditions stated in Assumption Set II (or III), it follows from [24, Chapter VII], [42, Problem 7.10.8], and [43] that for large N , the real and the imaginary parts of the estimate $\hat{S}_{r_{xy}}(\omega_m)$ ($m \neq 0$) are bivariate Gaussian, and $\hat{S}_{r_{xy}}(\omega_m)$ is independent of $\hat{S}_{r_{xy}}(\omega_n)$ ($n \neq 0$) for $m \neq n$ ($m, n = Ml - \bar{M}$, $1 \leq l \leq L_B/2M - 1$) such that

$$\begin{aligned} E\{\hat{S}_{r_{xy}}(\omega_m)\} &= S_{r_{xy}}(\omega_m) + O(\Delta_N), \\ \text{var}\{\text{Re}\{\hat{S}_{r_{xy}}(\omega_m)\}\} &= \frac{1}{2N\Delta_N} [S_{r_{xx}}(\omega_m)S_{yy}(\omega_m) \\ &\quad + \text{Re}\{S_{r_{xy}}^2(\omega_m)\}] + O(N^{-1}), \end{aligned} \quad (4-9)$$

$$\begin{aligned} & \text{cov} \{ \text{Re} \{ \hat{S}_{r_x y}(m) \}, \text{Im} \{ \hat{S}_{r_x y}(m) \} \} \\ &= \frac{1}{2N\Delta_N} \text{Im} \{ S_{r_x y}^2(\omega_m) \} + O(N^{-1}). \end{aligned} \quad (4-10)$$

In the above, as in Section III-A-1), $\Delta_N = M/L_B$ is the bandwidth of the cross-spectrum estimates. Moreover, as in Section III-A-1), we must have $\Delta_N \rightarrow 0$ and $N\Delta_N \rightarrow \infty$ as $N \rightarrow \infty$ to obtain an unbiased and mean-square consistent estimator. Similar results hold for $\hat{S}_{r_x x}(m)$.

2) *Overdetermined Linear System of Equations:* Returning to (4-3) we set

$$\hat{H}_{IP}(e^{j\omega_n}) = \hat{S}_{r_x y}^*(n) [\hat{S}_{r_x x}^*(n)]^{-1}. \quad (4-11)$$

Mimicking Section III-A-2), we solve (3-15) and (3-16) for a_l 's and b_l 's with $n = lM - \bar{M}$, $1 \leq l \leq L_B/2M - 1$ and using the above estimate of $\hat{H}_{IP}(e^{j\omega_n})$.

B. Nonlinear Estimator

We follow a quadratic transfer function matching approach. Let $H(e^{j\omega}|\theta)$ be as in Section III-B. Lemmas 3 and 4 are counterparts of Lemmas 1 and 2, respectively.

Lemma 3: Under the Assumption Set II (or III), we have $\lim_{N \rightarrow \infty} \hat{S}_{r_x x}(m) = S_{r_x x}(\omega_m)$ i.p. and $\lim_{N \rightarrow \infty} \hat{S}_{r_x y}(m) = S_{r_x y}(\omega_m)$ i.p. •

Lemma 4: Under the Assumption Set II (or III) as $N \rightarrow \infty$, the following results are true for any fixed $0 < \omega_m, \omega_{m'} < \pi$.

A) Let $H'_m = \sqrt{N\Delta_N} [\hat{H}_{IP}(e^{j\omega_m}) - H(e^{j\omega_m}|\theta_0)]$. Then $[\text{Re } H'_m \text{ Im } H'_m]^T$ converges in distribution to a real bivariate normal distribution $\mathcal{N}_2(0, \Sigma)$ where (Σ_{ij}) denotes the ij -element of matrix Σ) $\Sigma_{11} = \Gamma_1 + \text{Re } \Gamma_2$, $\Sigma_{22} = \Gamma_1 - \text{Re } \Gamma_2$, $\Sigma_{12} = \text{Im } \Gamma_2$

$$\begin{aligned} \Gamma_1 &= 0.5d(m)S_{r_x x}(\omega_m)S_{yy}(\omega_m)|S_{r_x x}(\omega_m)|^{-2}, \\ d(m) &= 1 + |\alpha_m|^2 \frac{S_{xx}(\omega_m)}{S_{yy}(\omega_m)} - 2\text{Re} \left\{ \alpha_m \frac{S_{xy}(\omega_m)}{S_{yy}(\omega_m)} \right\}, \\ \Gamma_2 &= 0 \end{aligned}$$

$$\text{and } \alpha_m = S_{r_x y}^*(\omega_m)/S_{r_x x}^*(\omega_m)$$

B) $\hat{H}_{IP}(e^{j\omega_m})$ and $\hat{H}_{IP}(e^{j\omega_{m'}})$ are statistically independent for $m \neq m'$. •

The negative log-likelihood of the asymptotically complex Gaussian vector $\{\hat{H}_{IP}(e^{j\omega_m}), m \in D_{r_x}\}$ where $D_{r_x} := \{m|m = lM - \bar{M}, 1 \leq l \leq (L_B/(2M)) - 1\}$, is similar to that in Section III-B. As in Section III-B, we choose θ to minimize the cost (cf. (3-19))

$$J_N^{(IP)}(\theta) = \sum_{m \in D_{r_x}} \frac{S_{r_x y}^*(m)}{S_{r_x x}^*(m)} - H(e^{j\omega_m}|\theta) \bigg/ \hat{\sigma}_m^2 \quad (4-12)$$

where

$$\hat{\sigma}_m^2 = \hat{d}(m)\hat{S}_{r_x x}(m)\hat{S}_{yy}(m)/|\hat{S}_{r_x x}(m)|^2 \quad (4-13)$$

and $\hat{d}(m)$ follows similarly by replacing the variables in $d(m)$ with their consistent estimates. As in Section III-B, it is easy to show that $\hat{\sigma}_m^2$ tends to σ_m^2 i.p. as $N \rightarrow \infty$ provided $S_{r_x x}(\omega_m) \neq 0$. Minimization of (4-12) w.r.t. θ is a nonlinear optimization problem that is initialized by the linear estimator of Section IV-A.

C. Summary of Algorithms

Summarizing the above two algorithms, we fit an ARMA(n_a, n_b) model as follows.

- i) This is same as item i) of Section III-C.
- ii) Estimate the required integrated polyspectra using (4-7) and (4-8), and the spectra $\hat{S}_{r_x x}$, $\hat{S}_{r_x y}$ and \hat{S}_{yy} using similar equations.
- iii) Estimate the model coefficients via an ordinary least-squares formulation using (4-11), (3-15), and (3-16) with $\hat{H}_B(\cdot)$ replaced with $\hat{H}_{IP}(\cdot)$. (Use all possible frequencies in (3-15) and (3-16) unless $|\hat{S}_{r_x x}(m)|$ is too small. Since the spectrum estimates at distinct frequencies are approximately statistically independent, the estimates at distinct frequencies carry "new" information.) Stop if desire only linear estimators.
- iv) Using the estimate obtained in iii) as an initial guess, refine the model coefficient estimates by minimizing (4-12). Again, if possible, use all possible frequencies as in iii) above.

V. CONSISTENCY

In this section we discuss the (weak) consistency of the proposed approaches (as $N \rightarrow \infty$). Let $H(e^{j\omega}; \theta_0)$ denote the transfer function of the true model (2-1) with $n_a = n_{a0}$, $n_b = n_{b0}$ and $\theta = \theta_0$. Consider the system of equations (3-14) rewritten as follows after replacing $H(e^{j\omega})$ with $H(e^{j\omega}; \theta_0)$

$$\begin{aligned} & - \sum_{i=1}^{n_a} a_i H(e^{j\omega_l}; \theta_0) e^{-j\omega_l i} + \sum_{i=1}^{n_b} b_i e^{-j\omega_l i} \\ &= H(e^{j\omega_l}; \theta_0), \quad 1 \leq l \leq L. \end{aligned} \quad (5-1)$$

Note that in (5-1) ω_l represents an arbitrary frequency, not necessarily equal to $2\pi l/L_B$.

The following result is central to the consistency results.

Lemma 5: Given the transfer function $H(e^{j\omega}; \theta_0)$ of model (2-1) at frequencies $0 < \omega_1 < \omega_2 < \dots < \omega_L < \pi$ such that $n_a + n_b \leq 2L$ and $\min(n_a - n_{a0}, n_b - n_{b0}) \geq 0$. Then the set of solutions to (5-1) is such that $H(e^{j\omega}; \theta) \equiv H(e^{j\omega}; \theta_0)$. •

Proof: If (5-1) is satisfied for some θ (defined in (2-4)), then $H(e^{j\omega_l}; \theta) = H(e^{j\omega_l}; \theta_0)$ for $1 \leq l \leq L$. Define

$$\begin{aligned} \bar{A}(z; \theta, \theta_0) &= A(z; \theta_0)B(z; \theta) \\ &= \left[\sum_{i=0}^{n_{a0}} a_i(\theta_0)z^{-i} \mid \sum_{i=1}^{n_b} b_i(\theta)z^{-i} \right] \\ &= \sum_{i=1}^{n_{a0}+n_b} \bar{a}_i(\theta, \theta_0)z^{-i} \end{aligned} \quad (5-2)$$

where $a_0(\theta_0) := 1$ so that $\bar{a}_1(\theta, \theta_0) = b_1(\theta)$. Also define

$$\begin{aligned} \bar{B}(z; \theta, \theta_0) &= A(z; \theta)B(z; \theta_0) \\ &= \left[\sum_{i=0}^{n_a} a_i(\theta)z^{-i} \mid \sum_{i=1}^{n_{b0}} b_i(\theta_0)z^{-i} \right] \\ &= \sum_{i=1}^{n_a+n_{b0}} \bar{b}_i(\theta, \theta_0)z^{-i} \end{aligned} \quad (5-3)$$

where $a_0(\theta) := 1$ so that $\bar{b}_1(\theta, \theta_0) = b_1(\theta_0)$. Clearly if $H(e^{j\omega_l}; \theta) = H(e^{j\omega_l}; \theta_0)$ for some l , then

$$\bar{A}(e^{j\omega_l}; \theta, \theta_0) = \bar{B}(e^{j\omega_l}; \theta, \theta_0) \quad (5-4)$$

since $H(e^{j\omega}; \theta) = B(e^{j\omega}; \theta)A^{-1}(e^{j\omega}; \theta)$ for any ω and θ . Using (5-2) and (5-3) this in turn implies that

$$\sum_{i=1}^{\bar{n}} [\bar{a}_i(\theta, \theta_0) - \bar{b}_i(\theta, \theta_0)] e^{-j\omega_l i} = 0 \quad (5-5)$$

where $\bar{n} = \max(n_{a0} + n_b, n_a + n_{b0})$ and we define $\bar{a}_i(\theta, \theta_0) = 0$ for $n_{a0} + n_b + 1 \leq i \leq \bar{n}$ and $\bar{b}_i(\theta, \theta_0) = 0$ for $n_a + n_{b0} + 1 \leq i \leq \bar{n}$. Since the coefficients $\bar{a}_i(\theta, \theta_0)$'s and $\bar{b}_i(\theta, \theta_0)$'s are real-valued, it also follows from (5-5) that

$$\sum_{i=1}^{\bar{n}} [\bar{a}_i(\theta, \theta_0) - \bar{b}_i(\theta, \theta_0)] e^{j\omega_l i} = 0. \quad (5-6)$$

By the hypothesis of the lemma, (5-5) and (5-6) are true for $1 \leq l \leq L$. This implies that the $(\bar{n} - 1)$ -degree polynomial equation

$$\sum_{i=0}^{\bar{n}-1} [\bar{a}_{i+1}(\theta, \theta_0) - \bar{b}_{i+1}(\theta, \theta_0)] z^i = 0 \quad (5-7)$$

has $2L$ roots. Under the hypothesis of the lemma, $2L \geq n_a + n_b \geq \bar{n}$ because $\min(n_a - n_{a0}, n_b - n_{b0}) \geq 0$. Now (5-7) can have only $\bar{n} - 1 < 2L$ roots; hence, we must have

$$\bar{a}_{i+1}(\theta, \theta_0) = \bar{b}_{i+1}(\theta, \theta_0) \quad \text{for } 0 \leq i \leq \bar{n} - 1 \quad (5-8)$$

leading to $H(e^{j\omega}; \theta) \equiv H(e^{j\omega}; \theta_0)$. \square

A. Bispectrum Based Approaches

Lemma 5 combined with the results of Theorems 1 and 2 (discussed later) motivate the following definition of persistence of excitation of inputs to linear systems for the purpose of consistent parameter estimation using the bispectrum. This is completely analogous to the concept of persistent excitation when using second-order statistics (see [7, Section 5.4]). Similar to the second-order case, if the input is persistently exciting as defined below, the matrix F_∞ defined in the proof of Theorem 1 will have full rank, leading to parameter identifiability.

Definition 1: A stationary input $\{u(t)\}$ is persistently exciting of order L w.r.t. the bispectral statistics if its bispectrum $B_{uuu}(\omega_m, \omega_n)$ is nonzero at L distinct bifrequencies in the interior of its principal domain.

Theorem 1: The linear parameter estimator discussed in Section III-A is (weakly) consistent under the Assumption Set I if (3-15) and (3-16) are solved at L frequencies $0 < \omega_1 < \omega_2 < \dots < \omega_L < \pi$ such that $n_a + n_b \leq 2L$, $\min(n_a - n_{a0}, n_b - n_{b0}) = 0$, and $B_{uuu}(\omega_m, \omega_{n-m}) \neq 0$ for all bifrequencies used in (3-13).

Proof: Equations (3-15) and (3-16) can be expressed as a linear system of equations

$$F_N \theta = f_N \quad (5-9)$$

where θ is the $(n_a + n_b)$ -column vector of unknown parameters, the matrix F_N is $2L \times (n_a + n_b)$ consisting of appropriate parts of the left side of (3-15) and (3-16), and f_N is an $2L$ -column vector consisting of the right side of (3-15) and (3-16). By (3-13), Lemma 1, and Slutsky's Theorem

$$\lim_{N \rightarrow \infty} \hat{H}_B(e^{j\omega_n}) = H(e^{j\omega_n}; \theta_0) \text{ i.p.} \quad (5-10)$$

Let F_∞ and f_∞ denote F_N and f_N , respectively, when the transfer function estimates are replaced with their true values. Then by Slutsky's Theorem we have

$$\lim_{N \rightarrow \infty} F_N = F_\infty \text{ i.p.} \quad \text{and} \quad \lim_{N \rightarrow \infty} f_N = f_\infty \text{ i.p.} \quad (5-11)$$

Since $\min(n_a - n_{a0}, n_b - n_{b0}) = 0$, by Lemma 5, (3-15) and (3-16) have a unique solution given by $\theta = \theta_0$ provided that $\hat{H}_B(e^{j\omega_n}) = H(e^{j\omega_n}; \theta_0)$ in (3-15) and (3-16). Hence, F_∞ has full rank so that $[F_\infty^T F_\infty]^{-1}$ exists; therefore, by Slutsky's Theorem and (5-11), $\lim_{N \rightarrow \infty} [F_N^T F_N]^{-1} = [F_\infty^T F_\infty]^{-1}$ i.p. Similar arguments lead to

$$\begin{aligned} \hat{\theta}_N &:= [F_N^T F_N]^{-1} F_N^T f_N \\ \hat{\theta}_0 &:= [F_\infty^T F_\infty]^{-1} F_\infty^T f_\infty \quad \text{as } N \rightarrow \infty. \end{aligned} \quad (5-12)$$

This proves the desired result. \square

Define

$$\hat{\theta}_N := \arg \left\{ \inf_{\theta \in \Theta_c} J_N^{(B)}(\theta) \right\} \quad (5-13)$$

where $J_N^{(B)}(\theta)$ is given by (3-19) and $\Theta_c \subset \Theta$ is a compact set. Convergence of this nonlinear estimator is discussed next.

Theorem 2: Suppose that Assumption Set I holds and $J_N^{(B)}(\theta)$ utilizes at least L distinct bifrequencies (ω_m, ω_n) in the interior of the principal domain of $B_{uuu}(\omega_m, \omega_n)$ such that $n_a + n_b \leq 2L$, and $B_{uuu}(\omega_m, \omega_n) \neq 0$ for all bifrequencies used in (3-19). If $\theta_0 \in \Theta_c$, then $\hat{\theta}_N$ defined in (5-13) converges i.p. to a set D_0 as $N \rightarrow \infty$ where

$$D_0 = \left\{ \theta \mid \frac{B(z; \theta)}{A(z; \theta)} = \frac{B(z; \theta_0)}{A(z; \theta_0)} \right\}.$$

Proof: See the Appendix. \square

The following corollary follows from Theorem 2 and some standard results (see, e.g., [7, Section 6.3]). The additional condition imposed in Corollary 1 ensures that the set D_0 consists of a single element θ_0 .

Corollary 1: Under the hypotheses of Theorem 2, if $\min(n_a - n_{a0}, n_b - n_{b0}) = 0$, then $\hat{\theta}_N$ converges i.p. to θ_0 as $N \rightarrow \infty$.

B. Integrated Polyspectrum Based Approaches

The following results mimic the corresponding results of Section V-A with obvious modifications. Therefore, we will simply state the main results without any proofs.

Definition 2: A stationary input $\{u(t)\}$ is persistently exciting of order L w.r.t. the integrated polyspectral statistics if its integrated polyspectrum $S_{r_{uu}}(\omega)$ is nonzero at L distinct frequencies in the interval $(0, \pi)$. •

Theorem 3: The integrated polyspectrum-based linear parameter estimator discussed in Section IV-A is (weakly) consistent under the Assumption Set II (or III) if (3-15) and (3-16) are solved (after replacing $\hat{H}_B(e^{j\omega_n})$ with $\hat{H}_{IP}(e^{j\omega_n})$) at L frequencies $0 < \omega_1 < \omega_2 < \dots < \omega_L < \pi$ such that $n_a + n_b \leq 2L$, $\min(n_a - n_{a0}, n_b - n_{b0}) = 0$, and $S_{r_{uu}}(\omega_m) \neq 0$ for all frequencies used in (3-15) and (3-16). •

Theorem 4: Consider the nonlinear parameter estimator defined by

$$\hat{\theta}_N := \arg \left\{ \inf_{\theta \in \Theta_C} J_N^{(IP)}(\theta) \right\}$$

where $\Theta_C \subset \Theta$ is a compact set. Suppose that Assumption Set II (or III) holds and $J_N^{(IP)}(\theta)$ utilizes at least L distinct frequencies ω_m in the interval $(0, \pi)$ such that $n_a + n_b \leq 2L$, $\min(n_a - n_{a0}, n_b - n_{b0}) = 0$, and $S_{r_{uu}}(\omega_m) \neq 0$ for all frequencies used in (4-12). If $\theta_0 \in \Theta_C$, then $\hat{\theta}_N$ converges i.p. to θ_0 as $N \rightarrow \infty$. •

VI. SIMULATION EXAMPLES

We now present two simulation examples to illustrate the proposed approaches. Example 1 is from [39], and Example 2 is from [34] and [40]. In both the examples the proposed approaches were applied using a block length $L_B = 64$ and a smoothing window $M = 1$ ($\bar{M} = 0$, i.e., no smoothing). The software package NL2SOL [15] was used for nonlinear optimization using the results of the linear approaches as initial guesses. Also the nonlinear cost functions were simplified somewhat by setting $\hat{g}(m, n) \equiv 1$ in (3-20) and $\hat{d}(m) \equiv 1$ in (4-13); this has no effect on the consistency results but will influence the accuracy of the estimates.

A. Example 1 [39]

The system to be identified is given by

$$\begin{aligned} s(t) &= 1.5s(t-1) - 0.7s(t-2) \\ &+ u(t-1) - 0.5u(t-2). \end{aligned} \quad (6-1)$$

Thus, we have $b_1 = 1.0$, $b_2 = -0.5$, $a_1 = -1.5$, and $a_2 = 0.7$. The input $\{u(t)\}$ is generated as

$$u(t) = 0.3u(t-1) + e(t) \quad (6-2)$$

where $\{e(t)\}$ is an i.i.d. binary sequence with values one and -1 , each with probability 0.5. Thus, we have $E\{e^2(t)\} = 1$, $\gamma_{3e} = 0$, and $\gamma_{4e} = -2$. The noisy input-output observations are given by (2-2) and (2-3). The mutually uncorrelated colored Gaussian noises $\{v_i(t)\}$ and $\{v_o(t)\}$ are generated as

$$v_i(t) = 0.8v_i(t-1) + f_i(t), \quad (6-3)$$

$$v_o(t) = -0.9v_o(t-1) + f_o(t) \quad (6-4)$$

where $\{f_i(t)\}$ and $\{f_o(t)\}$ are mutually independent i.i.d., zero-mean Gaussian sequences. The variances of $f_i(t)$ and

$f_o(t)$ are selected to yield a signal to noise power ratio of 20 dB at the input sensor and the output sensor, respectively.

Thirty independent realizations of 4000 input-output data pairs were generated. The methods proposed in Section IV-A were applied using the integrated trispectrum, along with several existing approaches. For the linear estimator, we used $1 \leq l \leq L_B/2 - 1 = 30$, i.e., 30 frequency points in the interval $(0, \pi)$. The nonlinear estimator minimizing $J_N^{(IP)}(\theta)$ given by (4-12) was initialized by the linear estimator. The frequency points used in (4-12) were as that for the linear estimator.

Table I displays the arithmetic means, standard deviations and root mean-square (RMS) errors of the results of the various parameter estimators. The approach of [39] is based upon the fourth cumulant of a generalized error signal at zero lag, and the approach of [35] uses the fourth-order cross- and auto-cumulants of the input-output data at various lags. The results pertaining to the approach of [35] have been taken from [35]. For comparison the results of a least-squares criterion (labeled MSE in Table I) are also shown. It is seen that the MSE criterion relying only on the second-order statistics of the input-output record, produces a substantial bias (and low variance) for this example whereas the proposed frequency-domain approaches proposed in this paper yield very good results: the variance is comparable to the MSE criterion and the bias is much reduced. The proposed approaches perform much better than the approaches of [39] and [35].

B. Example 2 [34], [40]

The system to be identified is given by

$$\begin{aligned} s(t) &= 1.5s(t-1) - 0.7s(t-2) \\ &+ u(t) + 0.5u(t-1). \end{aligned} \quad (6-5)$$

Thus, we have $b_0 = 1.0$, $b_1 = 0.5$, $a_1 = -1.5$, and $a_2 = 0.7$.

The input $\{u(t)\}$ is obtained as

$$u(t) = e(t) - 0.2e(t-1) + 0.3e(t-2) \quad (6-6)$$

where, $\{e(t)\}$ is an i.i.d., zero-mean, unit variance (one-sided) exponential sequence. Thus, we have $E\{e^2(t)\} = 1$, and $\gamma_{3e} = 2$. The noisy input-output observations are given by (2-2) and (2-3). The mutually correlated colored Gaussian noises $\{v_i(t)\}$ and $\{v_o(t)\}$ are generated as

$$\begin{aligned} v_i(t) = & f_i(t) - 2.33f_i(t-1) + 0.75f_i(t-2) \\ & + 0.5f_i(t-3) + 0.3f_i(t-4) \\ & - 1.4f_i(t-5), \end{aligned} \quad (6-7)$$

$$\begin{aligned} v_o(t) = & v_i(t) + 0.2v_i(t-1) \\ & - 0.3v_i(t-2) + 0.4v_i(t-3) \end{aligned} \quad (6-8)$$

where $\{f_i(t)\}$ is an i.i.d., zero-mean Gaussian sequence. The variances of $v_i(t)$ and $v_o(t)$ are selected to yield a signal to noise variance ratio of 5 dB at the input sensor and the output sensor, respectively.

One hundred independent realizations of 4000 input-output data pairs were generated. The methods proposed in Sections III-B and IV-A (integrated bispectrum based) were applied along with several existing approaches. The nonlinear estimator minimizing $J_N^{(IP)}(\theta)$ given by (4-12) was initialized by the linear estimator of Section IV-A for which we used $1 \leq l \leq L_B/2 - 1 = 30$, i.e., 30 frequency points in the interval $(0, \pi)$. The frequency points used in (4-12) were identical to that for the linear estimator. A similar procedure was followed for minimization of $J_N^{(B)}(\theta)$ where we selected all the frequency points in the interior of D_{FFV} .

Table II displays the arithmetic means, standard deviations and root mean-square (RMS) errors of the results of the various parameter estimators. The approach of [31] uses the third-order cross- and auto-cumulants of the input-output data at various lags; so do the approaches of [34] and [40]. The results pertaining to the approaches of [34] and [40] have been quoted from [40]. It is seen from Table II that the frequency-domain approaches proposed in this paper yield the best results and the approaches of [31] and [34] the worst.

Note that $\hat{\theta}_N$ minimizing $J_N^{(B)}(\theta)$ is, asymptotically, a maximum likelihood parameter estimator under the restriction that only the third-order statistics are used. The other approaches ([31], [34], and [40]) also restrict themselves to third-order statistics of input-output record, but are not maximum likelihood. Since maximum likelihood parameter estimators are, in general, efficient, the proposed nonlinear estimator is expected to outperform other "nonoptimal" approaches. This seems to be the case for the simulation example considered here. Similar remarks are apply to integrated polyspectrum-based approaches.

VII. CONCLUSIONS

Two new classes of parametric frequency domain approaches were presented for estimation of the parameters of scalar, linear errors-in-variables models. One of the proposed classes of approaches consists of linear estimators where

the bispectrum or the integrated polyspectrum (bispectrum or trispectrum) of the input and the cross-bispectrum or the integrated cross-polyspectrum, respectively, of the input-output are exploited. Based on these polyspectra the system transfer function is first estimated at a number of frequencies exceeding one-half the number of unknown parameters. The estimated transfer function is then used to estimate the unknown parameters using an overdetermined linear system of equations. In the second class of approaches, quadratic transfer function matching criteria are optimized by using the results of the linear estimators as initial guesses. Both classes of the parameter estimators are shown to be consistent in any measurement noise that has symmetric probability density function when the bispectral approaches are used. The proposed parameter estimators are shown to be consistent in Gaussian measurement noise when trispectral approaches are used. The input to the system need not be a linear process but must have nonvanishing bispectrum or trispectrum. We emphasize that unlike the second-order statistics case, one can not, in general, model a stationary random process with a given higher-order cumulant spectrum as having been generated by driving a linear system with an i.i.d. sequence [27].

Computer simulation results were presented in support of the proposed approaches. Performance comparisons with several existing approaches show that the proposed approaches outperform them. On the theoretical side, the proposed estimators are consistent under sufficient conditions that are more general than that for existing approaches. Moreover the integrated polyspectrum-based approaches apply with almost equal computational and programming ease to both cases, those involving third-order statistics as well as those concerned with the fourth-order statistics. It should be noted, however, that higher-order statistics based methods typically yield high-variance estimates requiring "large" record sizes to reduce the variance.

We considered only SISO models. There are no essential difficulties in extending them to multiple-input multiple-output models although details remain to be worked out.

APPENDIX

In this Appendix we provide a proof of Theorem 2. First we need some auxiliary results.

Lemma 6. Under the Assumption Set I, it follows that

$$\begin{aligned} \lim_{N \rightarrow \infty} J_N^{(B)}(\theta) &= J_{\infty}^{(B)}(\theta) \\ &= \sum_{(m,n) \in \mathcal{S}_I \subset D_{xy}^0} [|H(e^{j(\omega_m + \omega_n)})| \theta_0] \\ &\quad - H(e^{j(\omega_m + \omega_n)} | \theta)|^2] / [\sigma_{mn}^2(\theta_0)] \quad (\text{A1}) \end{aligned}$$

1 p uniformly in θ for $\theta \in \Theta_c$ where $\Theta_c \subset \Theta$ is an arbitrary compact set, \mathcal{S}_I is a fixed collection of L bilfrequencies and $\sigma_{mn}^2(\theta_0) = q(m, n) S_r(\omega_m) S_r(\omega_n) S_y(\omega_m + \omega_n) / |B_{1,x}(\omega_m, \omega_n)|^2$.

Proof. By (3-17), (3-20), Lemma 1, and Slutsky's Theorem, we have

$$\begin{aligned} \lim_{N \rightarrow \infty} \sigma_{mn}^2 &= \sigma_{mn}^2(\theta_0) \quad 1 p, \quad (\text{A2}) \\ \lim_{N \rightarrow \infty} H(e^{j(\omega_m + \omega_n)}) \sigma_{mn}^{-1} &= H(e^{j(\omega_m + \omega_n)} | \theta_0) \\ \sigma_{mn}^{-1}(\theta_0) \quad 1 p \quad (\text{A3}) \end{aligned}$$

Consider

$$\begin{aligned} D_{mn}(\theta) &= |H(e^{j(\omega_m + \omega_n)}) - H(e^{j(\omega_m + \omega_n)} | \theta)|^2 \sigma_{mn}^{-2} \\ &\quad - |H(e^{j(\omega_m + \omega_n)} | \theta_0) - H(e^{j(\omega_m + \omega_n)} | \theta)|^2 \sigma_{mn}^{-2} \quad (\text{A4}) \end{aligned}$$

$$\begin{aligned} |H(e^{j(\omega_m + \omega_n)} | \theta)|^2 \sigma_{mn}^{-2} &= |H(e^{j(\omega_m + \omega_n)} | \theta_0)|^2 \sigma_{mn}^{-2} \\ &\quad + 2 \operatorname{Re} \{ H(e^{j(\omega_m + \omega_n)} | \theta) [H(e^{j(\omega_m + \omega_n)} | \theta_0)]^* \sigma_{mn}^{-2} \} \quad (\text{A5}) \end{aligned}$$

By compactness of Θ_c and continuity of $H(e^{j(\omega_m + \omega_n)} | \theta)$ in θ as well as in ω_m and ω_n , we have

$$\sup_{\omega_m \in [-\pi, \pi]} \sup_{\omega_n \in [-\pi, \pi]} \sup_{\theta \in \Theta_c} |H(e^{j(\omega_m + \omega_n)} | \theta)| \leq M < \infty \quad (\text{A6})$$

By (A2), (A3), and Slutsky's Theorem, given any ϵ and $\delta > 0$ there exists an integer $N(\epsilon, \delta)$ such that

$$\begin{aligned} P\{ ||[H(e^{j(\omega_m + \omega_n)})]^2 - |H(e^{j(\omega_m + \omega_n)} | \theta_0)|^2] \sigma_{mn}^{-2} | < \epsilon \} \\ > 1 \quad (\text{A7}) \end{aligned}$$

and

$$\begin{aligned} P\{ ||[H(e^{j(\omega_m + \omega_n)}) - H(e^{j(\omega_m + \omega_n)} | \theta_0)] \sigma_{mn}^{-2} | < \epsilon \} \\ > 1 - \delta \quad (\text{A8}) \end{aligned}$$

for every $N \geq N(\epsilon, \delta)$. Hence it follows that given any $\epsilon_1 (= \epsilon + 2M\epsilon)$ and $\delta > 0$ there exists an integer $N(\epsilon_1, \delta)$ such that

$$P\{|D_{mn}(\theta)| < \epsilon_1\} > 1 - \delta \quad \forall \theta \in \Theta_c, \quad \forall N \geq N(\epsilon_1, \delta) \quad (\text{A9})$$

That is, convergence of $D_{mn}(\theta)$ is uniform in θ . The desired result now follows by using the uniform convergence of $D_{mn}(\theta)$, Slutsky's Theorem, and noting that

$$\begin{aligned} |J_{\infty}^{(B)}(\theta) - J_N^{(B)}(\theta)| &\leq \sum_{(m,n) \in \mathcal{S}_I \subset D_{xy}^0} |D_{mn}(\theta)| \leq L\epsilon_1 \\ & \quad (\text{A10}) \end{aligned}$$

if $|D_{mn}(\theta)| \leq \epsilon_1$ \square

Lemma 7. Under the Assumption Set I, we have

$$J_{\infty}^{(B)}(\theta) = 0 \quad \text{for any } \theta \in \Theta \Leftrightarrow \theta \in D_0$$

Proof. From (A1)

$$\begin{aligned} J_{\infty}^{(B)}(\theta) = 0 &\Rightarrow H(e^{j(\omega_m + \omega_n)} | \theta_0) = H(e^{j(\omega_m + \omega_n)} | \theta) \\ &\quad \text{for } (m, n) \in \mathcal{S}_I \subset D_{xy}^0 \\ &\Rightarrow H(e^{j\omega} | \theta_0) = H(e^{j\omega} | \theta) \quad \forall \omega \in (-\pi, \pi], \text{ by Lemma 5} \\ &\Rightarrow \theta \in D_0 \end{aligned}$$

Conversely

$$\begin{aligned} \theta \in D_0 &\Rightarrow H(e^{j(\omega_m + \omega_n)} | \theta_0) = H(e^{j(\omega_m + \omega_n)} | \theta) \\ &\quad \text{for } (m, n) \in \mathcal{S}_I \subset D_{xy}^0 \\ &\Rightarrow J_{\infty}^{(B)}(\theta) = 0 \end{aligned}$$

This completes the proof \square

Proof of Theorem 2. Define a set

$$\Theta(\rho) = \Theta_c - S(D_0, \rho)$$

where

$$S(D_0, \rho) = \{\theta | \theta \in \Theta, \inf_{\bar{\theta} \in D_0} \|\theta - \bar{\theta}\| < \rho\}$$

Since $S(D_0, \rho)$ is open, $\Theta(\rho)$ is a closed subset of a compact set $\Theta_c \subset \Theta$, hence compact. By continuity of $J_{\infty}^{(B)}(\theta)$ in θ and compactness of $\Theta(\rho)$, there exists some $\theta^* \in \Theta(\rho)$ such that

$$\begin{aligned} \inf_{\theta \in \Theta(\rho)} J_{\infty}^{(B)}(\theta) &= J_{\infty}^{(B)}(\theta^*) = \mu(\rho) > 0 \\ &= J_{\infty}^{(B)}(\theta_0) \quad (\text{A11}) \end{aligned}$$

where we have used Lemma 7 in deducing that $\mu(\rho) > 0$. By Lemma 6, given any $\epsilon \leq \mu(\rho)/3$ and $\delta > 0$ there exists an integer $N_1(\epsilon, \delta)$ such that $\forall \theta \in \Theta(\rho)$ and $\forall N \geq N_1(\epsilon, \delta)$

$$P\{J_N^{(B)}(\theta) > J_{\infty}^{(B)}(\theta) - \epsilon \geq \mu(\rho) - \epsilon\} > 1 - \delta \quad (\text{A12})$$

The above equation may be rewritten as

$$\begin{aligned} P\{ \inf_{\theta \in \Theta(\rho)} J_N^{(B)}(\theta) > \mu(\rho) - \epsilon \} &> 1 - \delta \\ \forall N &\geq N_1(\epsilon, \delta) \quad (\text{A13}) \end{aligned}$$

Similarly, by Lemma 6, given any $\epsilon \leq \mu(\rho)/3$ and $\delta > 0$ there exists an integer $N_2(\epsilon, \delta)$ such that $\forall \theta \in \Theta_c$ and $\forall N \geq N_2(\epsilon, \delta)$ we have

$$P\{J_N^{(B)}(\theta) < J_{\infty}^{(B)}(\theta) + \epsilon\} > 1 - \delta \quad (\text{A14})$$

In particular, we have

$$\begin{aligned} P\{J_N^{(B)}(\theta_0) < J_{\infty}^{(B)}(\theta_0) + \epsilon = \epsilon\} &> 1 - \delta \\ \forall N &\geq N_2(\epsilon, \delta) \quad (\text{A15}) \end{aligned}$$

Since

$$\inf_{\theta \in \Theta_c} J_N^{(B)}(\theta) \leq J_N^{(B)}(\theta_0)$$

however, it follows from (A14) and (A15) that

$$\begin{aligned} P\left\{\inf_{\theta \in \Theta_c} J_N^{(B)}(\theta) < \epsilon \leq \mu(\rho)/3\right\} &> 1 - \delta \\ \forall N \geq N_2(\epsilon, \delta). \end{aligned} \quad (\text{A16})$$

Consider $\hat{\theta}_N$ as defined in (5-13). Then we have

$$\begin{aligned} P\{\hat{\theta}_N \in S(D_0, \rho)\} &= P\left\{\inf_{\theta \in \Theta_c} J_N^{(B)}(\theta) < \inf_{\theta \in \Theta(\rho)} J_N^{(B)}(\theta)\right\} \\ &\geq P\left\{\inf_{\theta \in \Theta_c} J_N^{(B)}(\theta) < \epsilon \leq \mu(\rho)/3, \right. \\ &\quad \left. \mu(\rho) - \epsilon < \inf_{\theta \in \Theta(\rho)} J_N^{(B)}(\theta)\right\} \\ &\geq 1 - P\left\{\inf_{\theta \in \Theta_c} J_N^{(B)}(\theta) \geq \mu(\rho)/3 \geq \epsilon\right\} \\ &\quad - P\left\{\inf_{\theta \in \Theta(\rho)} J_N^{(B)}(\theta) \leq \mu(\rho) - \epsilon\right\} \\ &\geq 1 - 2\delta \quad \forall N \geq N(\epsilon, \delta) = \max\{N_1(\epsilon, \delta), N_2(\epsilon, \delta)\} \end{aligned} \quad (\text{A17})$$

where we used (A13) and (A16) to obtain (A17). This proves the desired result. \square

Jitendra K. Tugnait (M'79-SM'93-F'94) was born in Jabalpur, India on Dec. 3, 1950. He received the B.Sc. (Hons.) degree in electronics and electrical communication engineering from the Punjab Engineering College, Chandigarh, India in 1971, the M.S. and the E.E. degrees from Syracuse University, Syracuse, NY and the Ph.D. degree from the University of Illinois, Urbana-Champaign in 1973, 1974, and 1978, respectively, all in electrical engineering.

From 1978 to 1982 he was an Assistant Professor of Electrical and Computer Engineering at the University of Iowa, Iowa City. He has also been associated with the School of Radar Studies, Indian Institute of Technology, New Delhi, India, and Space Applications Centre, Ahmedabad, India, during 1975-1976. He was with the Long Range Research Division of the Exxon Production Research Company, Houston, TX, from June 1982 to Sept. 1989. He joined the Department of Electrical Engineering, Auburn University, Auburn, AL, in 1989 as a Professor. His research interests are in statistical signal processing and stochastic systems analysis (with emphasis on higher-order statistics), with applications to communications, control and image/signal processing.

Dr. Tugnait served as an Associate Editor of the IEEE TRANSACTIONS ON AUTOMATIC CONTROL during 1985 and 1986, as an appointed member of the Board of Governors of the IEEE Control Systems Society in 1986, and as a member of the Operating Committee of the 1991 CDC in Brighton, UK. He is currently a member of the statistical signal and array processing technical committee of the IEEE Signal Processing Society and is an Associate Editor of the IEEE TRANSACTIONS ON SIGNAL PROCESSING.

Yisong Ye (S'90-M'93) was born in Shanghai, People's Republic of China on April 30, 1965. He received the B.E.E. degree from Shanghai Jiao Tong University, Shanghai, China in 1986 and the M.S.E.E. degree from Auburn University, Auburn, AL in 1992. He is currently a Ph.D. candidate in electrical engineering at Auburn University.

Mr. Ye's research interests include system identification, signal processing and communications.

Minimum Bias Priors for Estimating Parameters of Additive Terms in State-Space Models

Bertrand Hochwald, *Student Member, IEEE*, and Arye Nehorai, *Fellow, IEEE*

Abstract—We treat the problem of estimating parameters of additive terms, sometimes called bias terms, in state-space models. We consider models that depend linearly on the state but possibly nonlinearly on the parameters, where both the state and observation are corrupted by additive noise. A prior density for the parameters is introduced that, when combined with the likelihood function to form a posterior density, minimizes the bias of the posterior mean. The result is a useful prior based on ignorance. Two examples and simulations illustrate the use of the prior.

I. INTRODUCTION

THE problem of determining unknown additive terms in state-space models has been addressed by many authors; for some early examples, see [4] and [8]. These models appear frequently when, for example, noise of unknown mean is encountered, sensors with systematic errors are used, or moving objects are being tracked. We consider the problem of obtaining the posterior mean estimate of parameters that appear nonlinearly in the additive terms. The posterior mean is important because of its wide use in estimation theory and its close connection to the Kalman filter estimate of the additive terms [4]. For example, when the parameters appear linearly in the additive terms and have a jointly Gaussian prior distribution, the Kalman and posterior mean estimates coincide.

We then suggest a method to choose a prior density for the parameters that conveys ignorance. When information about parameters is unavailable, there are various criteria for choosing noninformative priors. One is convenience: If we assume that the parameters have a distribution amenable to simple recursive updating equations, then estimates are often easy to compute. Another is lack of favoritism: If we assume the parameters have a uniform distribution over some interval, then it is widely accepted that we are not giving preference to any particular parameter value. There are also information theoretic criteria that, for example, maximize the Kullback–Liebler–Lindley distance between the posterior density and the prior [6], [9]. These criteria, however, while broad in scope, often cannot predict precisely what

effect the priors they recommend will have on a particular estimate.

By focusing on the posterior mean, we are able to show the effect of any prior density, and we choose a prior to minimize bias (to be defined shortly). If the true prior is used to construct a posterior density, then the posterior mean has the well-known minimum mean-square error property. This optimality is measured as an average over possible realizations of the parameters drawn in accordance with their distribution. If, however, a prior other than the true one is used to construct a posterior density, then this ensemble average property of the posterior mean is generally lost.

In this paper we obtain a prior density function that satisfies an optimality condition within a realization instead: When used to make a posterior density function of the parameters, the prior, asymptotically in the number of observations, minimizes the posterior mean's bias over all possible priors. Let θ be the parameter we wish to estimate and $\hat{\theta}_t$ be the posterior mean computed at time t using the prior f_θ . Supposing θ_0 denotes the true value of θ and E_{θ_0} denotes expectation conditioned on θ_0 , we show that $E_{\theta_0}\hat{\theta}_t = \theta_0 + O(t^{-1})$, as $t \rightarrow \infty$, for most f_θ . But the proposed f_θ (which can depend on t) satisfies $E_{\theta_0}\hat{\theta}_t = \theta_0 + o(t^{-1})$. Hence the name “minimum bias prior.”

As more observations become available, the density we propose varies. Contrast this with the traditional prior density that reflects what is known about the parameters before observations are made. We draw on the work of Hartigan [5], in which minimum bias priors are first developed. He determines that (asymptotically) the first-order effect of the prior appears in the posterior mean. Effects on the higher order moments of the posterior density are negligible by comparison. The minimum bias prior makes the first-order effect as small as possible.

In Section II the state-space model with parameterized additive terms is described and the estimation problem formulated. We show how to recursively calculate the unnormalized posterior density function of the parameters in a simple and efficient manner. In Section III we introduce the minimum bias prior. The prior is developed in [5] under the assumption that identically distributed observations of the parameters are available. Our model will not satisfy this assumption, requiring us to extend the prior's theory. A method is also given to approximate the prior with an adaptive scheme, since an exact closed-form solution cannot always be obtained. The prior used in the adaptive scheme is, however, particularly

simple. Two examples and simulations demonstrate the results in Section IV, and we conclude in Section V.

II. MODEL AND PROBLEM FORMULATION

Consider the state-space model

$$x_t = Ax_{t-1} + Bg(\theta) + w_{t-1}, \quad (2.1a)$$

$$y_t = Cx_t + Dh(\theta) + v_t \quad (2.1b)$$

where $t = 1, 2, \dots$ is the time index. The vector $y_t \in \mathbb{R}^{m \times 1}$ is the observation, $x_t \in \mathbb{R}^{n \times 1}$ is the state, and $\theta \triangleq [\theta_1, \dots, \theta_p]^T \in \mathbb{R}^{p \times 1}$ is the unknown parameter vector. The noise vectors $w_t \sim \mathcal{N}(0, Q)$, $v_t \sim \mathcal{N}(0, R)$ (have zero-mean Gaussian distributions with respective variances) and w_s are assumed to be independent of v_t for all s and t . It is supposed that $Q \in \mathbb{R}^{n \times n}$ is positive semidefinite and $R \in \mathbb{R}^{m \times m}$ is positive definite for all t . The parameter vector θ and initial state x_0 are random and independent. Furthermore, we suppose that $g(\theta) \in \mathbb{R}^{q \times 1}$ and $h(\theta) \in \mathbb{R}^{r \times 1}$ are known functions of θ representing the additive terms. All matrices are assumed to have the appropriate dimensions and to be known.

A common approach to simultaneous estimation of the state and parameter vectors is to extend the state-vector to include the additive terms by letting $\tilde{x}_t \triangleq [x_t^T, g^T(\theta), h^T(\theta)]^T$, whence

$$\begin{bmatrix} A & B & 0 \\ 0 & I & 0 \\ 0 & 0 & I \end{bmatrix} \tilde{x}_{t-1} + \begin{bmatrix} w_{t-1} \\ 0 \\ 0 \end{bmatrix} \quad (2.2a)$$

$$y_t = [C \quad 0 \quad D] \tilde{x}_t + v_t. \quad (2.2b)$$

If we assume that the initial vector \tilde{x}_0 has some covariance matrix, then the model is in a form suitable for applying the Kalman filtering equations to estimate \tilde{x}_t [4]. This provides recursive estimates of g and h . If $\theta \mapsto (g(\theta), h(\theta))$ is one-to-one we may invert the estimates of g and h to get estimates of θ .

While this method is attractive because of its computational simplicity, we may not want to be forced into assigning g and h a covariance that can, at best, be a guess. This is true especially because the parameter of interest is θ and not $(g(\theta), h(\theta))$. Moreover, the criterion we consider in this paper is bias, and the extended-state Kalman filter, which essentially obtains the posterior mean of g and h under the assumption that they have a joint-Gaussian prior, may have a bias when estimating θ that is higher than that obtainable with the minimum bias prior. (Due to the nonlinearities in g and h , this holds even when g and h can be estimated with no bias.) Example 2 in Section IV demonstrates this.

We use the term realization to denote a series of measurements obtained via (2.1) in which θ is fixed at θ_0 . When we speak of an average within a realization, the expectation is over all possible values of the observations (assuming θ is fixed) and the relevant density is $f_{Y^t|\theta_0}$, where Y^t is shorthand for y_1, \dots, y_t . This expectation is denoted E_{θ_0} .

Suppose a collection of t observations from one realization is available and $\hat{\theta}_t = \int \theta f_{\theta|Y^t} d\theta$. Our goal is to minimize

the asymptotic bias, $E_{\theta_0} \hat{\theta}_t - \theta_0$, by modifying $f_{\theta|Y^t}$, through selecting an appropriate prior, f_θ . We will use f_θ to denote a prior density for the parameters, whether it is the true prior or not. The true prior plays no role in the bias criterion so there should be no source of confusion, and it will not matter what law is used to choose θ . Similarly, we will not distinguish between posterior densities and means computed using different f_θ .

Assumptions:

A1) $f_{x_0|\theta} = \mathcal{N}(m_0, P_0)$.

A2) The noise is "white," implying that $f_{x_t|x_{t-1}, Y^{t-1}, \theta} = f_{x_t|x_{t-1}, \theta}$ and $f_{y_t|x_t, Y^{t-1}, \theta} = f_{y_t|x_t, \theta}$.

We begin by computing the joint posterior density function of x_t and θ . Define $l(\theta) = [g^T(\theta), h^T(\theta)]^T$.

Lemma 1:

$$f_{x_t, \theta|Y^t} = f_{x_t|Y^t, \theta} \cdot f_{\theta|Y^t} \quad (2.3)$$

where

$$f_{x_t|Y^t, \theta} = \mathcal{N}(M_t l(\theta) + z_t, P_t), \quad (2.4)$$

$$f_{\theta|Y^t} \propto f_\theta \cdot \exp \{ \alpha_t^T l(\theta) + l^T(\theta) \Lambda_t l(\theta) \} \quad (2.5)$$

and z_t, α_t, M_t, P_t , and Λ_t may be computed recursively.

Proof: See Appendix A.

Given t observations, the posterior mean of x_t and θ is $\int [x_t^T, \theta^T]^T f_{x_t, \theta|Y^t} d x_t d \theta$; (2.3)–(2.5) yield

$$\hat{x}_t = \frac{1}{c_t} M_t \int l(\theta) f_\theta \cdot \exp \{ \alpha_t^T l(\theta) + l^T(\theta) \Lambda_t l(\theta) \} \cdot d\theta + z_t, \quad (2.6a)$$

$$\hat{\theta}_t = \frac{1}{c_t} \int \theta f_\theta \cdot \exp \{ \alpha_t^T l(\theta) + l^T(\theta) \Lambda_t l(\theta) \} d\theta \quad (2.6b)$$

where $c_t = \int f_\theta \cdot \exp \{ \alpha_t^T l(\theta) + l^T(\theta) \Lambda_t l(\theta) \} d\theta$ is a normalizing constant. Observe the notation: \hat{x}_t the estimate of x_t , and $\hat{\theta}_t$ the estimate of the constant θ_0 .

In what follows we concern ourselves exclusively with $\hat{\theta}_t$ and examining its behavior as a functional of f_θ . Generally, $\hat{\theta}_t$ converges in probability to θ_0 as $t \rightarrow \infty$. We will, in fact, give conditions that imply convergence of θ_t to θ_0 in expectation, and choose f_θ to optimize the speed with which this happens.

III. MINIMUM BIAS PRIORS

The minimum bias prior minimizes the first-order effect of the prior on the posterior density [5]. When θ is a scalar we show that there is a closed-form solution for the prior. When θ is a vector, we can show only that it satisfies a certain set of differential equations that do not necessarily yield a closed-form solution. To handle this, we propose a simple adaptive approximation of the prior.

The minimum bias prior depends on the likelihood function. Jeffreys [7] first suggested using the likelihood function to design priors, with the Jeffreys prior being a well-known example. It turns out that in one dimension the minimum bias prior is the square of the Jeffreys prior (see [2] for other uses of the Jeffreys prior). In more than one dimension, the

minimum bias prior and the square of the Jeffreys prior no longer necessarily coincide.

We would like to apply the results of Hartigan in [5] but some justification is needed. He considers a model for which independent identically distributed observations are available. That is, in his case, $\log f_{Y^t|\theta} = \sum_{r=1}^t \log f_{Y_r|\theta}$ and $\{\log f_{Y_r|\theta}\}_{r=1,2,\dots}$ is a collection of independent identically distributed random variables; many of his results are based on the asymptotic behavior of this sum. In our case, $\log f_{Y^t|\theta} = \sum_{r=1}^t \log f_{Y_r|Y^{r-1},\theta}$, and the summands are not identically distributed. As we shall momentarily see, however, the summands are independent and have the same distribution asymptotically, allowing us to use the results of [5] anyway.

The first step is to observe that from (A.2), (A.6), and (A.7), $f_{Y_t|Y^{t-1},\theta} = \mathcal{N}(N_t l(\theta) + C A z_{t-1}, S_t)$, where $N_t = C A M_{t-1} + [C B, D]$ and $S_t = C(A P_{t-1} A^T + Q) C^T + R$. The asymptotic behavior of $\log f_{Y_t|Y^{t-1},\theta}$ is principally governed by N_t and S_t which are shown to converge under the following assumption.

Assumption

A3) The pair (C, A) is detectable and $(A, Q^{1/2})$ is stabilizable [1].

Lemma 2: The matrices N_t and S_t tend to limits exponentially fast as $t \rightarrow \infty$.

Proof We have $S_t = A P_{t|t-1} A^T + R$ where $P_{t|t-1} = A P_{t-1} A^T + Q$. That $P_{t|t-1}$ tends to a unique positive definite matrix exponentially fast under Assumption A3) can be found in [1]. Therefore, the lemma is proved for S_t . To prove the result for N_t , we observe that it is sufficient to prove the result for M_t . From (A.4), $M_t = (A - K_t C A) M_{t-1} + [(I - K_t C) B, -K_t D]$, where $K_t = P_{t|t-1} C^T S_t^{-1}$. It is well known that K_t converges exponentially quickly to some K_∞ such that the eigenvalues of $A - A K_\infty C$ have modulus less than one, whence $A - K_t C A$ has eigenvalues with modulus less than one for t sufficiently large. Therefore M_t converges at an exponential rate as well. \square

Define

$$\eta_t(\theta) = \log f_{Y_t|Y^{t-1},\theta}, \quad t = 1, 2, \dots, \\ = -\frac{1}{2} [\log \det 2\pi S_t + (y_t - N_t l(\theta) - C A z_{t-1})^T \\ \cdot S_t^{-1} (y_t - N_t l(\theta) - C A z_{t-1})] \quad (3.1)$$

$N_\infty \triangleq \lim_{t \rightarrow \infty} N_t$, $S_\infty \triangleq \lim_{t \rightarrow \infty} S_t$, and $\eta_\infty(\theta) \triangleq -\frac{1}{2} [\log \det 2\pi S_\infty + \varepsilon_\infty^T(\theta) S_\infty^{-1} \varepsilon_\infty(\theta)]$ where $\varepsilon_\infty \sim \mathcal{N}(N_\infty [l(\theta_0) - l(\theta)], S_\infty)$. We use Lemma 2 to show that $\eta_t(\theta)$ converges in distribution to $\eta_\infty(\theta)$ exponentially quickly.

Lemma 3

- i) The random variables η_s and η_t are independent for $s \neq t$.
- ii) The random variables η_t converge in distribution, as $t \rightarrow \infty$, to η_∞ . Furthermore, the expectation of any power of any derivative of η_t with respect to θ tends exponentially quickly to the expectation of the same power and derivative of η_∞ .

Proof: See Appendix B.

Lemma 3 shows us that $\log f_{Y_t|Y^{t-1},\theta}$, $t = 1, 2, \dots$, are

almost identically distributed. The fact that they are not exactly identically distributed turns out to be of no consequence. We show this in the lemma that follows, extending Lemma 1 of Hartigan's paper to our model. First, some regularity conditions on f_θ and $\eta_t(\theta)$ similar to those appearing in [5] are stated.

Assumptions

- B1) θ_0 is an interior point of Θ where $\Theta \subset \mathbb{R}^p$ is closed.
- B2) $l(\theta)$ is continuous for $\theta \in \Theta$ and continuously four times differentiable in some neighborhood of θ_0 .
- B3) The parameters are identifiable: For $\theta \neq \theta_0$, $|N_t[l(\theta) - l(\theta_0)]|$ is bounded from below by a positive constant, uniformly in t .
- B4) $\log f_\theta$, $(\partial/\partial\theta) \log f_\theta$ and $(\partial^2/\partial\theta\partial\theta^T) \log f_\theta$ exist and are continuous in a neighborhood of θ_0 .
- B5) The prior density f_θ may be improper [$\notin L^1(\Theta)$], but $\int_\Theta f_{Y_t|Y^{t-1},\theta} f_\theta d\theta$ exists and is a bounded function of y_t , uniformly in Y^{t-1} and t .
- B6) Either Θ is bounded, or for some $k > 0$, $\sup_{|\theta| > k} [\eta_t(\theta) - \eta_t(\theta_0)]$ has first moment bounded from above by a negative constant and bounded fourth moment, both uniformly in t .

Lemma 4 For any $c > 0$ there exists a $\delta > 0$ such that $f_{Y^t|\theta}/f_{Y^t|\theta_0}$ is $O(e^{-t\delta})$ with probability $1 - O(t^{-2})$, uniformly in θ for $|\theta - \theta_0| > c$.

Proof See Appendix C.

To extend his results completely we need to also show that

$$\sum_{i=1}^t \frac{\partial^s \eta_i(\theta)}{\partial \theta^s} \bigg|_{\theta=\theta_0} = t c_{i,s} + O_p(t^1) \\ i = 1, \dots, p, s = 1, \dots, 4$$

for some $c_{i,s} \in \mathbb{R}$. But that this is true with $c_{i,s} = E_{\theta_0} \{\partial^s \eta_\infty(\theta) / \partial \theta^s |_{\theta=\theta_0}\}$ follows directly from Chebyshev's inequality and Lemma 3. We are now in a position to use the results on minimum bias priors.

Let $V(d, \theta)$ be a smooth nonnegative loss function with unique minimum at $\theta = d$ and

$$\theta_t = \arg \min_d \int V(d, \theta) f_{\theta|Y^t} d\theta.$$

For a scalar θ , under assumptions B1–B6 we have the asymptotic expansion

$$\arg \min_{\theta \in \Theta} E_{\theta_0} V(\hat{\theta}_t, \theta) = \theta_0 - p_2^{-1} [q_1 - (p_{12} + p_1)/p_2 \\ - \frac{1}{2} (V_{12} + V_{21})/V_{20}] |_{\theta=d=\theta_0} \\ + o(t^{-1}) \quad (3.2)$$

as $t \rightarrow \infty$, where

$$q_1 \triangleq \frac{\partial \log f_\theta}{\partial \theta}, \\ p_{12} \triangleq E_\theta \left\{ \frac{\partial \log f_{Y^t|\theta}}{\partial \theta} \frac{\partial^2 \log f_{Y^t|\theta}}{\partial \theta^2} \right\}, \\ p_1 \triangleq E_\theta \frac{\partial^2 \log f_{Y^t|\theta}}{\partial \theta^2}, \\ V_{i,s} \triangleq \frac{\partial^i}{\partial d^i} \frac{\partial^s}{\partial \theta^s} V(d, \theta).$$

See [5, p. 1147] for the derivation.

For the quadratic loss function, $V(d, \theta) = (d - \theta)^2$, it is easily verified that $\hat{\theta}_t$ is the posterior mean and $\arg \min_{\theta \in \Theta} E_{\theta_0} V(\hat{\theta}_t, \theta) = E_{\theta_0} \hat{\theta}_t$. Thus, in this special case, (3.2) gives an asymptotic expansion of the expected value of the posterior mean. The influence of the prior on the expected value is seen in the q_1 term.

From Lemma 3 we see that $p_2^{-1} = O(t^{-1})$ and the terms within the brackets of (3.2) are $O(1)$. Therefore, in general, $E_{\theta_0} \hat{\theta}_t = \theta_0 + O(t^{-1})$. Because $V_{12} = V_{21} = 0$, we can conclude that $E_{\theta_0} \hat{\theta}_t = \theta_0 + o(t^{-1})$ if and only if

$$[q_1 = (p_{12} + p_{31})/p_2]_{\theta=\theta_0}. \quad (3.3)$$

The prior that satisfies (3.3) is therefore the minimum bias prior.

Observe that

$$(p_{12} + p_{31})/p_2 = \frac{\partial}{\partial \theta} \log \left(-E_{\theta} \left\{ \frac{\partial^2 \log f_{Y|I|\theta}}{\partial \theta^2} \right\} \right)$$

upon interchanging the operations of differentiation and expectation (which is easily justified). Hence, a prior satisfying (3.3) is given by

$$f_{\theta} = -E_{\theta} \left\{ \frac{\partial^2 \log f_{Y|I|\theta}}{\partial \theta^2} \right\}. \quad (3.4)$$

Equation (3.4) is, for a scalar θ , a closed-form solution for the minimum bias prior. It is, in fact, the square of the Jeffreys prior. For the multivariate case, the situation is more complicated. Using the results [5, p. 1149] for a vector θ , where the loss function is given by $V(d, \theta) = \sum_{i=1}^p (d_i - \theta_i)^2$, $E_{\theta_0} \hat{\theta}_t = \theta_0 + o(t^{-1})$ if and only if

$$q_i = \sum_{j,k=1}^p (J^{-1})_{j,k} (p_{i,j,k} + p_{i,k,j}) \quad i = 1, \dots, p, \quad \theta = \theta_0 \quad (3.5)$$

where

$$\begin{aligned} p_{i,j,k} &\triangleq \frac{\partial}{\partial \theta_j} \log f_{\theta} \cdot \frac{\partial}{\partial \theta_k} \log f_{Y|I|\theta} \\ &\triangleq E_{\theta} \left\{ \frac{\partial^2 \log f_{Y|I|\theta}}{\partial \theta_i \partial \theta_j} \cdot \frac{\partial \log f_{Y|I|\theta}}{\partial \theta_k} \right\}, \\ p_{i,j,k} &\triangleq E_{\theta} \left\{ \frac{\partial^3 \log f_{Y|I|\theta}}{\partial \theta_i \partial \theta_j \partial \theta_k} \right\} \end{aligned}$$

and $J \triangleq E_{\theta} \{ \partial^2 \log f_{Y|I|\theta} / \partial \theta \partial \theta^T \}$. Equation (3.5) consists of p differential equations that the multivariate minimum bias prior must satisfy. We apply (3.5) to the model (2.1) and simplify the results in the following theorem.

Theorem 1: $E_{\theta_0} \hat{\theta}_t = \theta_0 + o(t^{-1})$ if and only if

$$h_i = \frac{1}{2} \frac{\partial}{\partial \theta_i} [\log \det(-J)] + \text{tr} \{ J^{-1} U_i \} \Big|_{\theta=\theta_0}, \quad i = 1, \dots, p \quad (3.6)$$

where

$$J = \frac{\partial l(\theta)}{\partial \theta} 2\Lambda_t \frac{\partial l(\theta)}{\partial \theta^T}, \quad (3.7)$$

$$(U_i)_{j,k} \triangleq \frac{\partial l^T(\theta)}{\partial \theta_i} 2\Lambda_t \frac{\partial^2 l(\theta)}{\partial \theta_j \partial \theta_k}, \quad j, k = 1, \dots, p \quad (3.8)$$

and Λ_t is defined recursively in (A.8b).

Proof: See Appendix D.

As it must, Theorem 1 yields (3.4) in the special case $p = 1$. To verify this, observe that

$$J = \frac{\partial l^T(\theta)}{\partial \theta} 2\Lambda_t \frac{\partial l(\theta)}{\partial \theta}, \quad U_1 = \frac{\partial l^T(\theta)}{\partial \theta} 2\Lambda_t \frac{\partial^2 l(\theta)}{\partial \theta^2}$$

and therefore $U_1 = \frac{1}{2} \partial J / \partial \theta$. It follows that $J^{-1} U_1 = \frac{1}{2} J^{-1} \partial J / \partial \theta = \frac{1}{2} \partial \log(-J) / \partial \theta$. Hence, from Theorem 1, the minimum bias prior satisfies $q_1 = \partial \log(-J) / \partial \theta$. The solution to this is (3.4).

The set of differential equations given by (3.6), with a closed-form solution for scalar θ , may not have a closed-form solution in the multivariate case for all θ . The problem, however, can be made tractable by observing that Theorem 1 requires the differential equations to hold only at θ_0 . θ_0 is unknown, but with an estimate we may construct a simple prior that satisfies the conditions of Theorem 1 approximately. This prior can then be used to obtain the next estimate of θ_0 , which in turn feeds the next prior, and so on, reducing the bias through an iterative procedure. This bootstrapping method is now stated and proved to have a beneficial effect on the bias.

Theorem 2. Define $\nu(\theta) = [\nu_1(\theta), \dots, \nu_p(\theta)]^T$, where

$$\nu_i(\theta) \triangleq \frac{1}{2} \frac{\partial}{\partial \theta_i} [\log \det(-J)] + \text{tr} \{ J^{-1} U_i \}, \quad i = 1, \dots, p. \quad (3.9)$$

Let Θ be a closed bounded set such that $\nu(\theta)$ is continuous for all $\theta \in \Theta$ and sufficiently large t . For every t , suppose some mechanism is used to "project" $\hat{\theta}_{t-1}$ onto Θ . Let $\hat{\theta}_{t-1}$ be this projection and

$$f_{\theta}(\hat{\theta}_{t-1}) = \exp \left(\theta^T \cdot \nu(\hat{\theta}_{t-1}) \right) \quad (3.10)$$

be the prior used at time t . Then, $E_{\theta_0} \hat{\theta}_t = \theta_0 + o(t^{-1})$ as $t \rightarrow \infty$.

Proof: See Appendix E.

This provides a practical method for achieving the minimum bias effect without having to explicitly solve for the minimum bias prior. The prior defined in (3.10) has a simple form and is readily calculated at any time t . It is adaptive since it depends on $\hat{\theta}_{t-1}$ and therefore also Y^{t-1} .

Remarks: The projection mechanism should modify only estimates that fall outside Θ by, say, assigning them boundary values of Θ . The actual mechanism will not be important because θ_0 is an interior point of Θ , and given enough observations, $|\hat{\theta}_t - \theta_0|$ will be large with only small probability. Hence the projection mechanism will generally modify the estimates only when t is small. The mechanism's main use is

to provide a deterministic bound for the random variable $\tilde{\theta}_t$, and to ensure that the prior given by (3.10) is always well defined.

The choice of initial prior (before any estimate of θ_0 is available) is arbitrary and will not affect the convergence behavior of $E_{\theta_0} \tilde{\theta}_t$ for large enough t . A convenient choice that generally provides good initial parameter estimates is the uniform density, that is $f_{\theta} = c$ for some arbitrary constant $c > 0$. In fact, a good rule of thumb is to employ the uniform density until the terms neglected in the asymptotic expansions can safely be ignored. At this point, the adaptive prior may be employed. Otherwise, if (3.10) is used too early, erratic estimate behavior could result. That is, a poor estimate of θ_0 used to construct $f_{\theta}(\tilde{\theta}_{t-1})$ may lead to a possibly worse estimate, and so on. Nevertheless, even this process will eventually correct itself as t becomes larger. The smallest t for which the minimum bias prior should be applied can be determined by experimentation.

IV. EXAMPLES AND SIMULATIONS

We give two examples, one that has a closed-form solution for the minimum bias prior and one that does not.

Example 1—Linear in the Parameters: Let $g(\cdot)$ and $h(\cdot)$ be linear so $l(\theta) = \theta$. The posterior density of the parameters is given by Lemma 1

$$f_{\theta|Y} \propto f_{\theta} \exp \{ \alpha_t^T \theta + \theta^T \Lambda_t \theta \}.$$

Calculating the minimum bias prior using Theorem 1 yields $J = 2\Lambda_t$, $U_t = 0$, $t = 1, \dots, p$. Therefore, the prior satisfies $q_t = 0$, $t = 1, \dots, p$. A closed-form solution is given by the uniform density $f_{\theta} = c$ for some arbitrary $c > 0$. The posterior mean, when $f_{\theta} = c$, is $\tilde{\theta}_t = -(1/2)\Lambda_t^{-1}\alpha_t$, since $f_{\theta|Y} \propto \exp \{ \alpha_t^T \theta + \theta^T \Lambda_t \theta \}$ is a Gaussian distribution. It follows from (A.8) that $E_{\theta_0} \tilde{\theta}_t = \theta_0$, and it is straightforward to verify that using the prior $f_{\theta} = c$ is equivalent to employing (2.2) and initializing the inverse covariance of θ to zero.

This example shows that when g and h are linear, closed-form solutions for $\tilde{\theta}_t$ and the minimum bias prior are available at every time step. The minimum bias prior, in this case, yields a completely unbiased estimate for all t . We next give an example with nonlinear g in which the adaptive prior must be employed to minimize bias.

Example 2—Determining the Thrust of an Accelerating Target: We look at the problem of estimating the thrust of a moving target in two dimensions, where we are allowed vector measurements of the x and y -axis coordinate positions and velocities. The target is assumed to have a fixed unknown thrust a along an unknown direction φ during the observation interval. The direction is taken with respect to the y -axis and the observation intervals have length T . The velocity obeys

$$\begin{aligned} \begin{bmatrix} u_x(t) \\ u_y(t) \end{bmatrix} &= \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} u_x(t-1) \\ u_y(t-1) \end{bmatrix} \\ &+ \begin{bmatrix} Ta \sin \varphi \\ T[a \cos \varphi - g] \end{bmatrix} + w_t' \end{aligned} \quad (4.1)$$

where

$$E w_t' w_t'^T = \begin{bmatrix} 2 & 0 \\ 0 & 1 \end{bmatrix}$$

and g is gravitational acceleration. The unequal noise variances are due to the greater atmospheric disturbance parallel to the x -axis. The equations of position $r(t)$ are assumed to obey

$$r(t) = r(t-1) + \frac{t}{2} [u(t-1) + u(t)]. \quad (4.2)$$

Letting $x_t \triangleq [u_x(t), u_y(t), r_x(t), r_y(t)]^T$ and combining (4.1) and (4.2) we see that

$$\begin{aligned} x_t &= \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ T & 0 & 1 & 0 \\ 0 & T & 0 & 1 \end{bmatrix} x_{t-1} \\ &+ \begin{bmatrix} Ta \sin \varphi \\ T[a \cos \varphi - g] \\ (T^2/2)a \sin \varphi \\ (T^2/2)[a \cos \varphi - g] \end{bmatrix} + w_{t-1} \end{aligned} \quad (4.3)$$

and

$$E w_t w_t^T = \begin{bmatrix} 0 & T & 0 \\ T & 0 & T/2 \\ 0 & T/2 & 0 \\ 0 & T/2 & 0 & T^2/4 \end{bmatrix}$$

We assume the observations follow the model $y_t = C'x_t + v_t$, where $E v_t v_t^T = I$ and C' describes the sensors' outputs as a function of target velocity and position.

We wish to estimate $\theta = [a, \varphi]^T$ using the minimum bias prior. For simplicity we suppose that $C'^T C' = I$, $m_0 = 0$ and $P_0 = I$ [see Assumption A1]. We have

$$\begin{aligned} B &= \begin{bmatrix} T & 0 \\ 0 & T \\ T^2/2 & 0 \\ 0 & T^2/2 \end{bmatrix} \\ g(\theta) &= [a \sin \varphi, a \cos \varphi - g]^T, \\ h(\theta) &\equiv 0 \end{aligned}$$

From (3.6)

$$\frac{\partial \log f_{\theta}}{\partial a} = \frac{\xi_t - 1}{a \xi_t} [1 - 2\xi_t \cos^2 \varphi + (\xi_t - 1) \cos^4 \varphi], \quad (4.4a)$$

$$\frac{\partial \log f_{\theta}}{\partial \varphi} = \frac{\xi_t - 1}{\xi_t} [1 + 2\xi_t + (\xi_t - 1) \cos^2 \varphi] \sin \varphi \cos \varphi \quad (4.4b)$$

where $\xi_t \triangleq (\Lambda_t)_{2,2}/(\Lambda_t)_{1,1}$. We do not know of a closed-form expression for f_{θ} satisfying these equations.

Instead, we use the prior density of Theorem 2. Then, at time t

$$f_{\theta}(\tilde{\theta}_{t-1}) = \exp \left(a \nu_1(\tilde{\theta}_{t-1}) + \varphi \nu_2(\tilde{\theta}_{t-1}) \right)$$

where $\nu_1(\tilde{\theta}_{t-1})$ and $\nu_2(\tilde{\theta}_{t-1})$ are the right-hand sides of, respectively, (4.4a) and (4.4b) evaluated at $a = \tilde{a}_{t-1}$ and

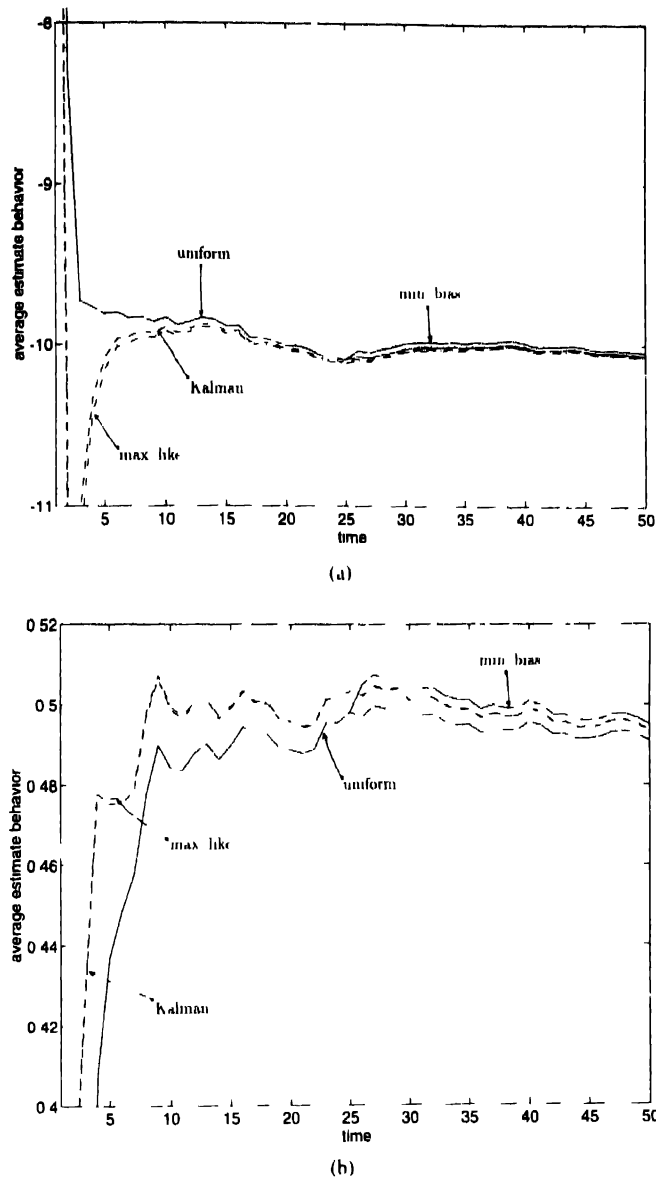

Fig. 1 Posterior mean estimates computed with adaptive minimum bias and uniform priors, averaged over 100 trials. The minimum bias prior was applied when $t \geq 25$. Also shown are the extended-state Kalman filter and maximum likelihood estimates. Solid lines correspond to minimum bias and uniform priors, dashed to Kalman filter, dash-dotted to maximum likelihood (a) Estimates of $a_0 = -10$ (b) Estimates of $\varphi_0 = 0.5$

$\varphi = \tilde{\varphi}_{t-1}$. Observe that from (4.4), $\nu(\theta)$ is continuous except when $a = 0$. To fulfill the conditions of Theorem 2 it therefore suffices to let $\Theta = \{\theta \in \mathbb{R}^2 \mid \delta \leq |a| \leq 50, \varphi \in [-\pi, \pi)\}$ where δ is any small positive number. This imposes a weak and practical restriction on the choice of parameters since the choice $a = 0$ is not identifiable in φ and therefore does not satisfy Assumption B3) anyway.

We simulated the system with $T = 0.25$, $a_0 = -10$, and $\varphi_0 = 0.5$. The posterior mean estimates with the minimum bias and the uniform priors and, for the sake of comparison, the extended-state Kalman filter and the maximum likelihood estimates are all shown in Fig. 1. Plotted are the estimates' responses averaged over 100 trials; the averages approximate the expected curve values. We show the first 50 out of the total of 250 time steps to demonstrate the effect of application

TABLE I
BIAS PERFORMANCE OF VARIOUS ESTIMATES

Estimate	Deviation around	
	a_0	φ_0
min. bias	5.23	1.03
uniform	6.80	1.41
Kalman	7.45	1.16
max. like.	7.92	1.15

of the minimum bias prior at $t = 25$. The prior was uniform for $t < 25$ (see remarks after Theorem 2). The extended-state Kalman filter used the fact that the state-space model is linear in $g(\theta)$ to get estimates of $a \sin \varphi$ and $a \cos \varphi - g$, which were converted into estimates of a and φ . The $g(\theta)$ portion of the initial covariance matrix was set to $10^3 I$ to approximately convey ignorance, and the initial mean was $[0, -\bar{g}]^T$. The maximum likelihood estimate was evaluated in the usual way.

Table I is a measure of the bias of each method. We show the magnitude of the difference from the true parameter of each curve summed from time steps 25–250. From the table it is clear that the posterior mean using the minimum bias prior has the least deviation of all the estimates. That the minimum bias prior causes less deviation than the uniform prior is predicted by the theory. That it happens to cause less deviation than the Kalman filter and maximum likelihood estimates may be just fortuitous. Nevertheless, this example demonstrates the viability of the minimum bias prior.

V. CONCLUSION

The minimum bias prior was proposed as an alternative to other prior densities based on ignorance because of its beneficial effect on the posterior mean. Within a realization, for t sufficiently large, the dominant effect of any prior appeared as bias. The minimum bias prior ensured that $E_{\theta_0} \hat{\theta}_t - \theta_0 = o(t^{-1})$, as $t \rightarrow \infty$, as opposed to $O(t^{-1})$ for other priors.

In Example 2, the proposed estimate was shown to have bias performance superior to the maximum likelihood and Kalman filter estimates. Some additional tests were performed indicating that this improvement held for other parameter values as well. It would be of interest to determine analytically if this is a general phenomenon.

When the bias contribution to the realization mean-square error, $E_{\theta_0}(\hat{\theta}_t - \theta_0)^2$, is significant, we can expect the minimum bias prior to reduce this error. We performed some numerical experiments to see if $E_{\theta_0}(\hat{\theta}_t - \theta_0)^2$ was lowest for the minimum bias estimate in Example 2, but the realization mean-square errors of all the estimates in Table I were essentially equal. We discovered that this was due to the overwhelming contribution of the variance over the bias to the realization mean-square error in this example. This, of course, raises the question: Is there a systematic way to choose priors to minimize this error?

Bayes estimates other than the posterior mean can be analyzed by choosing nonquadratic V in the asymptotic expansion (3.2). The minimum bias prior and its adaptive version vary

with V , and so do their interpretations. This is a potential subject for further investigation.

APPENDIX A PROOF OF LEMMA 1

The notion of recursively calculating density functions in state-space models can be found, for example, in [3] and the proof of Lemma 1 follows the same, now standard, ideas. Due to the structure of the state-space model (2.1), the recursive scheme for computing the posterior density function is particularly simple.

Given θ , (2.1) obeys a standard linear state-space model with known additive terms, implying that

$$f_{x_t|x_{t-1}, \theta} = \mathcal{N}(Ax_{t-1} + Bg(\theta), Q),$$

$$f_{y_t|x_t, \theta} = \mathcal{N}(Cx_t + Dh(\theta), R).$$

Using Assumptions A1)–A2), given θ and Y^t we observe that the density of x_t is Gaussian. That is

$$f_{x_t|Y^t, \theta} = \mathcal{N}(m_t, P_t) \quad (\text{A.1})$$

where m_t and P_t may be computed iteratively. The equations for the recursion are given by the Kalman filter:

- i) $m_t = Am_{t-1} + Bg(\theta) + K_t[y_t - C(Am_{t-1} + Bg(\theta)) - Dh(\theta)]$,
- ii) $K_t = (AP_{t-1}A^T + Q)C^T S_t^{-1}$,
- iii) $P_t = (I - K_t C)(AP_{t-1}A^T + Q)$,

where

$$S_t \triangleq C(AP_{t-1}A^T + Q)C^T + R \quad (\text{A.2})$$

for $t = 1, 2, \dots$. By inspecting i), we conclude that

$$m_t = M_t l(\theta) + z_t \quad (\text{A.3})$$

where

$$z_t = (I - K_t C)Az_{t-1} + K_t y_t, \quad (\text{A.4a})$$

$$M_t = (I - K_t C)AM_{t-1} + [(I - K_t C)B, -K_t D] \quad (\text{A.4b})$$

with M_0 equal to zero and $z_0 = m_0$. This gives (2.4).

Plainly, $f_{x_t, \theta|Y^t} = f_{x_t|Y^t, \theta} \cdot f_{\theta|Y^t}$, which is (2.3). We have dispensed with $f_{x_t|Y^t, \theta}$, so we need only to evaluate $f_{\theta|Y^t}$. By a standard argument

$$f_{\theta|Y^t} \propto f_{\theta} \cdot f_{Y^t|\theta} = f_{\theta} \cdot \prod_{r=1}^t f_{y_r|Y^{r-1}, \theta} \quad (\text{A.5})$$

and it follows from (2.1) and (A.1) that

$$f_{y_t|Y^{t-1}, \theta} = \mathcal{N}(N_t l(\theta) + CAz_{t-1}, S_t) \quad (\text{A.6})$$

where

$$N_t \triangleq CAM_{t-1} + [CB, D]. \quad (\text{A.7})$$

We may now prove (2.5) by induction. At $t = 0$, since Y^0 is the empty set, we set α_0 and Λ_0 to zero and (2.5) holds.

Now assume (2.5) holds at time $t-1 \geq 0$. We need to show that it also holds at time t . Equations (A.5) and (A.6) yield

$$f_{\theta|Y^t} \propto f_{\theta|Y^{t-1}} \cdot f_{y_t|Y^{t-1}, \theta}$$

$$\propto f_{\theta} \cdot \exp \{ \alpha_{t-1}^T l(\theta) + l(\theta)^T \Lambda_{t-1} l(\theta) \}$$

$$\cdot \mathcal{N}(y_t; N_t l(\theta) + CAz_{t-1}, S_t).$$

It is straightforward to find, upon substituting (A.3) for m_t , that the posterior density retains its form. The iterative equations are

$$\alpha_t = \alpha_{t-1} + N_t^T S_t^{-1} (y_t - CAz_{t-1}), \quad (\text{A.8a})$$

$$\Lambda_t = \Lambda_{t-1} - \frac{1}{2} N_t^T S_t^{-1} N_t \quad (\text{A.8b})$$

for $t = 1, 2, \dots$.

APPENDIX B PROOF OF LEMMA 3

The proof of part i) uses a conditioning argument to show that certain random variables, of which η_s and η_t are functions, are independent when $s \neq t$. This will imply the independence of η_s and η_t . The proof of part ii) is a simple application of Lemma 2.

i) Define $\varepsilon_t(\theta, Y^t) = y_t - N_t l(\theta) - CAz_{t-1}$, and assume that θ is given. Clearly $\varepsilon_t(\theta, Y^t)$ is a linear combination of Gaussian random variables and therefore also has a Gaussian distribution. Letting $\Delta_t(\theta_0, \theta) \triangleq N_t[l(\theta_0) - l(\theta)]$, we obtain

$$E_{\theta_0} \varepsilon_t(\theta, Y^t) = E_{\theta_0} \{ E_{\theta_0} \varepsilon_t(\theta, Y^t) | Y^{t-1} \}$$

$$= E_{\theta_0} \{ N_t [l(\theta_0) - l(\theta)] \}$$

$$= \Delta_t(\theta_0, \theta) \quad (\text{B.1})$$

because $f_{y_t|Y^{t-1}, \theta_0} = \mathcal{N}(N_t l(\theta_0) + CAz_{t-1}, S_t)$. Furthermore, for $s < t$

$$E_{\theta_0} \varepsilon_s(\theta, Y^s) \varepsilon_t^T(\theta, Y^t) = E_{\theta_0} \{ E_{\theta_0} \varepsilon_s(\theta, Y^s) \varepsilon_t^T(\theta, Y^t) | Y^{t-1} \}$$

$$= E_{\theta_0} \{ \varepsilon_s(\theta, Y^s) E_{\theta_0} \varepsilon_t^T(\theta, Y^t) | Y^{t-1} \}$$

$$= [E_{\theta_0} \varepsilon_s(\theta, Y^s)] \Delta_t^T(\theta_0, \theta)$$

$$= \Delta_s(\theta_0, \theta) \Delta_t^T(\theta_0, \theta) \quad (\text{B.2})$$

so ε_s and ε_t are uncorrelated. We show that they are jointly Gaussian and therefore also independent; it follows that $\eta_s = -\frac{1}{2} [\log \det 2\pi S_s + \varepsilon_s^T S_s^{-1} \varepsilon_s]$ and $\eta_t = -\frac{1}{2} [\log \det 2\pi S_t + \varepsilon_t^T S_t^{-1} \varepsilon_t]$ are independent as well.

We have $f_{\varepsilon_t, \varepsilon_s | \theta_0} = f_{\varepsilon_t | \varepsilon_s, \theta_0} \cdot f_{\varepsilon_s | \theta_0}$, where $f_{\varepsilon_s | \theta_0}$ is Gaussian. Moreover, $f_{\varepsilon_t | \varepsilon_s, \theta_0} = \int f_{\varepsilon_t | Y^{t-1}, \varepsilon_s, \theta_0} \cdot f_{Y^{t-1} | \varepsilon_s, \theta_0} dY^{t-1} = \int f_{\varepsilon_t | Y^{t-1}, \theta_0} \cdot f_{Y^{t-1} | \varepsilon_s, \theta_0} dY^{t-1}$. From (B.1) and the distribution of y_t , $f_{\varepsilon_t | Y^{t-1}, \theta_0} = \mathcal{N}(\Delta_t(\theta_0, \theta), S_t)$, and because ε_s is a linear combination of Y^s , $f_{Y^{t-1} | \varepsilon_s, \theta_0}$ is also Gaussian. Therefore, $f_{\varepsilon_t | \varepsilon_s, \theta_0}$ is Gaussian, and so is $f_{\varepsilon_t, \varepsilon_s | \theta_0}$.

ii) The random variable $S_t^{-1/2} \varepsilon_t(\theta, Y^t)$ is Gaussian with mean $S_t^{-1/2} \Delta_t(\theta_0, \theta)$ and covariance I . According to Lemma 2, $\Delta_t(\theta_0, \theta) \rightarrow \Delta_\infty(\theta_0, \theta) = N_\infty[l(\theta_0) - l(\theta)]$ and $S_t \rightarrow S_\infty$, as $t \rightarrow \infty$. Consequently, $S_t^{-1/2} \varepsilon_t(\theta, Y^t) \rightarrow S_\infty^{-1/2} \varepsilon_\infty$ in distribution. Since η_t depends continuously on $S_t^{-1/2} \varepsilon_t(\theta, Y^t)$, we have $\eta_t \rightarrow \eta_\infty$ in distribution as well.

To show convergence of the moments of the derivatives of η_t we give two examples: η_t itself and the square of its first

derivative. All of the remaining cases are shown in exactly the same way. For η_t we have

$$\begin{aligned} E_{\theta_0} \eta_t(\theta) &= -\frac{1}{2} [\log \det 2\pi S_t + \Delta_t^T S_t^{-1} \Delta_t \\ &\quad + \text{tr } S_t^{-1} E_{\theta_0}(\varepsilon_t - \Delta_t)(\varepsilon_t - \Delta_t)^T \\ &\quad + 2\Delta_t^T S_t^{-1} E_{\theta_0}(\varepsilon_t - \Delta_t)] \\ &= -\frac{1}{2} [\log \det 2\pi S_t + \Delta_t^T S_t^{-1} \Delta_t + m]. \quad (\text{B.3}) \end{aligned}$$

Similarly, $E \eta_\infty = -\frac{1}{2} [\log \det 2\pi S_\infty + \Delta_\infty^T S_\infty^{-1} \Delta_\infty + m]$. The result now follows from Lemma 2. For the square of the first derivative

$$\begin{aligned} E_{\theta_0} \frac{\partial \eta_t(\theta)}{\partial \theta_i} \frac{\partial \eta_t(\theta)}{\partial \theta_j} &= E_{\theta_0} \frac{\partial \varepsilon_t^T}{\partial \theta_i} S_t^{-1} \varepsilon_t \varepsilon_t^T S_t^{-1} \frac{\partial \varepsilon_t}{\partial \theta_j} \\ &\quad + \frac{\partial l^T(\theta)}{\partial \theta_i} N_t^T S_t^{-1} E_{\theta_0} \varepsilon_t \varepsilon_t^T \\ &\quad + S_t^{-1} N_t \frac{\partial l(\theta)}{\partial \theta_j} \\ &= \frac{\partial l^T(\theta)}{\partial \theta_i} N_t^T S_t^{-1} (S_t + \Delta_t \Delta_t^T) \\ &\quad + S_t^{-1} N_t \frac{\partial l(\theta)}{\partial \theta_j}. \end{aligned}$$

Similarly

$$\begin{aligned} E \frac{\partial \eta_\infty(\theta)}{\partial \theta_i} \frac{\partial \eta_\infty(\theta)}{\partial \theta_j} &= \frac{\partial l^T(\theta)}{\partial \theta_i} N_\infty^T S_\infty^{-1} \\ &\quad + (S_\infty + \Delta_\infty \Delta_\infty^T) S_\infty^{-1} N_\infty \frac{\partial l(\theta)}{\partial \theta_j} \end{aligned}$$

and the result again follows from Lemma 2.

APPENDIX C PROOF OF LEMMA 4

This lemma is proved here using Chebyshev's inequality in much the same way as Lemma 1 of [5]. Our proof, however, accommodates the fact that $\log f_{1:\theta}$ is a sum of independent random variables that do not have identical distributions.

We start with $\log(f_{1:\theta}/f_{1:\theta_0}) = \sum_{r=1}^t \{\eta_r(\theta) - \eta_r(\theta_0)\}$, where $\eta_r(\theta)$ is defined in (3.1). From (B.3)

$$\begin{aligned} E_{\theta_0} \{\eta_t(\theta) - \eta_t(\theta_0)\} &= -\frac{1}{2} \Delta_t^T(\theta_0, \theta) S_t^{-1} \Delta_t(\theta_0, \theta) \\ &\quad + \frac{1}{2} \Delta_t^T(\theta_0, \theta_0) S_t^{-1} \Delta_t(\theta_0, \theta_0) \\ &= -\frac{1}{2} \Delta_t^T(\theta_0, \theta) S_t^{-1} \Delta_t(\theta_0, \theta). \end{aligned}$$

Therefore, Assumption B3) and Lemma 3 imply that $E_{\theta_0} \{\eta_t(\theta) - \eta_t(\theta_0)\}$ tends exponentially quickly, as $t \rightarrow \infty$, to some $\mu_1(\theta) < 0$ when $\theta \neq \theta_0$. In general, $\eta_r(\theta) - \eta_r(\theta_0)$ has s th central moment converging exponentially quickly to some $\mu_s(\theta)$. The moments are continuous functions of θ , so if we let $\mu_s \triangleq \max_{\epsilon < |\theta - \theta_0| \leq k} \mu_s(\theta)$ for any $0 < \epsilon < k$, then

for any θ obeying $\epsilon \leq |\theta - \theta_0| \leq k$

$$\begin{aligned} &P \left\{ \sum_{r=1}^t \eta_r(\theta) - \eta_r(\theta_0) > \frac{1}{2} t \mu_1 + O(1) \right\} \\ &\leq P \left\{ \sum_{r=1}^t \eta_r(\theta) - \eta_r(\theta_0) > \frac{1}{2} t \mu_1(\theta) + O(1) \right\} \\ &\leq P \left\{ \left| \sum_{r=1}^t [\eta_r(\theta) - \eta_r(\theta_0)] - t \mu_1(\theta) \right| > -\frac{1}{2} t \mu_1(\theta) \right\} \\ &\leq \frac{3t(t-1)\mu_2^2(\theta) + t\mu_4(\theta) + O(1)}{(1/16)t^4\mu_1^4(\theta)} \\ &\leq \frac{3t(t-1)\mu_2^2 + t\mu_4 + O(1)}{(1/16)t^4\mu_1^4} = O(t^{-2}) \end{aligned}$$

as $t \rightarrow \infty$. Equivalently, $f_{Y^{1:\theta}}/f_{Y^{1:\theta_0}}$ is $O(e^{-t\delta})$ with probability $1 - O(t^{-2})$. The constants in the $O(\cdot)$ terms are independent of θ so the approximation is uniform. From Assumption B6), the result holds for $|\theta| > k$ when k is sufficiently large. We therefore have uniformity in $|\theta - \theta_0| > \epsilon$ for any $\epsilon > 0$.

APPENDIX D PROOF OF THEOREM 1

We prove Theorem 1 by evaluating the expressions of (3.5) and simplifying. From (A.6) we obtain

$$f_{1:\theta} = \prod_{r=1}^t \mathcal{N}(y_r; N_r l(\theta) + C A z_{r-1}, S_r).$$

So

$$\frac{\partial \log f_{1:\theta}}{\partial \theta_i} = \sum_{r=1}^t \frac{\partial l^T(\theta)}{\partial \theta_i} N_r^T S_r^{-1} \varepsilon_r,$$

where $\varepsilon_r(\theta, Y^r) = y_r - N_r l(\theta) - C A z_{r-1}$. Also

$$\begin{aligned} \frac{\partial^2 \log f_{1:\theta}}{\partial \theta_i \partial \theta_j} &= \sum_{r=1}^t \left[\frac{\partial^2 l^T(\theta)}{\partial \theta_i \partial \theta_j} N_r^T S_r^{-1} \varepsilon_r \right. \\ &\quad \left. - \frac{\partial l^T(\theta)}{\partial \theta_i} N_r^T S_r^{-1} N_r \frac{\partial l(\theta)}{\partial \theta_j} \right] \\ \frac{\partial^3 \log f_{1:\theta}}{\partial \theta_i \partial \theta_j \partial \theta_k} &= \sum_{r=1}^t \left[\frac{\partial^3 l^T(\theta)}{\partial \theta_i \partial \theta_j \partial \theta_k} N_r^T S_r^{-1} \varepsilon_r \right. \\ &\quad - \frac{\partial^2 l^T(\theta)}{\partial \theta_i \partial \theta_j} N_r^T S_r^{-1} N_r \frac{\partial l(\theta)}{\partial \theta_k} \\ &\quad - \frac{\partial l^T(\theta)}{\partial \theta_i} N_r^T S_r^{-1} N_r \frac{\partial^2 l(\theta)}{\partial \theta_j \partial \theta_k} \\ &\quad \left. - \frac{\partial^2 l^T(\theta)}{\partial \theta_i \partial \theta_k} N_r^T S_r^{-1} N_r \frac{\partial l(\theta)}{\partial \theta_j} \right]. \end{aligned}$$

Therefore

$$\begin{aligned} (J)_{j,k} &= - \sum_{r=1}^t \frac{\partial l^T(\theta)}{\partial \theta_j} N_r^T S_r^{-1} N_r \frac{\partial l(\theta)}{\partial \theta_k} \\ &= \frac{\partial l^T(\theta)}{\partial \theta_j} 2\Lambda_t \frac{\partial l(\theta)}{\partial \theta_k} \quad (\text{D.1}) \end{aligned}$$

where the last equality is a consequence of (A.8b). Furthermore

$$p_{ijk} = E_{\theta} \left\{ \sum_{r=1}^t \left[\frac{\partial^2 l^T(\theta)}{\partial \theta_i \partial \theta_j} N_r^T S_r^{-1} \right. \right. \\ \left. \left. - \frac{\partial l^T(\theta)}{\partial \theta_i} N_r^T S_r^{-1} N_r \frac{\partial l(\theta)}{\partial \theta_j} \right] \right. \\ \left. \cdot \sum_{s=1}^t \frac{\partial l^T(\theta)}{\partial \theta_k} N_s^T S_s^{-1} \varepsilon_s \right\}. \quad (D.2)$$

From (B.1) and (B.2), $E_{\theta} \varepsilon_t = \Delta_t(\theta, \theta) = 0$; whenever $s \neq t$, $E_{\theta} \varepsilon_s \varepsilon_t^T = \Delta_s(\theta, \theta) \Delta_t^T(\theta, \theta) = 0$; $E_{\theta} \varepsilon_t \varepsilon_t^T = S_t + \Delta_t(\theta, \theta) \Delta_t^T(\theta, \theta) = S_t$. It follows that

$$p_{ijk} = - \frac{\partial^2 l^T(\theta)}{\partial \theta_i \partial \theta_j} 2\Lambda_t \frac{\partial l(\theta)}{\partial \theta_k} \quad (D.3)$$

Similarly

$$p_{ijk} = \frac{\partial^2 l^T(\theta)}{\partial \theta_i \partial \theta_j} 2\Lambda_t \frac{\partial l(\theta)}{\partial \theta_k} + \frac{\partial^2 l^T(\theta)}{\partial \theta_j \partial \theta_k} 2\Lambda_t \frac{\partial l(\theta)}{\partial \theta_i} \\ + \frac{\partial^2 l^T(\theta)}{\partial \theta_i \partial \theta_k} 2\Lambda_t \frac{\partial l(\theta)}{\partial \theta_j}. \quad (D.4)$$

Combining (D.3) and (D.4), we obtain

$$p_{ijk} + p_{ikj} = \frac{\partial^2 l^T(\theta)}{\partial \theta_i \partial \theta_k} 2\Lambda_t \frac{\partial l(\theta)}{\partial \theta_j} + \frac{\partial^2 l^T(\theta)}{\partial \theta_j \partial \theta_k} 2\Lambda_t \frac{\partial l(\theta)}{\partial \theta_i}$$

and using (3.5) and (D.1), we see that the minimum bias prior must satisfy

$$= \sum_{j,k=1}^p (J^{-1})_{j,k} \\ - \frac{1}{2} \frac{\partial}{\partial \theta_i} \{ (J)_{j,k} \} + \frac{\partial l^T(\theta)}{\partial \theta_i} 2\Lambda_t \frac{\partial^2 l(\theta)}{\partial \theta_j \partial \theta_k} \\ - \frac{1}{2} \left\{ \text{tr} \left\{ J^{-1} \frac{\partial J}{\partial \theta_i} \right\} + \text{tr} \{ J^{-1} U_i \} \right\}_{\theta=\theta_0} \\ = \left[\frac{1}{2} \frac{\partial}{\partial \theta_i} [\log \det(-J)] + \text{tr} \{ J^{-1} U_i \} \right]_{\theta=\theta_0}, \\ i = 1, \dots, p.$$

This concludes the proof.

APPENDIX E PROOF OF THEOREM 2

We prove the result for a scalar θ ; the extension to the multivariate case is straightforward.

We first verify that the prior defined in (3.10) satisfies Assumptions B4) and B5). To verify B4) observe that $\log f_{\theta}(\hat{\theta}_{t-1}) = \theta \cdot \nu(\hat{\theta}_{t-1})$, and the derivatives $(\partial/\partial\theta) \log f_{\theta}(\hat{\theta}_{t-1}) = \nu(\hat{\theta}_{t-1})$, $(\partial^2/\partial\theta^2) \log f_{\theta}(\hat{\theta}_{t-1}) = 0$, exist and are continuous for all θ . For $\theta \in \Theta$, it follows from (A.6) and Lemma 2 that $f_{\theta}(\hat{\theta}_{t-1})$ is bounded as a function of y_t , uniformly in Y^{t-1} and t . Because Λ_t/t converges as $t \rightarrow \infty$ and Θ is bounded, $\nu(\theta)$ is continuous in θ uniformly in (sufficiently large) t . Thus, $f_{\theta}(\hat{\theta}_{t-1})$ is bounded and B5) is satisfied.

The fact that the prior is now a function of the observations modifies the asymptotic expansion (3.2). Since $\hat{\theta}_{t-1} \in \Theta$ and

$\nu(\theta)$ is continuous on Θ uniformly in t , we are assured that $q_1 = (\partial/\partial\theta) \log f_{\theta}(\hat{\theta}_{t-1}) = \nu(\hat{\theta}_{t-1})$ is still $O(1)$. Hence, the expansion (3.2) becomes

$$E_{\theta_0} \hat{\theta}_t = \theta_0 - p_2^{-1} [E_{\theta_0} q_1 - (p_{12} + p_{33})/p_2]_{\theta=\theta_0} \\ + o(t^{-1}) \quad (E.1)$$

as $t \rightarrow \infty$. It remains to show that $[E_{\theta_0} q_1 - (p_{12} + p_{33})/p_2]_{\theta=\theta_0} = o(1)$.

From [5, Theorem 2], $\hat{\theta}_t$ converges in probability to θ_0 , and since θ_0 is an interior point of Θ , $\hat{\theta}_t$ converges in probability to θ_0 (the projection mechanism has no effect in a small enough neighborhood of θ_0 ; see remarks after statement of theorem). For any $\delta > 0$ we have

$$|E_{\theta_0} q_1 - (p_{12} + p_{33})/p_2|_{\theta=\theta_0} = |E_{\theta_0} \nu(\hat{\theta}_{t-1}) - \nu(\theta_0)| \\ \leq E_{\theta_0} 1_{\{|\hat{\theta}_{t-1} - \theta_0| < \delta\}} |\nu(\hat{\theta}_{t-1}) - \nu(\theta_0)| \\ + E_{\theta_0} 1_{\{|\hat{\theta}_{t-1} - \theta_0| \geq \delta\}} |\nu(\hat{\theta}_{t-1}) - \nu(\theta_0)| \quad (E.2)$$

Let $\epsilon > 0$ be chosen. Because $\nu(\theta)$ is continuous at θ_0 , the first term on the right-hand side of (E.2) is bounded by ϵ for δ small enough. We know $\hat{\theta}_{t-1} \in \Theta$ is bounded and $\nu(\theta)$ is continuous for $\theta \in \Theta$, so the second term is bounded by a constant multiple of $P\{|\hat{\theta}_{t-1} - \theta_0| \geq \delta\}$. For t sufficiently large this term is also bounded by ϵ . Thus, $[E_{\theta_0} q_1 - (p_{12} + p_{33})/p_2]_{\theta=\theta_0} = o(1)$ as $t \rightarrow \infty$, and $E_{\theta_0} \hat{\theta}_t = \theta_0 - p_2^{-1} o(1) + o(t^{-1}) = \theta_0 + o(t^{-1})$, which was to be shown.

Nonlinear L_1 Optimal Controllers for Linear Systems

A. A. Stoorvogel

Abstract—In this paper we study the L_1 optimal control problem for linear systems. We will show that by allowing the class of controllers to include nonlinear controllers, we can make the closed-loop L_1 norm strictly smaller than we could do using only linear controllers.

I. INTRODUCTION

The L_1 optimal control problem has been studied extensively in the literature. The L_1 problem was originally formulated in [1] and [8]. A solution to the problem was presented in [3] (for discrete-time systems) and [2] (for continuous-time systems). In these papers it became obvious that, when searching for optimal linear controllers for these problems, we need infinite-dimensional (continuous-time) or very high order (discrete-time) compensators. Especially for discrete-time systems, there is now a good theory available for the design of linear compensators (see e.g., [5]). The approach taken in these papers, however, is a method based on linear programming, and the method is therefore essentially constrained to linear compensators.

The objective of the current paper is to study whether we can improve by extending the class of compensators to include nonlinear compensators. For H_∞ , it is known, for instance, that this is not possible: the minimum over all stabilizing linear compensators of the closed-loop H_∞ norm is equal to the minimum over all stabilizing (possibly) nonlinear compensators (see [6]).

In [7] it has been shown that, although for the L_1 optimal control problem optimal and near optimal linear state feedback compensators are in general dynamic, there always exists static nonlinear compensators which achieve the same or better performance. Moreover, in [4] it was shown that nonlinear controllers which are differentiable in the origin cannot do better than linear controllers. Via an example, it was shown in that paper that nonlinear controller can do better for individual disturbances w . But, for this example, the worst-case L_1 norm could not be improved via nonlinear controllers. The objective of this paper is to show that we can achieve smaller L_1 norm if we allow for nonlinear, continuous controllers. This will be shown by means of a very simple static example. Hence the example applies equally well to continuous and discrete time. For ease of exposition we will concentrate on continuous-time systems only.

The paper has the following structure. In the next section we will give a problem formulation. Then we present our example and we conclude with some final remarks.

II. PROBLEM FORMULATION

We will consider systems of the form

$$\begin{cases} \dot{x} = Ax + Bu + Ew, \\ y = C_1x + D_{11}u + D_{12}w, \\ z = C_2x + D_{21}u + D_{22}w. \end{cases} \quad (2.1)$$

Manuscript received March 1, 1994.

The author is with the Department of Mathematics and Comp. Science, Eindhoven University of Technology, P.O. Box 513, 5600 MB Eindhoven, The Netherlands

IEEE Log Number 9408781.

We will assume that x , u , w , y , and z take values in finite-dimensional vector spaces $x(t) \in \mathbb{R}^n$, $u(t) \in \mathbb{R}^m$, $w(t) \in \mathbb{R}^l$, $y(t) \in \mathbb{R}^q$, and $z(t) \in \mathbb{R}^p$. A special case are static systems where x is absent ($n = 0$) and we just have

$$\Sigma: \begin{cases} y = D_{11}u + D_{12}w, \\ z = D_{21}u + D_{22}w. \end{cases} \quad (2.2)$$

For a vector in \mathbb{R}^n we define the L_∞ -norm by

$$\|p\|_\infty = \sup |p_i| \quad (2.3)$$

where $p = (p_1, p_2, \dots, p_n)^T$. We define the function space L_∞ as the class of time-signals f for which the norm

$$\|f\|_\infty = \sup_{t \in \mathbb{R}^+} \|f(t)\|_\infty$$

is finite. This norm will be referred to as the L_∞ norm. We define the L_∞ -induced operator norm of an operator \mathcal{G} mapping w to z by

$$\|\mathcal{G}\|_1 = \sup_{w \neq 0, t \in \mathbb{R}^+} \frac{\|z\|_\infty}{\|w\|_\infty}$$

This norm is also referred to as the L_1 norm of \mathcal{G} . This is due to the fact that for operators \mathcal{G} described by a linear time invariant system of the form

$$\Sigma: \begin{cases} \dot{x} = Fx + Gw, \\ z = Hx + Ju \end{cases} \quad (2.4)$$

we find that the L_∞ -induced operator norm is equal to the L_1 norm of the impulse response which is defined by

$$\|H\|_1 = \int_0^\infty \|H(t)\|_\infty dt$$

where for a matrix $M = \{M_{ij}\}$ we have

$$\|M\| = \max_i \sum_j |M_{ij}|.$$

Clearly, this interpretation only holds for linear time-invariant systems and in particular does not hold for the closed-loop system we obtain by applying a nonlinear controller to (2.1). Nevertheless, since the L_∞ -induced operator norm yields a natural extension of the L_1 norm to nonlinear systems, we will often refer to the L_∞ -induced operator norm of a nonlinear system as the L_1 norm.

Note that for a static, time-invariant system like (2.2), first of all, it is obviously of no use to consider dynamic compensators. Hence we only consider static, time invariant but possibly nonlinear controllers. Then the output at time t of the closed-loop system is only affected by the disturbance at time t and the input at time t , and we obtain a finite dimensional optimization problem. Find a function K from \mathbb{R}^l to \mathbb{R}^m such that $I - D_{11}K$ is invertible and the closed-loop operator G_{cl} from \mathbb{R}^l to \mathbb{R}^p defined by

$$G_{cl} := D_{22} + D_{21}K(I - D_{11}K)^{-1}D_{12}$$

has minimal L_∞ -induced operator norm where the L_∞ norm of the input and output vectors are defined by (2.3)

III. EXAMPLE

In this section we will study the following very simple example

$$\begin{cases} y = u \\ \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \end{bmatrix} = \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \end{bmatrix} u + \begin{bmatrix} 0 & 3 & 0 \\ -1.5 & 1.5 & -3 \\ -3 & 0 & 0 \\ 0 & 0 & -3 \end{bmatrix} \end{cases} \quad (3.1)$$

We claim that for this static example the minimal achievable I_1 norm is 3. The latter can only be achieved, however, via a nonlinear controller. Via a linear controller the minimal achievable I_1 norm is equal to 3.75.

A. Linear Controllers

We will study the optimal input u for four specific disturbances

$$\begin{aligned} u_1 &= \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \end{pmatrix}, & u_2 &= \begin{pmatrix} 1 \\ 1 \\ 1 \\ -1 \end{pmatrix} \\ u_3 &= \begin{pmatrix} -1 \\ 1 \\ 1 \\ 1 \end{pmatrix}, & u_4 &= \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \end{pmatrix} \end{aligned} \quad (3.2)$$

Each of these disturbances has norm one. Hence to achieve an I_1 norm equal to 3 we have to have that for u and the corresponding control input u we obtain an output with norm less than or equal to 3. For u_1 , u_2 and u_3 we find that $\|y\|_\infty = 3 + \|u\|_\infty$. For u_4 we have $\|y\|_\infty = \max\{6 - u_1, u_1 - 3\}$. Since we only allow linear controllers and $u_1 = u_1 - u = -u_4$, we must have $u_1 = u_1 - u = -u_4$. We find that to make $\|y\|_\infty < 3.75$ then either $u_1 = u$ or u_4 must be larger than 0.75 and hence u_1 or u_4 must have norm larger than 3.75. This implies that we can never make the I_1 norm less than 3.75 by linear controllers. Moreover, the linear controller

yields the closed loop system

$$\begin{bmatrix} 0.75 & 2.25 & 0.75 \\ -0.75 & 0.75 & -2.25 \\ -2.25 & -0.75 & 0.75 \\ 0.75 & -0.75 & -2.25 \end{bmatrix}$$

and it clearly achieves a closed loop I_1 norm of 3.75.

B. Nonlinear Controllers

To find an optimal nonlinear controller for the system (3.1) we again look at the four disturbances from (3.2). Since we have $\|y\|_\infty = 3 + \|u\|_\infty$, it is obvious that we cannot make the I_∞ induced operator norm less than three. We will now construct an optimal nonlinear controller which achieves an I_1 norm equal to three. Consider the eight corners of the cube $\|u\|_\infty = 1$. Besides the four corners given by (3.2) we have

$$\begin{bmatrix} -1 \\ -1 \\ -1 \\ -1 \end{bmatrix}, \quad u_5 = \begin{bmatrix} -1 \\ -1 \\ 1 \\ 1 \end{bmatrix}$$

$$u_6 = \begin{bmatrix} 1 \\ -1 \\ -1 \\ -1 \end{bmatrix}, \quad u_7 = \begin{bmatrix} -1 \\ 1 \\ 1 \\ -1 \end{bmatrix} \quad (3.3)$$

We find that the optimal input for each corner is $u_1 = 0, u_2 = 0, u_3 = 0, u_4 = 3, u_5 = 0, u_6 = 0, u_7 = 0, u_8 = -3$. This yields an output with norm three for each corner. We next extend our function to each face of the cube. For any u with $\|u\|_\infty = 1$ we find

$$u = \lambda_1 u_1 + \lambda_2 u_2 + \lambda_3 u_3 + \lambda_4 u_4$$

for some $\lambda_i \geq 0$ with $\lambda_1 + \lambda_2 + \lambda_3 + \lambda_4 = 1$. The choice of λ_i is not unique but it is straightforward to derive a continuous selection rule. We choose the corresponding input as

$$u = \lambda_1 u_1 + \lambda_2 u_2 + \lambda_3 u_3 + \lambda_4 u_4$$

and the resulting output is

$$y = \lambda_1 y_1 + \lambda_2 y_2 + \lambda_3 y_3 + \lambda_4 y_4$$

Finally we note that

$$\begin{aligned} \|y\|_\infty &\leq \lambda_1 \|y_1\|_\infty + \lambda_2 \|y_2\|_\infty + \lambda_3 \|y_3\|_\infty + \lambda_4 \|y_4\|_\infty \\ &= 3 + 3\|u\|_\infty \end{aligned}$$

In this way we have defined a continuous function f on the cube $\|u\|_\infty = 1$. We can extend this function to the whole \mathbb{R}^4 by

and the closed loop system resulting from $u = f(u)$ can be easily checked to have I_1 induced operator norm equal to three. We have already seen that this feedback is therefore optimal.

IV. CONCLUSION

In previous papers the first step was to use the Youla parameterization to bring the closed loop operator in the form $T_1 + T_2 Q I_1$, where Q is the design variable which should be a stable system and which determines uniquely the corresponding controller. In [4] it has been shown that for $I_1 = I$ nonlinear controllers can not achieve a smaller I_1 norm. This paper gives an example where $T_1 = I$ and we can do better by nonlinear controllers. $T_1 = I$ is connected to estimation problems while $T_2 = I$ is connected to control problems. This shows a clear lack of duality and the best we can hope for is a kind of separation structure for I_1 controllers which will be of the form of a linear estimator interconnected to a nonlinear static state feedback. Nonlinear static state feedbacks were already studied in [7].

This paper basically only tells us that we should study nonlinear compensators if we want to obtain optimal controllers.

Simultaneous Observation of Linear Systems

Y. X. Yao, M. Darouach, and J. Schaefer

Abstract—This note considers the problem of designing an observer which can observe the states for each of a given set of plants. The concept of the simultaneous observation is introduced. The simultaneous observation is achieved using coprime factorization techniques. Necessary and sufficient conditions for the existence of simultaneous observation are derived. The observer design is discussed, and an example is given.

I. INTRODUCTION

In this note we are interested in the problem of designing an observer which can observe the states for each of a given set of plants. Specifically, suppose that $G_0(s), G_1(s), \dots, G_n(s)$ are a finite number of given plants, we would like to know whether or not there exists a common observer for this given set of plants. This is referred to as the simultaneous observation problem in this note.

There are two reasons at least to study the simultaneous observation problem like the simultaneous stabilization problem [1] in which a compensator stabilizes each of a given set of plants. First, because the structure of the plant is often subjected to unexpected change, such as components fault or variation in operating condition, we wish to design an observer which can continue to observe the states of the plant in the presence of the plant change. Specifically, $G_0(s)$ corresponds to the nominal plant description to be observed, while $G_1(s), G_2(s), \dots, G_n(s)$ correspond to the plant description after some sort of structural change. The problem to design an observer which can continue to observe the states of the plant after this sort of structural change is equivalent to find an observer which can observe the states for each of the plants $G_0(s), G_1(s), \dots, G_n(s)$. Secondly, it may arise in the observer design of a nonlinear system at various operating conditions. The nonlinear system is often linearized at the various operating points, and some of linearized models can be obtained. If the states of each of these linearized models can be observed using a common observer, then a fixed observer can be used for the nonlinear system.

IEEE Log Number 9408777.

The proposed problem is motivated by the simultaneous control system design problem, particularly the simultaneous stabilization problem which was first posed in [2] and [3]. For a given set of plants, one would like to know whether or not there exists a common controller such that all plants are simultaneously stabilized in the simultaneous stabilization problem. It is also natural that one would like to know whether or not there exists a common observer such that the states for each of given plants are simultaneously observed.

This note focuses on the existence of simultaneous observation. The observer design is also discussed.

II. PROBLEM DESCRIPTION AND PRELIMINARIES

Consider a set of the linear time-invariant systems described by

$$\dot{x}(t) = A_i x(t) + B_i u(t) \quad (1)$$

$$y(t) = C_i x(t) + D_i u(t), \quad i = 0, 1, \dots, n \quad (2)$$

where $x(t) \in R^n$ is the state vector, $u(t) \in R^p$ is the input vector and $y \in R^m$ is the observation vector, and A_i, B_i, C_i and D_i are constant matrices of the appropriate dimensions. Taking Laplace transformation of (1) and (2), gives

with

$$G_i(s) = C_i(sI - A_i)^{-1} B_i + D_i.$$

It is desired to design an observer which will produce an estimation for

$$\hat{x}(t) = L_i x(t) \quad (4)$$

with $L_i \in R^{k \times n}$. An observer for the systems (1)–(3) is expressed as a dynamic system

$$\dot{r}(s) = F(s)u(s) + H(s)y(s) \quad (5)$$

with the property that the estimation error satisfies

$$\lim_{t \rightarrow \infty} (L_i x(t) - r(t)) = 0 \quad (6)$$

for all $u(s)$, where $F(s)$ and $H(s)$ are RH_∞ matrices, i.e., they are stable transfer function matrices. If such an observer exists, we say that $G_0(s), G_1(s), \dots, G_n(s)$ in (3) are simultaneously observable.

Our main problem to be solved is: given $n+1$ plants as (1), (2), or (3), we would like to know whether or not there exists a common observer for this given set of plants. This is referred to as the simultaneous observation problem.

The right-coprime and left-coprime factorization of the i th plant G_i are

$$G_i(s) = N_i(s)M_i^{-1}(s) = \hat{M}_i^{-1}(s)\hat{N}_i(s) \quad (7)$$

respectively, and $N_i(s), M_i(s)$ are right-coprime RH_∞ matrices, $\hat{M}_i(s)$ and $\hat{N}_i(s)$ are left-coprime RH_∞ matrices. For the double-coprime factorization of $G_i(s)$ there exist RH_∞ transfer functions $Y_i(s), X_i(s), \hat{Y}_i(s)$ and $\hat{X}_i(s)$ such that

$$\begin{aligned} & \begin{bmatrix} Y_i(s) & X_i(s) \\ -\hat{N}_i(s) & \hat{M}_i(s) \end{bmatrix} \begin{bmatrix} M_i(s) & -\hat{X}_i(s) \\ N_i(s) & Y_i(s) \end{bmatrix} \\ &= \begin{bmatrix} M_i(s) & \hat{X}_i(s) \\ -N_i(s) & \hat{Y}_i(s) \end{bmatrix} \begin{bmatrix} Y_i(s) & -X_i(s) \\ \hat{N}_i(s) & \hat{M}_i(s) \end{bmatrix} \\ &= \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix}. \end{aligned} \quad (8)$$

Each matrix in Bezout identity (8) can be calculated by using the existing algorithms given in [1]. The state-space construction of the right-coprime factors $N_i(s)$ and $M_i(s)$ is given in the following

$$N_i(s) = C_{ki}(sI - A_{ki})^{-1}B_i + D_i, \quad (9)$$

$$M_i(s) = K_i(sI - A_{ki})^{-1}B_i + J \quad (10)$$

where K_i is matrix such that $A_{ki} = A_i + B_i K_i$ is stable and $C_{ki} = C_i + D_i K_i$.

Define the partial-state $\xi(s)$ as follows

$$M_i(s)\xi(s) = u(s).$$

Then from (7), (3) can be written as

$$M_i(s)\xi(s) = u(s) \quad (11)$$

$$y(s) = N_i(s)\xi(s) \quad (12)$$

and the variable $E_i x(s)$ according to (4) can be expressed by

$$z(s) = P_i(s)\xi(s) \quad (13)$$

where $P_i(s)$ can be calculated as follows.

From (7), the right-coprime factorization of the i th plant G_i can be written as

$$C_i(sI - A_i)^{-1}B_i + D_i = N_i(s)M_i^{-1}(s).$$

Using (9) and (10) we have

$$(sI - A_i)^{-1}B_i = (sI - A_{ki})^{-1}B_i M_i^{-1}(s) \quad (14)$$

which leads to

$$x(s) = (sI - A_i)^{-1}B_i u(s) = (sI - A_{ki})^{-1}B_i \xi(s).$$

Thus, the variable $z(s)$ in (13) is obtained with RH_∞ matrices

$$P_i(s) = E_i(sI - A_{ki})^{-1}B_i. \quad (15)$$

Then the problem of designing a common observer for the systems (1), (2), or (3) can be stated as finding RH_∞ -matrices $F(s)$ and $H(s)$ such that for all $u(s)$

$$z(s) - r(s) = 0. \quad (16)$$

Condition (16) is satisfied, i.e., $E_i x(t)$ can be observed if and only if the following condition holds [5]

$$F(s)M_i(s) + H(s)N_i(s) = P_i(s). \quad (17)$$

When only one plant is considered in (1), (2), or (3), the parameterization of the observer (5) has been given in [4], [6] using the factorization approach [1]. The result is given in the following lemma.

Lemma 1 [6]: The set of RH_∞ matrices $F(s)$, $H(s)$ that satisfy

$$F(s)M(s) + H(s)N(s) = P(s) \quad (18)$$

is given by

$$F(s) = P(s)Y(s) - Q(s)\hat{N}(s), \quad (19)$$

$$H(s) = P(s)X(s) + Q(s)\hat{M}(s), \quad Q(s) \in RH_\infty \quad (20)$$

and, for every RH_∞ matrix $Q(s)$ of appropriate dimensions, $F(s)$ and $H(s)$ satisfying (19) and (20) also fulfill the existence condition (18) of the observer.

Based on this parameterization, we now mainly consider the problem for the existence of the simultaneous observation. We would like to know whether or not there exists a common observer with the form (5) satisfying the observer existence condition (17) for the given set of plants (1), (2), or (3), and if this observer exists, how to design it?

III. MAIN RESULTS

First, we study the problem of simultaneously observing the states of two plants which can be stated as follows: Given two plants $G_0(s)$ and $G_1(s)$, when does there exist a common observer such that they are both observable?

Theorem 1: Given two plants $G_0(s)$ and $G_1(s)$, define

$$A(s) = Y_0(s)M_1(s) + X_0(s)N_1(s), \quad (21)$$

$$B(s) = -\hat{N}_0(s)M_1(s) + \hat{M}_0(s)N_1(s). \quad (22)$$

Then $G_0(s)$ and $G_1(s)$ can be simultaneously observed if and only if there exists an $R(s) \in RH_\infty$ such that

$$P_0(s)A(s) + R(s)B(s) = P_1(s) \quad (23)$$

holds.

Proof: From Lemma 1, the sets of observers that can observe $G_0(s)$ and $G_1(s)$ are given by

$$\begin{aligned} r(G_0) &= \{F_0(s) = P_0(s)Y_0(s) - Q_0(s)\hat{N}_0(s), H_0(s) \\ &= P_0(s)X_0(s) + Q_0(s)\hat{M}_0(s); Q_0(s) \in RH_\infty\}, \end{aligned} \quad (24a)$$

$$\begin{aligned} r(G_1) &= \{F_1(s) = P_1(s)Y_1(s) - Q_1(s)\hat{N}_1(s), H_1(s) \\ &= P_1(s)X_1(s) + Q_1(s)\hat{M}_1(s); Q_1(s) \in RH_\infty\}. \end{aligned} \quad (24b)$$

Hence $G_0(s)$ and $G_1(s)$ can be simultaneously observed if and only if there exist $Q_0(s)$, $Q_1(s) \in RH_\infty$ such that

$$P_0(s)Y_0(s) - Q_0(s)\hat{N}_0(s) = P_1(s)Y_1(s) - Q_1(s)\hat{N}_1(s), \quad (25)$$

$$P_0(s)X_0(s) + Q_0(s)\hat{M}_0(s) = P_1(s)X_1(s) + Q_1(s)\hat{M}_1(s). \quad (26)$$

Now (25), (26) can be rewritten as

$$\begin{aligned} [P_0(s) \quad Q_0(s)] \begin{bmatrix} Y_0(s) & X_0(s) \\ -\hat{N}_0(s) & \hat{M}_0(s) \end{bmatrix} \\ = [P_1(s) \quad Q_1(s)] \begin{bmatrix} Y_1(s) & X_1(s) \\ -\hat{N}_1(s) & \hat{M}_1(s) \end{bmatrix} \end{aligned} \quad (27)$$

which is equivalent to

$$\begin{aligned} [P_0(s) \quad Q_0(s)] \begin{bmatrix} Y_0(s) & X_0(s) & M_1(s) & -\hat{N}_1(s) \\ -\hat{N}_0(s) & \hat{M}_0(s) & N_1(s) & \hat{Y}_1(s) \end{bmatrix} \\ = [P_1(s) \quad Q_1(s)] \end{aligned} \quad (28)$$

from (8), or

$$[P_0(s) \quad Q_0(s)] \begin{bmatrix} A(s) & S(s) \\ B(s) & T(s) \end{bmatrix} = [P_1(s) \quad Q_1(s)] \quad (29)$$

where

$$\begin{bmatrix} A(s) & S(s) & Y_0(s) & X_0(s) \\ B(s) & T(s) & -\hat{N}_0(s) & \hat{M}_0(s) \end{bmatrix} \begin{bmatrix} M_1(s) & -\hat{N}_1(s) \\ N_1(s) & \hat{Y}_1(s) \end{bmatrix} \quad (30)$$

Thus $G_0(s)$ and $G_1(s)$ can be simultaneously observed if and only if there exists $Q_0(s)$, $Q_1(s) \in RH_\infty$ such that (29) holds. Therefore Theorem 1 is proved if we can establish that (29) holds if and only if $P_0(s)A(s) + R(s)B(s) = P_1(s)$ for some $R(s) \in RH_\infty$.

Suppose (29) holds for suitable $Q_0(s)$, $Q_1(s) \in RH_\infty$, then $P_0(s)A(s) + Q_0(s)B(s) = P_1(s)$. Conversely, suppose $P_0(s)A(s) + R(s)B(s) = P_1(s)$ for some $R(s) \in RH_\infty$, then (29) holds with $Q_0(s) = R(s)$, $Q_1(s) = (S(s) + Q_0(s)T(s))$. This completes the proof. \square

Theorem 1 shows that the problem of simultaneously observing two plants can be reduced to that of observing a single plant using a common observer.

It should be pointed out that the proof of Theorem 1 closely follows the corresponding proof of the simultaneous stabilization problem for two plants (e.g., see [1, Theorem 5.4.2]). In addition, it is seen that $A(s)$ and $B(s)$ in Theorem 1 are the same as those of Theorem

5.4.2 in [1]. It is shown in [1] that $A(s)$ and $B(s)$ are right coprime. Theorem 5.4.2 in [1] states that two systems $G_0(s)$ and $G_1(s)$ can be simultaneously stabilized if and only if the associated system $\hat{G}(s) = B(s)A(s)^{-1}$ is strongly stabilizable, i.e., it can be stabilized using a stable compensator.

Corollary 1: If condition (23) is satisfied for two given plants $G_0(s)$ and $G_1(s)$ in Theorem 1, then

$$F_0(s)M_1(s) + H_0(s)N_1(s) = P_1(s). \quad (31)$$

Proof: This is a direct result from Theorem 1; its proof is omitted here. \square

This corollary further indicates that the observer of the first plant $G_0(s)$ can be used to observe the second plant $G_1(s)$. Therefore two plants can be observed by a common observer. It is a more intuitive result in the following.

Corollary 2: Suppose $G_0(s)$ is stable and $G_1(s)$ is arbitrary. Then $G_0(s)$ and $G_1(s)$ can be simultaneously observed if and only if $G_1(s) - G_0(s)$ can be observed.

Proof: Suppose $\hat{M}_0^{-1}(s)\hat{N}_0(s)$ is a left-coprime factorization of $G_0(s)$ and $N_1(s)M_1^{-1}(s)$ is a right-coprime factorization of $G_1(s)$. If $G_0(s)$ is stable, then $\hat{N}_0(s) = G_0(s)$, $\hat{M}_0(s) = I$, $Y_0(s) = I$ and $X_0(s) = 0$. From

$$\begin{aligned} \hat{G}(s) &= B(s)A(s)^{-1} \\ &= (N_1(s) - G_0(s)M_1(s))M_1(s)^{-1} \\ &= G_1(s) - G_0(s) \end{aligned} \quad (32)$$

it can be seen that $(N_1(s) - G_0(s)M_1(s))M_1(s)^{-1}$ is a right-coprime factorization of $G_1(s) - G_0(s)$. From Theorem 1 it follows that

$$P_0(s)M_1(s) + R(s)(N_1(s) - G_0(s)M_1(s)) = P_1(s) \quad (33)$$

which can be written as

$$(P_0(s) - R(s)G_0(s))M_1(s) + R(s)N_1(s) = P_1(s) \quad (34)$$

define

$$\hat{F}(s) = (P_0(s) - R(s)G_0(s)) \quad (35)$$

$$\hat{H}(s) = R(s) \quad (36)$$

then (34) shows that $r(s) = \hat{F}(s)u(s) + \hat{H}(s)y(s)$ can observe the plant $G_1(s)$. It also can be proved that

$$(P_0(s) - R(s)G_0(s))M_0(s) + R(s)N_0(s) = P_0(s). \quad (37)$$

That is $r(s) = \hat{F}(s)u(s) + \hat{H}(s)y(s)$ can also observe the plant $G_0(s)$. Hence $G_0(s)$ and $G_1(s)$ can be simultaneously observed. \square

It can be seen that from (19) and (20), in fact, $r(s) = \hat{F}(s)u(s) + \hat{H}(s)y(s)$ is the observer of the first plant $G_0(s)$ with $Q_0(s) = R(s)$.

Next we turn to the simultaneous observation problem with more than two plants. We would like to know whether or not there exists an observer that can observe the states of each one of a given set of plants $G_0(s), G_1(s), \dots, G_n(s)$. In the following theorem, we give necessary and sufficient condition to observe simultaneously $n + 1$ plants using a common observer.

Theorem 2: Suppose G_0, G_1, \dots, G_n are given plants, define

$$A_i(s) = Y_0(s)M_i(s) + X_0(s)N_i(s), \quad (38)$$

$$B_i(s) = -\hat{N}_0(s)\hat{M}_i(s) + \hat{M}_0(s)N_i(s), \quad i = 1, 2, \dots, n. \quad (39)$$

Then $G_0(s), G_1(s), \dots, G_n(s)$ can be simultaneously observed if and only if there exists a $R(s) \in RH_\infty$, such that

$$P_0(s)A_i(s) + R(s)B_i(s) = P_i(s) \quad (40)$$

holds for $i = 1, 2, \dots, n$.

Proof: The proof closely parallels that of Theorem 1; it is omitted here. \square

It is shown in Theorem 2 that the problem of simultaneously observing $n + 1$ plants is equivalent to that of simultaneously observing n plants with a common observer.

Now suppose $R(s) \in RH_\infty$ exists which can observe the auxiliary plant $\hat{G}(s)$, then from (5), (19), and (20), the common observer for the plants $G_0(s)$ and $G_1(s)$ is just

$$\begin{aligned} r(s) &= [P_0(s)Y_0(s) - R(s)\hat{N}_0(s)]u(s) \\ &\quad + [P_0(s)X_0(s) + R(s)\hat{M}_0(s)]y(s). \end{aligned} \quad (41)$$

In the assumption of Corollary 2, the plant $G_0(s)$ is stable, then from (35) and (36), the observer has the following form

$$r(s) = (P_0(s) - R(s)G_0(s))u(s) + R(s)y(s), \quad R(s) \in RH_\infty \quad (42)$$

where $R(s)$ can be obtained from (23).

IV. DESIGN EXAMPLE

Consider the system

$$\begin{bmatrix} 0 & 1 \\ a_{21} & a_{22} \end{bmatrix} x(t) + \begin{bmatrix} 1 \\ 0 \end{bmatrix} u(t) \quad (43)$$

$$y = [2 \quad 7]x(t) \quad (44)$$

$$z = [1 \quad -1]x(t). \quad (45)$$

The parameter values (a_{21}, a_{22}) for the two operating conditions are.

$$1) (a_{21}, a_{22}) = (-1, -2);$$

$$2) (a_{21}, a_{22}) = (-2, -3).$$

For these conditions, we get

$$G_0(s) = \frac{2s-3}{s^2+2s+1}, \quad G_1(s) = \frac{2s-8}{s^2+3s+2}. \quad (46)$$

Because the plant $G_0(s)$ is stable, the related elements of double coprime factorization for the first plant are

$$\hat{N}_0(s) = \frac{2s-3}{s^2+2s+1} = G_0(s),$$

$$M_0(s) = 1, \quad X_0(s) = 0, \quad Y_0(s) = 1,$$

$$P_0(s) = \frac{s+3}{s^2+2s+1}$$

and the related elements of double-coprime factorization for the second plant are

$$M_1(s) = \frac{s^2+3s+2}{s^2+2s+3}, \quad N_1(s) = \frac{2s-8}{s^2+2s+3},$$

$$P_1(s) = \frac{s+5}{s^2+2s+3}.$$

From (21) and (22) in Theorem 1, we have

$$A(s) = Y_0(s)M_1(s) + X_0(s)N_1(s) = \frac{s^2+3s+2}{s^2+2s+3}, \quad (47)$$

$$\begin{aligned} B(s) &= -\hat{N}_0(s)M_1(s) + \hat{M}_0(s)N_1(s) \\ &= \frac{-(7s^2+9s+2)}{(s^2+2s+3)(s^2+2s+1)}. \end{aligned} \quad (48)$$

From (23), we get

$$R(s) = \frac{-s+1}{7s+2} \in RH_\infty. \quad (49)$$

Then from (42), the observer is given by

$$r(s) = \frac{9}{7s+2}u(s) + \frac{-s+1}{7s+2}y(s). \quad (50)$$

The observer (50) can observe simultaneously the two plants in (46).

V. CONCLUSION

In this note, a class of new observation problem, called simultaneous observation problem, is introduced and studied. This is achieved by using the coprime factorization approach. Necessary and sufficient conditions for the existence of simultaneous observation are derived. It was shown that a general solution for the simultaneous observation problem reduces the problem of observing n plants using a common observer to one of observing $n - 1$ plants using a common observer.

An Algorithm for Computing the Mask Value of the Supremal Normal Sublanguage of a Legal Language

Michel Barbeau, Guy Casteau, and Richard St-Denis

Abstract—We consider the problem of finding the mask value of the supremal normal sublanguage L_N of some given language L . We describe a straightforward algorithmic solution that can be applied to existing off-line procedures for determining the supremal controllable and normal sublanguage of L and that does not require an explicit calculation of L_N . This problem is fundamental because it is related to the supervisory control problem under partial observation. Our algorithm applies only to closed languages.

I. INTRODUCTION

One of the basic problems in supervisory control is to design a controller whose task is to enable and disable the controllable events of a discrete-event system (DES) such that the control requirements expressed as a legal language L are satisfied. A unifying theory has been developed by Ramadge and Wonham [11] to define and solve this problem. Lin and Wonham [10] and Cieslak *et al.* [6] have studied, in the framework of Ramadge and Wonham, the supervisory control problem under partial observation. Following the theory of Ramadge and Wonham, the uncontrolled DES is represented by a generator, which is a deterministic automaton $G = (Q, \Sigma, \delta, q_0, Q_m)$, where Q is a set of states, Σ a finite set of events, $\delta: \Sigma \times Q \rightarrow Q$

a transition function, $q_0 \in Q$ an initial state, and $Q_m \subseteq Q$ a set of marked states. Let $\Gamma = \{0, 1\}^\Sigma$ be the set of all binary assignments to the elements of Σ , and let $\gamma \in \Gamma$ and $\sigma \in \Sigma$. If $\gamma(\sigma) = 1$ then σ is enabled; otherwise, σ is disabled. Let Σ_c and Σ_u be fixed disjoint subsets of Σ denoting the sets of controllable and uncontrollable events respectively, such that $\Sigma = \Sigma_c \cup \Sigma_u$. A controller is a pair $C = (S, \phi)$, where $S = (Y, \Lambda, \zeta, y_0, Y_m)$ is a deterministic automaton and $\phi: Y \rightarrow \Gamma$ is a feedback function satisfying: i) $\phi(y)(\sigma) = 1$, if $\sigma \in \Sigma_u$; and ii) $\phi(y)(\sigma) \in \{0, 1\}$, otherwise.

To control a DES, Ramadge and Wonham introduced a transition function $\delta_c: \Gamma \times \Sigma \times Q \rightarrow Q$ defined by

$$\delta_c(\gamma, \sigma, q) = \begin{cases} \delta(\sigma, q), & \text{if } \delta(\sigma, q) \text{ is defined and } \gamma(\sigma) = 1 \\ \text{undefined}, & \text{if } \delta(\sigma, q) \text{ is undefined or } \gamma(\sigma) = 0. \end{cases}$$

The controlled discrete-event system (CDES) is then the generator $G_c = (Q, \Gamma \times \Sigma, \delta_c, q_0, Q_m)$ obtained from G by specifying the sets Σ_c and Σ_u .

Following the extensions proposed by Cieslak *et al.* [6], we consider the case in which C observes all the events of G , through a mask or observation function M that maps each event in Σ into an observed event in $\Lambda \cup \{-\}$. The events in $M^{-1}(\cdot)$ are those that cannot be seen by C . If C cannot distinguish between σ_1 and σ_2 , then $M(\sigma_1) = M(\sigma_2)$. If M is the identity function, then $\Lambda = \Sigma$ and all the original events are observed by C . The special case in which M simply erases some of the events in Σ occurs frequently and is called a natural projection [12] or natural mask [14].

Finally, the CDES and controller are embodied in a closed-loop system to constitute a supervised discrete-event system (SDES) C/G_c , which is defined to be the generator $(Y \times Q, \Sigma, (\zeta \circ M) \times \delta_c, (y_0, q_0), Y_m \times Q_m)$, where the function

$$(\zeta \circ M) \times \delta_c: \Sigma \times Y \times Q \rightarrow Y \times Q$$

is defined as $((\zeta \circ M) \times \delta_c)(\sigma, y, q) = (\zeta(M(\sigma), y), \delta_c(\phi(y), \sigma, q))$, if $\delta(\sigma, q)$ and $\zeta(M(\sigma), y)$ are defined, and $\phi(y)(\sigma) = 1$, and is undefined, otherwise.

Let $K \subseteq L \subseteq L(G) \subseteq \Sigma^*$ and $\Sigma' \subseteq \Sigma$. We recall that a language K is closed if $K = \bar{K}$, the prefix closure of K . In this paper, we assume that all languages are closed and denote by \bar{s} the prefix closure of a string $s \in \Sigma^*$. Language K is $(\Sigma', L(G))$ -controllable if $(\forall s \in K)(\forall \sigma \in \Sigma')[s\sigma \in L(G) \Rightarrow s\sigma \in K]$. Language K is $(M, L(G))$ -normal if $(\forall s \in K)(\forall s' \in L(G))[M(s) = M(s') \Rightarrow s' \in K]$. Finally, K is $(\Sigma', L(G))$ -observable if $(\forall s, s' \in K)(\forall \sigma \in \Sigma')[M(s) = M(s') \wedge s\sigma \in K \wedge s'\sigma \in L(G) \Rightarrow s'\sigma \in K]$.

The supervisory control problem under partial observation is formally stated as follows. Given a CDES G_c , its legal behavior $L \subseteq L(G)$, and a mask function M , find a controller $C = (S, \phi)$ such that $L(C/G_c)$ is the largest sublanguage of L that is closed, $(\Sigma_u, L(G))$ -controllable and $(M, L(G))$ -normal. This problem is slightly different from the supervisory control and observation problem (SCOP) first formulated by Lin and Wonham [10], in which M is a natural mask and $L(C/G_c)$ is constrained to contain a minimal acceptable language.

Let us consider a simple example. Fig. 1 depicts generator G of the language of a plant and automaton R of its legal language L . The observation function is shown in Table I. Note that the illegal event c of the plant is observed as the legal event b . Note also that the words $adcf$ and $bdcf$ of the plant are observed as the legal words

Fig. 1. Automata R and G .

ade and bde , respectively, but that $adef$ and $bdef$ are not admitted. The largest normal sublanguage of L clearly is: $L_R = \{a, ad\}$. To make R an automaton for L_R , the transition from x_0 to x_1 on event b must be removed as well as state x_3 with the incoming transition from x_2 . In this way, indistinguishable behaviors of the plant are all permitted by the controller if they are all legal, or all rejected if at least one of them is illegal.

Cieslak *et al.* [6] proved, under the assumption that $M^{-1}(M(\Sigma_n) - \{\varepsilon\}) \subseteq \Sigma_n$, that K_R , the supremal controllable and normal language contained in L , can be computed as follows:

- Step 1) Compute L_R , the largest $(M, L(G))$ -normal sublanguage of L .
- Step 2) Compute $M(L_R)$, $M(L(G))$, and $\Delta_n = M(\Sigma_n) - \{\varepsilon\}$.
- Step 3) Compute K , the largest $(\Delta_n, M(L(G)))$ -controllable sublanguage of $M(L_R)$, by using the algorithm developed by Ramadge and Wonham [15].
- Step 4) Compute $K_R = M^{-1}(K) \cap L(G)$.

This paper presents an alternate procedure for computing the supremal controllable and normal sublanguage K_R , in which Step 1) above is omitted. That is to say, our procedure does not require an intermediate representation of L_R . It includes a new algorithm for computing directly the mask value $M(L_R)$ of the supremal normal sublanguage L_R . Indeed, $L(G)$, $M(L_R)$, and $M(L(G))$ are the only languages required for completing the last two steps of the procedure. Compared with the approach of Cieslak *et al.* [6], our procedure provides a simpler and more straightforward algorithmic solution.

This paper is organized as follows. Section II presents a review of known related algorithms. Section III gives a description of our algorithm and a proof of its correctness. Section IV provides a comparison with existing algorithms and contains concluding remarks.

II. RELATED WORK

The supervisory control problem under partial observation has received much attention, and several algorithms for computing the supremal controllable and normal sublanguage of a given language have been proposed in the literature [4]–[6], [14]. They can all be used for the off-line derivation of a controller, but the worst-case computational complexity of all these algorithms is theoretically exponential because there is no polynomial-time algorithm for the SCOP unless $P = NP$ [13]. The exponential-time complexity

TABLE I
THE OBSERVATION FUNCTION M

σ	a	b	c	d	e	f
$M(\sigma)$	a	b	b	e	e	e

results from the construction of one or more deterministic automata from nondeterministic automata. But, it should be noted that in practice the worst-case occurs rarely [1]. An on-line approach was, however, suggested by Heymann and Lin [7] for improving this bound. They consider the required control action to be calculated at each step of the actual execution of the closed-loop system. The basic idea behind their algorithm is that a controller that has been designed for operation under full observation can be modified to operate under partial observation. The computational complexity at each step is polynomial in the product of the number of states in automaton R for the legal language L and the number of states in G . Furthermore, the closed-loop behavior thus achieved is a controllable and observable sublanguage larger than the supremal controllable and normal sublanguage. It should be noted, however, that the normality and observability properties are equivalent under the assumptions that the language is controllable and all controllable events are observable [9].

Nevertheless, the off-line approach is useful when there is a need to design a full controller because the plant is highly time-critical or the closed-loop system must be verified prior to its execution. In addition to the off-line procedure of Cieslak *et al.* [6], Brandt *et al.* [4], [14] propose the algebraic formula $L - M^{-1}(M(L(G) - L))$ for the off-line computation of L_R . These operations can be interpreted as follows. Take the set of illegal words, that is, $L(G) - L$. Compute how the illegal words are observed, that is, $M(L(G) - L)$. Compute the set of words, legal or illegal, that are observed as illegal words, that is, $M^{-1}(M(L(G) - L))$. Reject from L the legal words for which there are illegal words observed the same way. This formula can be effectively computed with the TCT tool [14] under the hypothesis that M is a natural mask. The computation of L_R includes, however, the construction of six intermediate automata.

Cho and Marcus [5] give two algorithms for computing L_R . The first one is based on a graphical characterization of the notion of normal language. Indeed, they prove, under the assumption that R is a strict-subautomaton of G , that a language L is normal if and only if T_n is a subautomaton of T , where T and T_n are the deterministic automata for $M(L(G))$ and $M(L)$, respectively. The main step of this algorithm consists of the elimination, from T_n , of states and edges so that the resulting automaton \tilde{T}_n is the largest subautomaton of T . Language L_R equals $L \cap M^{-1}(L(\tilde{T}_n))$. In comparison, our algorithm constructs a single intermediate nondeterministic finite automaton, that is, the one for T_n . Needless to say, elimination of states and edges is performed according to a different procedure.

The second algorithm provided by Cho and Marcus [5] constructs a nondeterministic automaton for the language L_R directly from G , R , and T , under the stronger assumption that G has a property called M -recognizable. If this assumption is satisfied, the cardinality of the state set of T is less than or equal to the cardinality of the state set of G . Unfortunately, G does not always exhibit this structural property, and the computational effort required for obtaining an M -recognizable nondeterministic automaton from G is equivalent to that of their first algorithm.

III. THE ALGORITHM FOR COMPUTING $M(L_R)$

In this section, an algorithm is presented for going from R , an automaton for the legal language L , to C_2 , an automaton for the

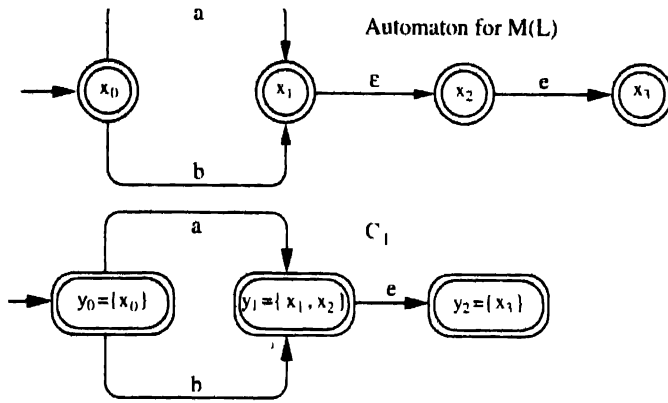

Fig. 2. Automaton for language $M(L)$, and automaton C_1 .

projection $M(L_R)$, with respect to a plant G and an observation function M . The algorithm comprises two steps.

In the first step, a deterministic automaton C_1 is constructed by applying the observation function M to every transition label of R and translating the result into a deterministic automaton. The states of C_1 are subsets of the states of R , and $L(C_1) = M(L)$. The algorithm of Lewis and Papadimitriou [8] can be used for this purpose.

Fig. 2 shows the automaton for language $M(L)$ and automaton C_1 , for the automaton R introduced in Section 1 and illustrated in Fig. 1.

Before describing the second step which computes $M(L_R)$ from G , R and M , let us state some easy-to-satisfy properties that G and R must have.

Let $T_1 = (X_1, \Sigma, f_1, x_{01}, X_1)$ and $T_2 = (X_2, \Sigma, f_2, x_{02}, X_2)$ be two deterministic automata of regular languages L_1 and L_2 , respectively, with $L_1 \subseteq L_2$. We say that T_1 refines T_2 if

$$\begin{aligned} (\forall s, t \in L_1) [f_1(s, x_{01}) = f_1(t, x_{01}) \\ \Rightarrow f_2(s, x_{02}) = f_2(t, x_{02})]. \end{aligned}$$

If T_1 refines T_2 , then it can be shown [6] that there exists a unique correspondence function $h: X_1 \rightarrow X_2$ such that

$$(\forall s \in L_1) [h \circ f_1(s, x_{01}) = f_2(s, x_{02})].$$

The correspondence function h can be intuitively interpreted as follows. Given a state x of T_1 reached after the occurrence of string s , $h(x)$ yields the state in which T_2 would be after encountering the same string.

For example, in Fig. 1, R refines G , and the correspondence function from the states of R to the states of G is

$$h(x_i) = q_i (i = 0, 1, 2, 3).$$

In the sequel,¹ let $G = (Q, \Sigma, \delta, q_0, Q)$, $R = (X, \Sigma, \xi, x_0, X)$, and $M: \Sigma \rightarrow \Lambda \cup \{\cdot\}$. We assume, without loss of generality, that R refines G . Moreover, let $h: X \rightarrow Q$ denote the correspondence function, and $C_1 = (Y_1, \Lambda, \zeta_1, y_0, Y_1)$ with $Y_1 \subseteq 2^X$.

A. The Concept of Normal Transition

A transition of C_1 , from a state y to a state y' , labeled with an event $\lambda \in (\Lambda \cup \{\cdot\})$, is normal if there is no state $x_i \in y$ and event $\tau \in \Sigma$ such that:

- in state $h(x_i)$ of the plant, event τ is active, that is, $\delta(\tau, h(x_i))$ ²;
- event τ is observed as λ , that is, $M(\tau) = \lambda$; and
- event τ is not admitted from x_i , that is, $\xi(\tau, x_i)$ is undefined.

¹In this paper, every state is marked and every language is closed.

² $\delta(\tau, h(x_i))$ means that $\delta(\tau, h(x_i))$ is defined.

Intuitively, C_1 is an intermediate structure that mirrors the legal language as observed through the mask function. A transition of C_1 labeled λ , from state y to state y' , is on the path leading to the acceptance of a word of the form $u\lambda v$, where $u, v \in \Lambda^*$. Such a word corresponds to a word in the legal language of the form $s\tau t$ with $s, t \in \Sigma^*$, $\tau \in \Sigma$, $M(s) = u$, $M(\tau) = \lambda$, and $M(t) = v$. If there exists another word $s'\tau't'$ in $L(G)$ but not in L , with $M(s') = u$, $M(\tau') = \lambda$, and $M(t') = v$, this word is illegal and observed the same way as the legal word $s\tau t$. A normal transition is one for which such a word $s'\tau't'$ does not exist. A normal transition labeled λ is called a normal λ -transition.

In the second step of the algorithm, generator C_2 is obtained from C_1 by pruning states and transitions. Pruned states are those for which nonnormal \cdot -transitions are active, and pruned transitions are those that do not have the normal property. The language of C_2 is $M(L_R)$.

The concept of normal transition is stated in an operational fashion as follows (let Σ_λ denote the set of events in Σ observed as λ , and $y \in Y_1 \subseteq 2^X$)

```
function normal (y, λ)
{precondition:  $\zeta_1(\lambda, y)!$ }
forall  $x_i \in y$  do
  forall  $\tau \in \Sigma_\lambda$  do
    if  $\delta(\tau, h(x_i))!$  and not  $\xi(\tau, x_i)!$  then
      return false
return true
```

B. The Computation of C_2

In this section, we present an algorithm for deriving a deterministic automaton C_2 from C_1 such that a word t in the language of C_2 : i) is the projection of some word s in L ; and ii) any word s' in $L(G)$ for which the projection is also t , is in L as well. More formally, the following two results will be proved (Lemmata 1, 2, 3, and Theorem 1)

$$\begin{aligned} 1) L(C_2) &= \{M(s) : s \in L \wedge (\forall s' \in s)(\forall s'' \in L(G)) \\ &\quad [M(s'') = M(s') \Rightarrow s'' \in L]\} \end{aligned}$$

and

$$2) L(C_2) = M(L_R).$$

The algorithm consists of two loops. The first one inspects every state $y \in Y_1$ of C_1 . By convention, the transition $\zeta_1(\cdot, y)$ is always defined. If this \cdot -transition is normal, then state y is copied into set Y_2 . Otherwise, the \cdot -transition is disabled by rejecting state y , because it is impossible to act on nonobservable transitions.

The second loop inspects every event $\lambda \in \Lambda$ that is active from a state $y \in Y_2$. If the transition on that event is defined in C_1 , is normal, and leads to a state in Y_2 , then it is also defined in C_2 .

If the initial state y_0 of C_1 is in Y_2 , then the algorithm returns an automaton $C_2 = (Y_2, \Lambda, \zeta_2, y_0, Y_2)$. Otherwise, it returns Φ , the empty automaton for the empty language, which has as its set of states the empty set. The computation of C_2 is performed by the following procedure

```
function step2 (M, G, R, h, C1)
{Selection of states with normal  $\cdot$ -transition}
Y2 ← {}
forall y ∈ Y1 do
  if normal(y, ·) then Y2 ← Y2 ∪ {y}
{Selection of normal λ-transitions, with λ ∈ Λ, from states in Y2}
if y0 ∈ Y2 then
```

```

We first discuss an application of our algorithm, using the example presented in Figs. 1 and 2 then formally demonstrate its correctness.

Example Referring to Figs. 1 and 2 it is easy to see that normal(y_1) returns true for $i = 0, 1$. This is not the case for $i = 2$ however, since we have $M(f) = \epsilon$, $\delta(f, h(i_1))$ defined (that is, $\delta(f, q_1)$) and $\xi(f, i_1)$ undefined. Hence state y_2 must be eliminated as well as the incoming transition on event i .

Similarly, normal(y_0, a) is true. The result of normal(y_0, b) is false however because we have $M(c) = M(b)$, $\delta(c, h(i_0))$ defined (that is, $\delta(c, q_0)$) and $\xi(c, i_0)$ undefined. Thus the transition from y_0 to y_1 on event b must be removed. The resulting automaton C_2 is shown in Fig. 3. Another application of our algorithm can be found in Barbeau *et al.* [3].

C Demonstration of Correctness

We now formally demonstrate the correctness of our algorithm. We first introduce the following two facts.

Fact 1) By construction of C_1 given $y \in Y_1$, $i \in \Sigma$ and $s \in \Sigma^*$

$$\begin{aligned} \zeta_1(M(s), y_0) &= y \wedge i \in y \\ &\Rightarrow (\exists t \in \Sigma^*) [\xi(t, i_0) = i \wedge \delta(t, q_0) \\ &= h(i_1) \wedge M(t) = M(s)] \end{aligned}$$

Fact 2) Given $s \in I$ (that is $\xi(s, i_0)$ is defined) such that $(\forall s' \in I(G)) [M(s') = M(s) \Rightarrow s' \in I]$ if $\delta(s', q_0)$ is defined and $M(s') = M(s)$ then $\xi(s', i_0)$ is defined.

Lemma 1 Given $s \in L$,

$$\begin{aligned} (\forall s' \in L(G)) [M(s') = M(s) \Rightarrow s' \in I] \\ \Rightarrow \text{normal}(\zeta_1(M(s), y_0), \epsilon) \end{aligned}$$

Proof Since C_1 is a deterministic automaton for $M(L)$ then, for an s in L , $\zeta_1(M(s), y_0)$ is defined (it is denoted by y in the sequel).

Let $i \in \Sigma$ and $\tau \in \Sigma$ such that $\delta(\tau, h(i_1))$ is defined and $M(\tau) = M(s)$. From Fact 1) $(\exists t \in \Sigma^*) [\xi(t, i_0) = i \wedge \delta(t, q_0) = h(i_1) \wedge M(t) = M(s)]$. Thus, if we let $s' = t\tau$, $\delta(s', q_0) = \delta(t\tau, q_0) = \delta(\tau, \delta(t, q_0)) = \delta(\tau, h(i_1))$ is defined. Furthermore $M(s') = M(t\tau) = M(t)M(\tau) = M(s)$.

It follows from the hypothesis of Lemma 1 and Fact 2) that $\xi(s', i_0)$ is defined. Therefore $\xi(\tau, i) = \xi(\tau, \xi(t, i_0)) = \xi(t\tau, i_0) = \xi(s', i_0)$ is defined and by definition normal($\zeta_1(M(s), y_0)$) is true. \square

Lemma 2 Given $s \in L$

$$\begin{aligned} (\forall s' \in s)(\forall s'' \in I(G)) [M(s'') = M(s') \Rightarrow s'' \in I] \\ \Leftrightarrow M(s) \in I(C_2) \end{aligned}$$

The proof is by induction on the length $|s|$ of s .

Proof of \Rightarrow (Basis step) Let s be such that $|s| = 0$. Then $s = \epsilon$. By Lemma 1 normal($\zeta_1(M(s), y_0)$) is true. Since $M(\epsilon) = \epsilon$ and $\zeta_1(\epsilon, y_0) = y_0$ then normal(y_0) is true. By construction of C_2 $y_0 \in Y_2$. Therefore, $M(\epsilon) \in I(C_2)$.

(Induction step) Let s be such that $|s| = n + 1$ with $n \geq 0$. We may write s as $u\sigma$ for some $u \in \Sigma^*$ and some $\sigma \in \Sigma$ with $|u| = n$.

By hypothesis s is such that $(\forall s' \in s)(\forall s'' \in I(G)) [M(s'') = M(s') \Rightarrow s'' \in I]$. In particular u is such that $(\forall u' \in u)(\forall u'' \in I(G)) [M(u'') = M(u') \Rightarrow u'' \in I]$. By the induction hypothesis $M(u) \in I(C_2)$. Therefore $\zeta_2(M(u), y_0)$ is defined. For $\zeta_2(M(u\sigma), y_0)$ to be defined we have to show

- 1) that normal($\zeta_1(M(u\sigma), y_0)$) is true and
- 2) that the transition from state $\zeta_1(M(u), y_0)$ to state $\zeta_1(M(u\sigma), y_0)$ labeled $M(\sigma)$ is normal.

The first assertion follows from Lemma 1. The second assertion is verified by using an argument similar to the one developed in Lemma 1. Let $i \in \Sigma$ and $\tau \in \Sigma$ such that $\delta(\tau, h(i_1))$ is defined and $M(\tau) = M(\sigma)$. From Fact 1) $(\exists t \in \Sigma^*) [\xi(t, i_0) = i \wedge \delta(t, q_0) = h(i_1) \wedge M(t) = M(u)]$. Then if we let $s' = t\tau$, $\delta(s', q_0) = \delta(t\tau, q_0) = \delta(\tau, \delta(t, q_0)) = \delta(\tau, h(i_1))$ is defined. Furthermore, $M(s') = M(t\tau) = M(t)M(\tau) = M(u)M(\sigma) = M(u\sigma) = M(s)$. It follows from the hypothesis and Fact 2) that $\xi(s', i_0)$ is defined. Therefore $\xi(\tau, i) = \xi(\tau, \xi(t, i_0)) = \xi(t\tau, i_0) = \xi(s', i_0)$ is defined and, by definition normal($\zeta_1(M(u), y_0), M(\sigma)$) is true. By construction of C_2 $\zeta_1(M(u\sigma), y_0) \in Y_2$ and $\zeta_2(M(\sigma), \zeta_2(M(u), y_0))$ is defined. Therefore $M(s) \in I(C_2)$.

Proof of \Leftarrow (Basis step) Let s be such that $|s| = 0$. Then $s = \epsilon$ and $M(s) = \epsilon$. Let us suppose that there exists an $s'' \in I(G)$ such that $M(s'') = M(s)$. We may write $s'' = \tau_1\tau_2 \dots \tau_n$ and $M(\tau_1) = M(\tau_2) = \dots = M(\tau_n) = \epsilon$.

Since $M(s) \in I(C_2)$, then normal(y_0) is true, by construction of C_2 . Furthermore, since $\delta(\tau_1, q_0)$ is defined and $M(\tau_1) = \epsilon$, then $\xi(\tau_1, i_0)$ is defined and $\xi(\tau_1, i_0) = h^{-1}(\delta(\tau_1, q_0)) \in y_0$. In the

same way

$$\xi(\tau_2, \xi(\tau_1, x_0)) \in y_0, \dots, \xi(\tau_m, \xi(\dots, \xi(\tau_1, x_0) \dots)) \in y_0.$$

Therefore, $\xi(s'', x_0)$ is defined and $s'' \in L$.

(Induction step) Let $s \in L$, with $|s| = n + 1$ ($n \geq 0$), and $M(s) \in L(C_2)$. Since L and $L(C_2)$ are closed, for all proper prefixes s' of s , $s' \in L$, $M(s') \in L(C_2)$, and the conclusion is immediate by the induction hypothesis. It remains to be shown that the conclusion holds for $s' = s$.

We may write s as $t\sigma$ for some $t \in \Sigma^*$ and some $\sigma \in \Sigma$, with $|t| = n$. Assume that there is an $s'' \in L(G)$, with $M(s'') = M(s)$. There are two cases: $M(\sigma) = \varepsilon$ and $M(\sigma) \neq \varepsilon$.

If $M(\sigma) = \varepsilon$, then $t\sigma$ is observed as t which is a proper prefix of s and the conclusion is immediate.

Consider the case where $M(\sigma) \neq \varepsilon$. We may write $s'' = t''\tau u''$, where $t'', u'' \in \Sigma^*$, $\tau \in \Sigma$, $M(t'') = M(t)$, $M(\tau) = M(\sigma)$, and $M(u'') = \varepsilon$. Since $L(G)$ is closed, $t'' \in L(G)$ and by the induction hypothesis $t'' \in L$. Let $y = \zeta_2(M(t), y_0)$. By construction of C_2 , $\xi(t'', x_0) \in y$. Since $\zeta_2(M(t\sigma), y_0)$ is defined, then $\text{normal}(y, M(\sigma))$ is true, which implies that $\xi(t''\tau, x_0)$ is defined, and $\text{normal}(\zeta_2(M(\sigma), y), \varepsilon)$ is true, which implies that $\xi(u'', \xi(t''\tau, x_0))$ is defined. Consequently, $s'' = t''\tau u'' \in L$. \square

Lemma 3:

$$(\forall t \in \Sigma^*)[t \in L(C_2) \Rightarrow (\exists s \in L)[M(s) = t]].$$

Proof: Trivially true since C_2 is derived from C_1 , a deterministic automaton for $M(L)$, solely by pruning states and transitions. \square

Theorem 1: If L_R is the largest $(M, L(G))$ -normal sublanguage of L , then $M(L_R) = L(C_2)$.

Proof: We must show that:

- 1) if $s \in L_R$, then $M(s) \in L(C_2)$, that is, $M(L_R) \subseteq L(C_2)$; and conversely,
- 2) if $t \in L(C_2)$, then there exists an $s \in L_R$ such that $M(s) = t$, that is, $L(C_2) \subseteq M(L_R)$.

Proof of 1: Let $s \in L_R$. Since L_R is closed and $(M, L(G))$ -normal, we have that $s \in L$ and $(\forall s' \in \bar{s})(\forall s'' \in L(G))[M(s') = M(s'') \Rightarrow s'' \in L]$. From Lemma 2, we may conclude that $M(s) \in L(C_2)$.

Proof of 2: Let $t \in L(C_2)$. From Lemma 3, there exists an $s \in L$ such that $M(s) = t$, and, from Lemma 2, $(\forall s' \in \bar{s})(\forall s'' \in L(G))[M(s') = M(s'') \Rightarrow s'' \in L]$ (that is, $M^{-1}M(s') \cap L(G) \subseteq L$). From Proposition 3.3 of Cieslak *et al.* [6], we may conclude that $s \in L_R$. \square

IV. CONCLUSION

Table II gives the results of an analysis, conducted in [2], comparing the characteristics of our algorithm with those of the four other off-line algorithms mentioned in Section II.

As mentioned in the Introduction, the computation of $(M, L(G))$ -normal languages is significant because it is related to the problem of supervisory control under partial observation. The computation of L_R is an intermediate step in the solution of this problem.

Any of the algorithms listed in Table II for computing L_R can be used in combination with either of the two main algorithms for computing a controller C , namely, that of Wonham and Ramadge [15] and Cho and Marcus [5].

The algorithm in [15] is used in [6] for computing the largest $(\Delta_u, M(L(G)))$ -controllable sublanguage of $M(L_R)$ and works under the assumption that $M^{-1}(M(\Sigma_u) - \{\varepsilon\}) \subseteq \Sigma_u$. That is, no controllable event can be observed as an uncontrollable event. Furthermore, it takes as input the projection of L_R , that is, $M(L_R)$ rather than L_R . Therefore, the most suitable algorithm in that

context is the one which produces $M(L_R)$ with less effort. This is Algorithm 5 because it computes an automaton for $M(L_R)$ through the construction of only two automata.

The algorithm in Cho and Marcus [5] is more general than that in Wonham and Ramadge [15]. Indeed, the assumption that $M^{-1}(M(\Sigma_u) - \{\varepsilon\}) \subseteq \Sigma_u$ is not necessary. The former is based on the application in alternation of the algorithm of Wonham and Ramadge and an algorithm for computing an automaton that generates L_R . This process is therefore iterative, and generality is obtained at the price of a longer run-time. Any of the algorithms listed in Table II can be used for computing L_R . The most suitable one is Algorithm 4, however, because it does not require reconstruction of any intermediate automaton after the first iteration [5].

Decentralized Robust Control of Uncertain Interconnected Systems with Prescribed Degree of Exponential Convergence

Zhiming Gong

Abstract—This note considers the problem of decentralized control of an uncertain interconnected time-varying system which does not satisfy the so-called matching conditions. The uncertainties, which may be decomposed into two portions, a matched portion and a mismatched portion, may appear in the subsystems and also in the interconnections between the subsystems. A robust decentralized control scheme is proposed which guarantees the controlled system to converge exponentially, with a prescribed degree, to a residue set with a prescribed bound when the mismatched portion of the uncertainties satisfies a certain bound condition.

I. INTRODUCTION

In recent years, robust control of uncertain systems has attracted great attention. Since uncertainties reside inevitably in real interconnected systems, decentralized control of uncertain interconnected systems is of great practical and theoretical interest [1]–[10].

In robust control of uncertain systems, the so-called matching conditions [11] play an important role. It is well known that an uncertain system is stabilizable when the matching conditions are satisfied (see, e.g., [11]–[14]). Many efforts have been made to relax the matching conditions on the uncertainties, and a number of sufficient conditions for existence of stabilizing controllers for uncertain systems have been obtained. Some of them are stated in terms of bounds of mismatched uncertainties [7], [15], while others are stated in terms of existence of positive definite solutions of certain Riccati equations [16].

It is interesting that the matching conditions also play an important role in decentralized control. It has been shown that when the interconnections between the subsystems of an interconnected system are through the input matrices of each subsystem, i.e., the matching condition is satisfied, the interconnected system is decentrally stabilizable [4], [5]. This remains true when the subsystems (including the input matrices) and the interconnections are assumed to have uncertainties [10] and even when the interconnections have higher-order uncertainties [9]. For the case where the matching conditions are not satisfied, Siljak [1] considered a class of interconnected systems with uncertainties in the interconnections and, by using the concept of vector Lyapunov functions and the properties of Metzler matrices, obtained a sufficient condition for stability in terms of bounds of uncertainties. Chen [8] took uncertainties in the subsystems into account and obtained a sufficient condition for stability in terms of existence of positive definite solutions of certain Riccati equations.

In this note, we consider time-varying interconnected systems with uncertainties which do not satisfy the matching conditions. The uncertainties are possibly nonlinear and fast time-varying and may appear in the subsystems (including the input matrices) and also in the interconnections among the subsystems. By decomposing the uncertainties into two portions, a matched portion and a mismatched portion, and based on the bounds of the uncertainties, we propose a robust decentralized control scheme which guarantees the controlled

system to converge exponentially, with a prescribed degree, to a residue set with a prescribed bound when the mismatched portion of the uncertainties satisfies a certain bound condition.

II. PROBLEM STATEMENT

Consider an uncertain large-scale system which is composed of N interconnected subsystems described by

$$\begin{aligned} \dot{x}_i(t) = & A_i(t)x_i(t) + B_i(t)u_i(t) + w_i(t, x_i(t), u_i(t)) \\ & + \sum_{j=1, j \neq i}^N g_{ij}(t, x_j(t)) \end{aligned} \quad (2.1)$$

where $i = 1, 2, \dots, N$; $x_i(t) \in \mathbf{R}^{n_i}$ and $u_i(t) \in \mathbf{R}^{m_i}$ are, respectively, the state and control input of the i th subsystem, and $A_i(t)$ and $B_i(t)$, which represent the nominal part of the subsystem, are matrices of appropriate dimensions and with possibly time-varying elements. The unknown functions $w_i(t, x_i(t), u_i(t))$ represent internal uncertainties in the subsystems stemming from parameter uncertainties and input disturbances, and the unknown functions $g_{ij}(t, x_j(t))$ represent uncertain interconnections between the subsystems. It is assumed that $A_i(t)$, $B_i(t)$, $u_i(t, x_i(t), u_i(t))$ and $g_{ij}(t, x_j(t))$ fulfill the conditions for existence of the solutions of (2.1).

Equation (2.1) can be rewritten routinely in the following compact form

$$\dot{x}(t) = A(t)x(t) + B(t)u(t) + w(t, x(t), u(t)) + g(t, x(t)) \quad (2.2)$$

where $x(t) = [x_1^T(t), x_2^T(t), \dots, x_N^T(t)]^T \in \mathbf{R}^n$ and $u(t) = [u_1^T(t), u_2^T(t), \dots, u_N^T(t)]^T \in \mathbf{R}^m$ are the state and control input of the overall system; $A(t)$ and $B(t)$ are block-diagonal matrices with elements $A_i(t)$ and $B_i(t)$, respectively; and $w(t, x(t), u(t))$ and $g(t, x(t))$ are the corresponding functions determined by (2.1).

Note that in system (2.1) the uncertainties represented by $w_i(t, x_i(t), u_i(t))$ and $g_{ij}(t, x_j(t))$ do not satisfy the so-called matching condition, i.e., they may not be in the range of the input matrices $B_i(t)$. Without loss of generality, it is assumed that the uncertainties can be decomposed into two portions, a matched portion and a mismatched portion, so that

$$\begin{aligned} w_i(t, x_i(t), u_i(t)) = & B_i(t)d_i^*(t, x_i(t), u_i(t)) \\ & + d_i(t, x_i(t), u_i(t)) \end{aligned} \quad (2.3a)$$

$$g_{ij}(t, x_j(t)) = B_i(t)h_{ij}^*(t, x_j(t)) + h_{ij}(t, x_j(t)) \quad (2.3b)$$

where $d_i^*(\cdot, \cdot, \cdot)$, $d_i(\cdot, \cdot, \cdot)$, $h_{ij}^*(\cdot, \cdot)$, and $h_{ij}(\cdot, \cdot)$ are unknown functions. Clearly, this decomposition is nonunique. Generally speaking, it is desirable to keep the mismatched uncertainties $d_i(\cdot, \cdot, \cdot)$ and $h_{ij}(\cdot, \cdot)$ as small as possible by an appropriate decomposition, since the matched uncertainties do not impose big difficulty in the stabilization of the system, as shown later in this note.

The following further assumptions are made on system (2.1).

Assumption 1: The pair $(A_i(t), B_i(t))$ of each subsystem is uniformly completely controllable.

Assumption 2: For each $i, j \in \{1, 2, \dots, N\}$, there exists non-negative constants ξ_{ij} , ξ_{ij}^* , ζ_i , ζ_i^* , η_{ii} , and η_{ij}^* , such that

$$\|h_{ij}(t, x_j(t))\| \leq \xi_{ij}\|x_j(t)\| + \eta_{ij} \quad (2.4a)$$

$$\|h_{ij}^*(t, x_j(t))\| \leq \xi_{ij}^*\|x_j(t)\| + \eta_{ij}^* \quad (2.4b)$$

$$\|d_i(t, x_i(t), u_i(t))\| \leq \xi_i\|x_i(t)\| + \zeta_i\|u_i(t)\| + \eta_{ii} \quad (2.4c)$$

$$\|d_i^*(t, x_i(t), u_i(t))\| \leq \xi_i^*\|x_i(t)\| + \zeta_i^*\|u_i(t)\| + \eta_{ii}^* \quad (2.4d)$$

with

$$\zeta_i^* < 1 \quad (2.4e)$$

where $\|\cdot\|$ denotes the standard Euclidean norm

It should be noted that Assumption 1 above specifies a condition on the nominal part of each subsystem while Assumption 2 specifies the bounds of the internal uncertainties of each subsystem and the bounds of uncertain interconnections. Condition (2.4e) can be interpreted as that the uncertainties associated with $u_i(t)$ does not override totally the nominal control effect of $u_i(t)$ to each subsystem.

To state the problem studied in this note, the following definitions are required.

Definition 1 A closed set $S \subset \mathbf{R}^n$ is called a (global uniform) final attractor of a system with the state $x(t) \in \mathbf{R}^n$ iff for each initial condition $x(t_0) = x_0$ there exists a finite constant $L(x_0, S)$ such that

$$x(t) \in S \quad \forall t > t_0 + T(x_0, S) \quad (2.5)$$

Furthermore, if the final attractor of the system is a ball $B = \{x \in \mathbf{R}^n \mid \|x\| \leq r\}$, the radius r of B is called a final bound of the system.

Definition 2 Suppose that a system with the state $x(t) \in \mathbf{R}^n$ has a final attractor B . The system is said to possess a degree of exponential convergence α toward the final attractor iff for all initial conditions $x(t_0) = x_0 \in \mathbf{R}^n \setminus B$

$$\|x(t)\| \leq f(x_0)e^{-\alpha(t-t_0)} \quad \forall x(t) \in \mathbf{R}^n \setminus B \quad \forall t > t_0 \quad (2.6)$$

where α is a positive constant and $f(x_0)$ is a positive constant possibly depending on x_0 .

The problem studied in this note can now be stated as follows: Find a decentralized state feedback control law for the system (2.1) so that the resultant closed loop system

- i) has a final attractor B with a prescribed final bound r and
- ii) possesses a prescribed degree of exponential convergence α toward the final attractor B .

III. DECENTRALIZED ROBUST CONTROL DESIGN

For system (2.1) consider first the following matrix Riccati equations

$$\begin{aligned} -\dot{P}(t) &= (A_i(t) + \alpha_i I)^T P(t) + P(t)(A_i(t) + \alpha_i I) \\ &\quad - \rho_i P(t) B_i(t) B_i^T(t) P(t) + \beta_i I \end{aligned} \quad (3.1)$$

where I denote the $n_i \times n_i$ dimensional identity matrices and α_i, ρ_i and β_i are positive numbers. Under the assumption that the pairs $(A_i(t), B_i(t))$ are uniformly completely controllable, the Riccati equations (3.1) have positive symmetrical solutions $P(t, t_f, L)$ on $[0, t_f]$ corresponding to a terminal condition $P(t_f) = L \geq 0$ [17]. Let $P_i(t) = \lim_{t_f \rightarrow \infty} P(t, t_f, 0)$. It is known that this limit exists and $P_i(t)$ are positive symmetrical solutions of (3.1) [17], [18]. Also there exist positive constants μ_i and ν_i such that [18, Lemmas 5 and 6]

$$\mu_i I \leq P_i(t) \leq \nu_i I \quad (3.2)$$

It is clear that the minimum and the maximum eigenvalues of $P_i(t)$ over all time t can serve as the positive constants μ_i and ν_i .

Now consider the following decentralized controller

$$u_i(t) = -\gamma_i B_i^T(t) P_i(t) x_i(t) \quad i = 1, 2 \quad (3.3)$$

for system (2.1), where γ_i are positive numbers. The main result of this note can then be stated in the following theorem.

Theorem 1 Consider the case where the decentralized controller (3.3) is applied to system (2.1), which satisfies the conditions given in Assumptions 1 and 2. Choose γ_i for the decentralized control (3.3) so that

$$\gamma_i > \frac{1}{2(1 - \zeta_i^* - \theta_i)} \left(\rho_i + \beta_i + \sum_{j=1}^N \xi_{ij}^* \right) \quad (3.4)$$

and

$$\zeta_i^* + \theta_i < 1 \quad (3.5)$$

where θ_i and ζ_i^* are positive numbers. Then, if there exist positive numbers δ_i and $\sigma_i, i = 1, 2, \dots, N$ such that

$$\frac{1}{2\theta_i} \zeta_i^* + \sum_{j=1}^N \frac{1}{\sigma_j} \xi_{ji}^* \leq \frac{1}{\nu_i} \left\{ r_i - \delta_i - \sum_{j=1}^N (\omega_{ij} + \xi_{ij}^*) \right\} \quad (3.6)$$

the resultant closed loop system has a final attractor B , and possesses a degree of exponential convergence α given by

$$\alpha = \min\{\alpha_1, \alpha_2, \dots, \alpha_N\} \quad (3.7)$$

toward B . The final bound r of the closed loop system is given by

$$r = \frac{1}{\delta} \left(\sigma + \sqrt{\sigma^2 + \delta^2} \right) \quad (3.8)$$

where δ, σ and r are positive numbers given by

$$\delta = \min\{\delta_1, \delta_2, \dots, \delta_N\}, \quad \sigma = \sum_{i=1}^N \left(\nu_i \sum_{j=1}^N \eta_{ij} \right)$$

$$r_i = \sum_{j=1}^N \left(\sum_{l=1}^N \eta_{lj}^* \right)$$

Proof of Theorem 1 Consider a Lyapunov function candidate

$$V(x, t) = \sum_{i=1}^N x_i^T P_i(t) x_i \quad (3.9)$$

for the overall closed loop system. It is clear from (3.2) and (3.9) that

$$\mu \|x\|^2 \leq V(x, t) \leq \nu \|x\|^2 \quad (3.10)$$

where $\mu = \min\{\mu_1, \mu_2, \dots, \mu_N\}$ and $\nu = \max\{\nu_1, \nu_2, \dots, \nu_N\}$.

The total time derivative of $V(x, t)$ along the closed loop system is given by

$$\begin{aligned} \dot{V}(x, t) &= \sum_{i=1}^N \left(x_i^T \dot{P}_i(t) x_i + x_i^T P_i(t) \dot{x}_i + \dot{x}_i^T P_i(t) x_i \right) \\ &= - \sum_{i=1}^N \left\{ 2\alpha_i x_i^T P_i(t) x_i + (2\beta_i - \rho_i) \right. \\ &\quad \times x_i^T P_i(t) B_i(t) B_i^T(t) P_i(t) x_i + \beta_i x_i^T x_i \left. \right\} \\ &\quad + \sum_{i=1}^N 2x_i^T P_i(t) \left\{ u_i(t) + \sum_{j=1, j \neq i}^N q_{ij}(t, x_j) \right\} \end{aligned} \quad (3.11)$$

By (2.3) and Assumption 2

$$\begin{aligned} &\sum_{i=1}^N 2x_i^T P_i(t) \left\{ u_i(t) + \sum_{j=1, j \neq i}^N q_{ij}(t, x_j) \right\} \\ &\leq \sum_{i=1}^N 2\|P_i(t)\| \left\{ \zeta_i \|\gamma_i B_i^T P_i(t) x_i\| + \sum_{j=1}^N (\xi_{ij} \|x_j\| + \eta_{ij}) \right\} \\ &\quad + \sum_{i=1}^N 2\|B_i^T P_i(t)\| \left\{ \zeta_i^* \|\gamma_i B_i^T P_i(t) x_i\| + \sum_{j=1}^N (\xi_{ji}^* \|x_j\| + \eta_{ji}^*) \right\} \end{aligned} \quad (3.12)$$

By using the inequality

$$2ab \leq \frac{1}{\epsilon} a^2 + \epsilon b^2 \quad (3.13)$$

for any real numbers a, b and ϵ and the fact that

$$\|P_i r_i\| \leq \nu_i \|r_i\| \quad (3.14)$$

as P_i are symmetrical matrices, it follows that

$$\begin{aligned} & \sum_{i=1}^N 2r_i^T P_i \left\{ u_i(t, r_i, u_i) + \sum_{j=1, j \neq i}^N q_{ij}(t, r_j) \right\} \\ & \leq \sum_{i=1}^N \left\{ \frac{1}{2\theta_i} \gamma_i \zeta_i^2 \nu_i^2 \|r_i\|^2 + 2\theta_i \gamma_i \|B_i^T P_i r_i\|^2 \right. \\ & \quad \left. + \sum_{j=1}^N \left(\frac{1}{\omega_{ij}} \xi_{ij}^2 \nu_j^2 \|r_j\|^2 + \omega_{ij} \|r_j\|^2 + 2\eta_{ij} \nu_j \|r_j\| \right) \right\} \\ & \quad + \sum_{i=1}^N \left\{ 2\gamma_i \zeta_i^* \|B_i^T P_i r_i\|^2 + \sum_{j=1}^N \left(\xi_{ij}^* \|B_i^T P_i r_i\|^2 \right. \right. \\ & \quad \left. \left. + \xi_{ij}^* \|r_j\|^2 + 2\eta_{ij}^* \|B_i^T P_i r_i\| \right) \right\} \quad (3.15) \end{aligned}$$

Noticing the fact that

$$\sum_{i=1}^N \sum_{j=1}^N (\omega_{ij} + \xi_{ij}^*) \|r_j\|^2 = \sum_{i=1}^N \sum_{j=1}^N (\omega_{ji} + \xi_{ji}^*) \|r_i\|^2$$

substituting (3.15) into (3.11) gives

$$\begin{aligned} V(t, r) & \leq - \sum_{i=1}^N 2\alpha_i r_i^T P_i r_i \\ & \quad - \sum_{i=1}^N \left\{ 2\gamma_i (1 - \zeta_i^* - \theta_i) - \rho_i - \sum_{j=1}^N \xi_{ij}^* \right\} \\ & \quad \times \|B_i^T P_i r_i\|^2 - \sum_{i=1}^N \left\{ \beta_i - \sum_{j=1}^N (\omega_{ji} + \xi_{ji}^*) \right. \\ & \quad \left. - \nu_i^2 \left(\frac{1}{2\theta_i} \gamma_i \zeta_i^2 + \sum_{j=1}^N \frac{1}{\omega_{ij}} \xi_{ij}^2 \right) \right\} \|r_i\|^2 \\ & \quad + \sum_{i=1}^N \sum_{j=1}^N \left(2\eta_{ij} \nu_j \|r_j\| + 2\eta_{ij}^* \|B_i^T P_i r_i\| \right) \quad (3.16) \end{aligned}$$

By the choices of γ_i and θ_i as given in (3.4) and (3.5) and by the assumption (3.6), we have

$$\begin{aligned} V(t, r) & \leq - \sum_{i=1}^N \left\{ 2\alpha_i r_i^T P_i r_i + \beta_i \|B_i^T P_i r_i\|^2 + \delta_i \|r_i\|^2 \right. \\ & \quad \left. - \sum_{j=1}^N \left(2\eta_{ij} \nu_j \|r_j\| + 2\eta_{ij}^* \|B_i^T P_i r_i\| \right) \right\} \quad (3.17) \end{aligned}$$

Since

$$\begin{aligned} & \sum_{i=1}^N \left(-\beta_i \|B_i^T P_i r_i\|^2 + \sum_{j=1}^N 2\eta_{ij}^* \|B_i^T P_i r_i\| \right) \\ & \leq \sum_{i=1}^N \frac{1}{\epsilon} \left(\sum_{j=1}^N \eta_{ij}^* \right)^2 = \epsilon \quad (3.18) \end{aligned}$$

and

$$\sum_{i=1}^N \sum_{j=1}^N \eta_{ij} \nu_j \|r_j\| \leq \sum_{j=1}^N \left(\nu_j \sum_{i=1}^N \eta_{ij} \right) \|r_j\|$$

$$\sqrt{\sum_{i=1}^N \|r_i\|^2} = \sigma \|r\| \quad (3.19)$$

it follows that

$$\begin{aligned} V(t, r) & \leq -2\alpha V(t, r) - \delta \|r\|^2 + 2\sigma \|r\| + \epsilon \\ & = -2\alpha V(t, r) - (\|r\| - r)(\delta \|r\| \\ & \quad + \sqrt{\sigma^2 + \delta\epsilon} - \sigma) \quad (3.20) \end{aligned}$$

where $\alpha, \delta, \sigma, \epsilon$ and r are positive numbers as given in (3.7) and (3.8). From (3.20), it is clear that when $\|r\| \geq r$, we have

$$V(t, r) \leq -2\alpha V(t, r) \quad (3.21)$$

and therefore

$$V(t, r) \leq V(t_0, r_0) e^{-2\alpha(t-t_0)} \quad (3.22)$$

Hence, by (3.10), we have

$$\|r(t)\| \leq \sqrt{\frac{\nu}{\mu}} \|r_0\| e^{-\alpha(t-t_0)} \quad (3.23)$$

for all $t(t) \in \mathbf{R}^n \setminus \mathbf{B}$. Equation (3.23) implies that for each initial condition $r(t_0) = r_0$, there exists a finite constant $T(t_0, \mathbf{B})$, given by

$$T(t_0, \mathbf{B}) = \frac{1}{\mu} \ln \frac{\sqrt{\nu} \|r_0\|}{\mu} \quad (3.24)$$

when $r_0 \in \mathbf{R}^n \setminus \mathbf{B}$ and $I(t_0, \mathbf{B}) = 0$ when $r_0 \in \mathbf{B}$ such that

$$r(t) \in \mathbf{B} \quad \forall t \geq t_0 + T(t_0, \mathbf{B}) \quad (3.25)$$

According to Definitions 1 and 2 (3.23) and (3.25) imply that the system has a final attractor \mathbf{B} with the final bound r and possess the degree of exponential convergence α toward the final attractor \mathbf{B} . This completes the proof of Theorem 1.

Remark 1 If the uncertainties of the subsystems and the uncertain interconnections satisfy the matching conditions, i.e. $d_i(t, r_i(t), u(t))$ and $h_{ij}(t, r_j(t))$ in (2.3) are zero and therefore ξ_{ij}, ζ_i , and η_{ij} are zero, then (3.6) can always be satisfied. In this case, the proposed decentralized control scheme can always be successful and guarantees the controlled system having a prescribed degree of exponential convergence and a prescribed final bound. For the general case, however, there is no guarantee that the condition (3.6) is satisfied, as the increasing of the numbers β_i may also cause the increasing of ν_i which are associated with the solutions $P_i(t)$ of the Riccati equations (3.1). This reflects the fact that Assumptions 1 and 2 along can not guarantee the existence of a decentralized controller which stabilizes the system. This is true even in the case of linear time-invariant systems without uncertainties [19]–[21].

Remark 2 When the free portion of the uncertainties bounded by η_{ij} and η_{ij}^* in Assumption 2, are zero, as assumed by many authors [1]–[9], a zero final bound is achieved and the system is exponentially stabilized (assuming the proposed control scheme is successful). If some numbers η_{ij} and η_{ij}^* are not zeros, however, there exists no control scheme which guarantees the controlled system to have a zero final bound, since such uncertainties can always drive the system off the nominal equilibrium at any time. In this case, large numbers γ_i and β_i may be chosen so that the final bound is satisfactorily small.

Remark 3 From (3.20), it can be seen that there exists a number $r_1 < r$ such that the derivative of $V(t, r)$ is still negative when $r_1 \leq \|r\| < r$. Therefore, the closed-loop system has a final attractor \mathbf{B}_{r_1} . The system may not possess the degree of exponential convergence α toward the final attractor \mathbf{B}_{r_1} .

Based on Theorem 1, a design procedure of the decentralized robust control scheme is given as follows:

Step 1) Verify Assumptions 1 and 2

Step 2) For a given degree of exponential convergence α , choose numbers ρ and β , and solve the matrix Riccati equations (3.1)

Step 3) According to (3.4) and (3.5) choose the numbers γ and θ and check the condition (3.6) with different sets of the positive numbers ω_i

Step 4) If in Steps 2 and 3 a set of positive numbers $\alpha, \rho, \beta, \gamma, \theta$, and ω_i is found such that (3.6) is satisfied, go to next step. Otherwise, repeat Steps 2 and 3 with different set of numbers $\alpha, \rho, \beta, \gamma, \theta$ and ω_i . If no set of the numbers $\alpha, \rho, \beta, \gamma, \theta$ and ω_i can be found such that (3.6) is satisfied, this decentralized control scheme is not applicable to the system and this system is probably not decentralized stabilizable.

Step 5) Use (3.8) to estimate the final bound γ of the closed loop system and construct the decentralized feedback controller (3.3).

It should be noted that in the computing of γ , the largest numbers α and β which satisfy (3.4) and (3.6) should be used to estimate the smallest final bound of the closed loop system. Also the design procedure given above may be repeated with the numbers $\alpha, \rho, \beta, \gamma, \theta$ and ω_i adjusted to obtain a better control law and a better estimation of the final bound.

IV. CONCLUSION

In this note, a robust decentralized control scheme for uncertain time-varying interconnected systems is proposed. General uncertainties are considered which do not satisfy the matching conditions and may appear in the subsystems and in the interconnections between the subsystems as well. The proposed control scheme is simple in the structure and yet it guarantees the controlled systems to have a prescribed degree of exponential convergence and a predictable final bound when the uncertainties satisfy a certain bound condition.

Hedging-Point Production Control with Multiple Failure Modes

Paul Glasseyman

Abstract—We consider the control of a production facility subject to multiple failure modes. Motivated by work of Akella and Kumar [1] and Bielecki and Kumar [5] on single-failure-mode models, we study hedging-point policies, in which production is controlled to its maximum rate whenever inventory is below a critical level and set to zero whenever inventory is above that level. The maximum production rate varies with the state of the machine. Assuming that the machine state is governed by a semi-Markov process, we evaluate average and discounted inventory costs for any hedging point, thus providing a simple mechanism for identifying optimal hedging points. Our most explicit results require that intervals in which demand exceeds production are exponentially distributed. We drop the exponential assumption at the expense of obtaining asymptotics rather than exact results.

I. INTRODUCTION

We consider the control of a production facility subject to various types of failures. The facility or machine can be in any of n states, labeled 1, ..., n . In state i , the machine has maximum production rate μ_i ; the production rate can be controlled to any level not exceeding the maximum rate in the current state. The durations of visits to each state are stochastic and mutually independent; those

IEEE Log Number 9408775.

to state i have distribution F_i . Upon the completion of a holding time in state i , the machine state becomes j with probability R_{ij} , independent of everything else. Demands arrive at a constant rate d . Production in excess of demand accumulates as inventory; when the demand rate exceeds the production rate, the inventory level decreases. Negative inventories reflect unfilled demands. Broadly, the objective is to minimize costs associated with (positive) inventory and unmet demands.

Motivated by work of Akella and Kumar [1], Bielecki and Kumar [5], and Kimemia and Gershwin [10], we analyze the performance of a simple class of control rules based on a critical number z , sometimes called a hedging point: when the inventory level is below z , produce at the maximum possible rate; when the inventory level is at z , produce at the maximum possible rate or at the demand rate, whichever is smaller; when the inventory level is above z , do not produce. Our main result (Theorem 1, below) characterizes average and discounted costs associated with this class of policies under relatively mild assumptions.

To state the result, we need to introduce some further notation. Let $r_i = d - \bar{r}_i$ be the net rate of decrease of inventory in state i , i.e., the demand rate minus the maximum production rate in that state. To rule out trivial cases, we always assume that there is at least one strictly positive r_i . We assume throughout that the matrix R of machine-state transitions is irreducible; this implies the existence of limiting probabilities (π_1, \dots, π_n) for the machine states. For each $\gamma \geq 0$, define an $n \times n$ matrix-valued function $\Phi^\gamma(\cdot)$ with entries

$$\Phi_{ij}^\gamma(\theta) = R_{ij} \int_0^\infty \exp[(r_i \theta - \gamma)x] dF_i(x). \quad (1)$$

Each $\Phi^\gamma(\theta)$ has positive entries; when these are finite, the Perron-Frobenius Theorem (see, e.g., [15]) asserts that $\Phi^\gamma(\theta)$ has a real eigenvalue $\rho_\gamma(\theta)$ equal to its spectral radius. Denote by λ_γ the strictly positive solution (whenever it exists) to

$$\rho_\gamma(\lambda_\gamma) = 1, \quad \rho_\gamma'(\lambda_\gamma) < \infty. \quad (2)$$

Suppose that cost accrues at rate $f(x)$ whenever the inventory level is x , with f mapping $(-\infty, \infty)$ to $[0, \infty)$. Denote by X_t the inventory level at time t under policy parameter z , and suppose $X_0 = z$. Let

$$V(z) = \lim_{t \rightarrow \infty} t^{-1} \int_0^t f(X_s) ds$$

be the average cost under this policy, and let

$$V_\gamma^\gamma(z) = \mathbb{E}_z \int_0^\infty e^{-\gamma t} f(X_t) dt$$

be the corresponding expected γ -discounted cost starting in machine-state i . Part of the content of our main result is that $V(z)$ is well defined.

Call state i a deficit state if $r_i > 0$. We characterize V and V_γ^γ under the assumption that holding times in deficit states are exponentially distributed. Later, we drop the exponential requirement at the expense of obtaining asymptotics and bounds, rather than exact results.

Theorem 1: Suppose that F_i is an exponential distribution for all i with $r_i > 0$.

- i) If $\sum_i \pi_i r_i < 0$ and if $\lambda_0 > 0$ solves (2) at $\gamma = 0$, then there is a $C_0 \in (0, 1)$ such that

$$V(z) = (1 - C_0)f(z) + C_0 \int_0^\infty f(z - t) \lambda_0 e^{-\lambda_0 t} dt. \quad (3)$$

- ii) For any $\gamma > 0$, if $\lambda_\gamma > 0$ solves (2), then there are constants $C_{\gamma,i}$, $i = 1, \dots, n$, such that

$$\gamma V_\gamma^\gamma(z) = (1 - C_{\gamma,i})f(z) + C_{\gamma,i} \int_0^\infty f(z - t) \lambda_\gamma e^{-\lambda_\gamma t} dt. \quad (4)$$

In proving this result, we give expressions for the constants C_0 and $C_{\gamma,i}$; these are most easily evaluated when there is a unique deficit state. We also argue that the existence of $\lambda_\gamma > 0$ in (2) should be considered typical.

A consequence of Theorem 1 is that optimal hedging points can be identified by minimizing the expressions in (3) and (4). In a case of particular interest, costs for inventory and unfilled demand are linear; i.e., there are constants $c_+, c_- \geq 0$ for which

$$f(x) = c_+ \max\{x, 0\} + c_- \max\{-x, 0\}. \quad (5)$$

Write $\log_+ x$ for $\max\{0, \log x\}$. Using (5) in (3) and (4) and minimizing over z gives the following corollary.

Corollary 1: Suppose the assumptions of Theorem 1 hold and that f has the form in (5), then

- i) under the average-cost criterion, the optimal hedging point is

$$z^* = \frac{1}{\lambda_0} \log_+ \left(\frac{C_0(c_+ + c_-)}{c_+} \right) \quad (6)$$

- ii) under the γ -discounted criterion, the optimal hedging point from initial machine state i is

$$z_{\gamma,i}^* = \frac{1}{\lambda_\gamma} \log_+ \left(\frac{C_{\gamma,i}(c_+ + c_-)}{c_+} \right). \quad (7)$$

Akella and Kumar [1] and Bielecki and Kumar [5] consider a two-state version of this model with exponentially distributed holding times and the linear cost function in (5). In that setting, they prove that the class of policies considered here includes the optimal policy under discounted and average cost criteria, respectively. They also present counterparts of (6) and (7). We do not prove (or even suggest) that these policies remain optimal in our more general setting; however, their simplicity and relative tractability makes them appealing.

The key to our analysis is a link between the inventory process and a time-reversed, continuous-time random walk in a semi-Markov environment. Through this connection, we are able to draw on results for random walks, in particular the work of Asmussen [4]. For two-state models, there is an equivalence with queues, as pointed out by Hu and Xiang [8]; see Chen and Yao [6] and Kella and Whitt [9] for related observations. None of these related references considers discounted quantities. The matrix $\Phi_0(\theta)$ and its leading eigenvalue $\rho_0(\theta)$ play an important, related role in the large deviations theory for Markov additive processes, as developed by Ney and Nummelin [14].

We prove Theorem 1 in Sections II and III. Section IV presents asymptotically optimal hedging points when holding times in deficit states have general distributions.

II. AVERAGE-COST ANALYSIS

Let us take the hedging point z to be fixed and write $X_t \equiv X_t$ for the inventory level at time t , with $X_0 = z$. Let \tilde{J}_t denote the state of the machine at time t . Our analysis of the inventory level is simplified if we work with the process $Y_t = z - X_t$, $t \geq 0$, recording the deficit in the inventory level. The process Y has the advantage that its law does not depend on z : during intervals in which $\tilde{J}_t = i$, Y_t increases at rate r_i , unless $Y_t = 0$ and $r_i \leq 0$, in which case Y_t remains at zero. This description reveals that Y is the image under reflection at the origin of a free process evolving according to the same rule but without the constraint at zero. More precisely, let $\tilde{S}_0 = 0$ and let S_t increase at rate r_i whenever $\tilde{J}_t = i$. Then

$$Y_t = \sup_{0 \leq u \leq t} (\tilde{S}_t - \tilde{S}_u). \quad (8)$$

(This type of representation is standard in queueing theory.) From this formulation, we will evaluate $V(z)$ by evaluating the expectation of $f(z - Y_t)$ with respect to the stationary distribution of Y_t .

Now let (S_t, J_t) have the law of the time-reversal of $(\tilde{S}_t, \tilde{J}_t)$, defined as follows. The process J is a semi-Markov process on $\{1, \dots, n\}$, with the same holding-time distributions F_1, \dots, F_n as \tilde{J} , and with embedded transition probabilities $R_{ij}^* = \nu_j R_{ji} / \nu_i$, where (ν_1, \dots, ν_n) are the stationary probabilities associated with the matrix R ; i.e., $\nu R = \nu$. (See, e.g., [3, Section II.5] for background on time-reversal.) In particular, then J has the same stationary distribution as \tilde{J} , given by $\pi_i = \nu_i m_i / (\sum_j \nu_j m_j)$, $i = 1, \dots, n$, with m_i the mean of F_i [7, p. 342]. The process S_t starts at zero and increases at rate r_i throughout intervals in which $J_t = i$. We take J to be right continuous.

If we give \tilde{J}_0 the stationary distribution π , then, for each $t > 0$, we obtain a stationary version of $\{J_u, 0 \leq u \leq t\}$ by setting $J_u = \tilde{J}_{t-u}$, $0 \leq u \leq t$. Similarly, we can couple S to \tilde{S} by setting $S_u = \tilde{S}_{t-u}$, $0 \leq u \leq t$. With this construction, from (8) we get

$$Y_t = \sup_{0 \leq u \leq t} (S_t - S_u) = \sup_{0 \leq u \leq t} (\tilde{S}_t - \tilde{S}_{t-u}) = \sup_{0 \leq u \leq t} S_u.$$

Therefore, for any $x > 0$ and any $i, j \in \{0, 1, \dots, n\}$, the events $\{Y_t \leq x, \tilde{J}_0 = i, \tilde{J}_t = j\}$ and $\{\sup_{0 \leq u \leq t} S_u \leq x, J_0 = j, J_t = i\}$ coincide, and so have the same probability. Defining $M_t = \sup_{0 \leq u \leq t} S_u$ and using the stationarity of J and \tilde{J} , we conclude that

$$\pi_i P_i(Y_t \leq x, J_t = j) = \pi_j P_j(M_t \leq x, J_t = i) \quad (9)$$

where the subscripts on P indicate the initial machine state (J_0 on the left, J_t on the right). By summing over i , we get

$$\sum \pi_i P_i(Y_t \leq x, J_t = j) = \pi_j P_j(M_t \leq x) \quad (10)$$

Next, we consider the limit as t increases. Because M_t is almost surely increasing in t , the limit $M \triangleq \lim_{t \rightarrow \infty} M_t$ exists with probability one; moreover, under the drift condition $\sum_i \pi_i r_i < 0$ in Theorem 1-i), M is almost surely finite [2, p. 309]. Also, since (Y_t, J_t) is evidently regenerative, it has a limiting distribution not depending on the initial state; let (Y_∞, J_∞) have that limiting distribution. Then from (10) we get

$$\begin{aligned} P(Y_\infty \leq x, J_\infty = j) &= \lim_{t \rightarrow \infty} \sum \pi_i P_i(Y_t \leq x, J_t = j) \\ &= \lim_{t \rightarrow \infty} \pi_j P_j(M_t \leq x) \\ &= \pi_j P_j(M \leq x). \end{aligned} \quad (11)$$

Summing over j , we have proved the following (compare [3, Proposition 2.2]).

Lemma 1: Under the assumptions in Theorem 1-i), $P(Y_\infty \leq x) = \sum_j \pi_j P_j(M \leq x)$. Consequently, $V(z) = E[f(z - Y_\infty)] = \sum_j \pi_j E_j[f(z - M)]$.

In light of Lemma 1, to prove Theorem 1-i) it suffices to evaluate the distributions $P_j(M \leq \cdot)$, $j = 1, \dots, n$ and to show that the expression in the lemma coincides with (3). The properties we need can in principle be obtained from the analytical results of [2]. Instead, we use a change-of-measure argument based on similar techniques in [4], [13], [17]. We work with the discrete-time process $\{(S_{\tau_n}, J_{\tau_n}), n = 0, 1, \dots\}$, where τ_n is the epoch of the n th jump of J .

For fixed $\gamma \geq 0$, let λ_γ be as in (2). We need two preliminary results. They are easily verified by induction and similar to results in [4] so we omit their proofs.

Lemma 2: The quantity $E_j[\exp(\lambda_\gamma S_{\tau_n} - \gamma \tau_n); J_{\tau_n} = i]$ is the ji -entry of $(\Phi^\gamma(\lambda_\gamma))^n$.

By the Perron-Frobenius theorem, $\Phi^\gamma(\lambda_\gamma)$ has a strictly positive right-eigenvector h (depending on γ) associated with the maximal eigenvalue $\rho_\gamma(\lambda_\gamma) \equiv 1$; i.e., $\Phi^\gamma(\lambda_\gamma)h = h$. We have the following lemma.

Lemma 3: $E_j[\exp(\lambda_\gamma S_{\tau_n} - \gamma \tau_n)h(J_{\tau_n})/h(j)] = 1$, for all j and n .

A consequence of Lemma 3 is that, with $J_0 = j$, $\exp(\lambda_\gamma S_{\tau_n} - \gamma \tau_n)h(J_{\tau_n})/h(j)$ defines a change of measure. More explicitly, with

$$\tilde{F}_i(x) = \frac{Rh(i)}{h(i)} \int_0^x e^{(\lambda_\gamma - \gamma)u} F_i(du) \quad (12)$$

and $Rh(j) = \sum_i R_{ij}h(j)$, \tilde{F}_i is a probability distribution function. Let \tilde{P} and \tilde{E} denote probability and expectation, respectively, when the holding times in state i have distribution \tilde{F}_i , $i = 1, \dots, n$. These are related to the original process through a version of Wald's identity.

Lemma 4: For any $\gamma \geq 0$, suppose there is a $\lambda_\gamma > 0$ solving $\rho_\gamma(\lambda_\gamma) = 1$. If N is a stopping time for the process $\{(S_{\tau_n}, J_{\tau_n}), n \geq 0\}$ and if the event A is measurable with respect to $\{(S_{\tau_n}, J_{\tau_n}), 0 \leq n \leq N\}$, then $P_i(A; N < \infty) = E_i[\exp\{-(\lambda_\gamma S_{\tau_N} - \gamma \tau_N)\}h(i)/h(J_{\tau_N}); N < \infty]$.

Similar results are proved in [4], [13], and [17]. The proof is standard, so we omit it.

Under the new measure, S has positive drift.

Lemma 5: When the holding times have distributions F_i , $i = 1, \dots, n$, $\lim_{t \rightarrow \infty} t^{-1} S_t > 0$ (and is independent of the initial state).

Proof: By Lemma 5.3 of [14], $\lim_{t \rightarrow \infty} t^{-1} S_t = \rho_\gamma(\lambda_\gamma)$. From [15, Theorem 3.7], we know that $\rho_\gamma(\cdot)$ is convex. We now separate the cases $\gamma = 0$ and $\gamma > 0$. For the former, we find that $\Phi^0(0) = R$, a stochastic matrix, so $\rho_0(0) = 1$. Moreover, $\rho'_0(0)$ is the drift of S under the original measure and is therefore negative, by hypothesis. Thus, the convexity of ρ_0 implies that if $\lambda_0 > 0$ exists, then ρ_0 is increasing at λ_0 . In the case $\gamma > 0$, we see that $\Phi^\gamma(0)$ is strictly substochastic and therefore $\rho_\gamma(0) < 1$. Again, convexity implies that ρ_γ must be increasing at λ_γ . \square

Remark. The convexity of the functions $\rho_\gamma(\cdot)$, $\gamma \geq 0$, indicates that the existence of λ_γ solving (2) is typical, at least if the deficit-state holding-time distributions have exponential tails. Indeed, the only alternative then to $\rho_\gamma(\lambda_\gamma) = 1$ is the existence of a $\theta > 0$ for which $\rho_\gamma(\theta) < 1$ and $\rho_\gamma(\theta) = \infty$. Such cases must be considered exceptional; see [2] for a treatment of this case. The second part of (2) makes the new drift finite.

We can now evaluate the distribution of M from any initial state. Let $N_x = \inf\{n \geq 0 : S_{\tau_n} > x\}$ be the index of the first jump epoch at which S exceeds x . (In a simplifying abuse of notation, we write S_{N_x} and J_{N_x} for $S_{\tau_{N_x}}$ and $J_{\tau_{N_x}}$, and we write J_{N_x-} for the state of the machine when S first exceeds x .) Under the original (negative-drift) measure, N_x may be infinite, but under the new (positive-drift) measure, N_x is almost surely finite for all $x \geq 0$. By Lemma 4

$$\begin{aligned} P_j(M > x) &\equiv P_j(N_x < \infty) \\ &= \tilde{E}_j[\exp(-\lambda_0 S_{N_x})h(j)/h(J_{N_x})] \\ &= e^{-\lambda_0 x} h(j) \tilde{E}_j[\exp(-\lambda_0 [S_{N_x} - x])/h(J_{N_x})]. \end{aligned}$$

To evaluate the expectation on the right, we condition on J_{N_x-} , which is necessarily a deficit state. Given $J_{N_x-} = k$, the overshoot $S_{N_x} - x$ and the next state J_{N_x} are independent. Moreover, F_k exponential implies F_k exponential, so the overshoot is exponentially distributed with mean $r_k m_k$, where

$$m_k = \frac{Rh(k)}{h(k)} \int_0^\infty x e^{-\lambda_0 x} F_k(dx) = \frac{m_k}{1 - \lambda_0 r_k m_k} \quad (13)$$

is the mean of \tilde{F}_k . With $J_0 = k$, S_{τ_1} also has the exponential distribution \tilde{F}_k . Thus, we have shown that

$$\begin{aligned} P_j(M > x) &= h(j) \sum \tilde{P}_j(J_{N_x-} = k) \tilde{E}_k[\exp(-\lambda_0 S_{\tau_1})] \tilde{E}_k[1/h(J_{\tau_1})] e^{-\lambda_0 x} \\ &= h(j) \sum_k \tilde{P}_j(J_{N_x-} = k) \frac{1}{1 - \lambda_0 r_k m_k} Rh^{-1}(k) e^{-\lambda_0 x}. \end{aligned} \quad (14)$$

From (13) we find that $1/(1 + \lambda_0 r_k \bar{m}_k) = 1 - \lambda_0 r_k m_k$. So, setting

$$C_0 = \sum_j \pi_j h(j) \sum_k \bar{P}_j(J_{N_x-} = k) (1 - \lambda_0 r_k m_k) R h^{-1}(k)$$

we find from (11) and (14) that $P(Y_\infty > x) = C_0 e^{-\lambda_0 x}$, for all $x \geq 0$. Since $V(z) = E[f(z - Y_\infty)]$, this completes the proof of part (i) of Theorem 1.

The only unknown terms in our expression for C_0 are the probabilities $\bar{P}_j(J_{N_x-} = k)$. If there is just one deficit state—call it state 1—then

$$C_0 = \sum_j \pi_j h(j) (1 - \lambda_0 r_1 m_1) R h^{-1}(1). \quad (15)$$

Each of the terms appearing in this expression is easily computed through matrix calculations if the number of machine states is not too large—not more than 30, say. Choosing h so that $\pi h = 1$ eliminates the first factor on the right in (15).

III. DISCOUNTED-COST ANALYSIS

We now turn to the evaluation of $V_i^\gamma(z)$, $\gamma > 0$. As in the previous section, we take z to be fixed and suppress it as an argument. Let L be an exponentially distributed random variable with mean $1/\gamma$, independent of everything else. Then

$$\gamma V_i^\gamma = \gamma E_i \int_0^\infty e^{-\gamma t} f(X_t) dt = E_i[f(X_L)].$$

Thus, to evaluate V_i^γ , it suffices to find the distribution of the inventory level at the random time L . As in the previous section, we work with the process $Y_t = z - X_t$ rather than the inventory level itself, and now seek to evaluate

$$\gamma V_i^\gamma = E_i[f(z - Y_L)]. \quad (16)$$

From (9) we get

$$\begin{aligned} P_i(Y_L > x) &= \frac{1}{\pi_i} \sum_j \pi_j P_j(M_L > x, J_L = i) \\ &= \frac{1}{\pi_i} \sum_j \pi_j P_j(T_i < L, J_L = i) \end{aligned} \quad (17)$$

where $T_i = \inf\{t \geq 0 : S_t \geq x\}$ is the first time S reaches level x . Letting $L' = L - T_i$, we get

$$\begin{aligned} P_j(T_i < L, J_L = i) &= P_j(T_i < L) P_j(J_L = i | T_i < L) \\ &= E_j[e^{-\gamma T_i}] P_j(J_{T_i+L'} = i | T_i < L). \end{aligned}$$

Given $\{T_i < L\}$, L' is exponentially distributed with mean $1/\gamma$. Thus, we get

$$\begin{aligned} P_j(T_i < L, J_L = i) &= E_j[e^{-\gamma T_i}] \sum_k P_j(J_{T_i} = k | T_i < L) \\ &\quad \times P_k(J_L = i). \end{aligned}$$

We conclude from (17) that

$$\begin{aligned} P_i(Y_L > x) &= \frac{1}{\pi_i} \sum_j \pi_j E_j[e^{-\gamma T_i}] \\ &\quad \times \sum_k P_j(J_{T_i} = k | T_i < L) P_k(J_L = i). \end{aligned} \quad (18)$$

We evaluate $E_j[e^{-\gamma T_i}]$ by adapting a change-of-measure argument due to Glynn (personal communication) and Kollman [11]. Let $\gamma > 0$ be fixed and let h denote a strictly positive Perron-Frobenius right-eigenvector for $\Phi^\gamma(\lambda_\gamma)$, so that $\Phi^\gamma(\lambda_\gamma)h = h$. Via Lemma 4, define new holding-time distributions as specified by (12). Throughout this section \bar{P} and \bar{E} refer to probability and expectation based on these distributions. Let $N_t = \inf\{n \geq 0 : S_{\tau_n} > x\}$, as before.

Lemma 6: $E_j[e^{-\gamma T_i}] = b_j e^{-\lambda_\gamma x}$, where

$$b_j = h(j) \sum_k \bar{P}_j(J_{N_x-} = k) (1 + (\gamma - r_k \lambda_\gamma) m_k) R h^{-1}(k).$$

Proof: Because $T_i \leq \tau_{N_x}$, a.s., and because the evolution of S_t is deterministic between jumps, T_i is measurable with respect to $\{(S_{\tau_n}, J_{\tau_n}), 0 \leq n \leq \tau_{N_x}\}$; so, we may evaluate the expectation of $\exp(-\gamma T_i)$ by applying a measure transformation to $\{(S_{\tau_n}, J_{\tau_n}), 0 \leq n \leq N_x\}$ as follows

$$\begin{aligned} E_j[e^{-\gamma T_i}] &= \bar{E}_j[e^{-\gamma T_i} e^{\gamma \tau_{N_x} - \lambda_\gamma x_{N_x}} h(J_{N_x}) / h(J_{N_x-})] \\ &= e^{-\lambda_\gamma x} h(j) \bar{E}_j[e^{\gamma(\tau_{N_x} - T_i)} e^{-\lambda_\gamma(x_{N_x} - x)} / h(J_{N_x-})] \\ &= e^{-\lambda_\gamma x} h(j) \bar{E}_j[e^{(\gamma - \lambda_\gamma \tau_{N_x-})(\tau_{N_x} - T_i)} / h(J_{N_x-})] \end{aligned} \quad (19)$$

where we have written r_{N_x-} for $r_{J_{N_x-}}$ (the prevailing net rate when S first crosses x) and used the fact that $(S_{N_x} - x) = r_{N_x-}(\tau_{N_x} - T_i)$, a.s. Now we condition on J_{N_x-} , which is necessarily a deficit state. The corresponding holding-time distribution is therefore exponential; and given J_{N_x-} , the next state J_{N_x} is independent of $\tau_{N_x} - T_i$. Thus

$$\begin{aligned} E_j[e^{-\gamma T_i}] &= e^{-\lambda_\gamma x} h(j) \sum_k \bar{P}_j(J_{N_x-} = k) \bar{P}_k[e^{(\gamma - r_k \lambda_\gamma)\tau_1}] \\ &\quad \cdot \bar{E}_k[1/h(J_{\tau_1})] \\ &= e^{-\lambda_\gamma x} h(j) \sum_k \bar{P}_j(J_{N_x-} = k) \\ &\quad \cdot R h^{-1}(k) \\ &\quad \cdot [1 - (\gamma - r_k \lambda_\gamma) \bar{m}_k] \\ &= e^{-\lambda_\gamma x} h(j) \sum_k \bar{P}_j(J_{N_x-} = k) \\ &\quad \times (1 + (\gamma - r_k \lambda_\gamma) m_k) R h^{-1}(k), \\ &= b_j e^{-\lambda_\gamma x} \end{aligned}$$

where we have used

$$\begin{aligned} \bar{m}_k &= \frac{R h(k)}{h(k)} \int_0^\infty x e^{-(\gamma + r_k \lambda_\gamma)x} F_k(dx) \\ &= \frac{1}{1 + (\gamma - \lambda_\gamma r_k) m_k} \end{aligned} \quad \square$$

If we set

$$C_{\gamma,i} = \frac{1}{\pi_i} \sum_j \pi_j b_j \sum_k P_j(J_{T_i} = k | T_i < L) P_k(J_L = i) \quad (20)$$

then from (18) and Lemma 6, we find that $P_i(Y_L > x) = C_{\gamma,i} e^{-\lambda_\gamma x}$. Using this in (16) concludes the proof of part (ii) of Theorem 1.

As in the average-cost setting, a more explicit expression for $C_{\gamma,i}$ is available if we assume that only state 1 is a deficit state. With this assumption, $J_{N_x-} = 1$, a.s., and the sums over k in (18) and (20) collapse, resulting in

$$\begin{aligned} C_{\gamma,i} &= \frac{1}{\pi_i} \left(\sum_j \pi_j h(j) \right) (1 + (\gamma - r_1 \lambda_\gamma) m_1) \\ &\quad \times R h^{-1}(1) P_1(J_L = i). \end{aligned} \quad (21)$$

To conclude the evaluation of this constant, we need to find $g_i(j) \triangleq P_j(J_L = i)$ at $j = 1$. For $\gamma > 0$, let D_γ be the diagonal matrix with entries

$$D_\gamma(i,i) = 1 - \sum_j \Phi_{ij}^\gamma(0).$$

Let e_i be the n -dimensional vector $(0, \dots, 0, 1, 0, \dots, 0)'$ with i th component equal to one.

Lemma 7 $q_i = (I - \Phi(0))^{-1} D_i c_i$

Proof Notice that

$$q_i(t) \equiv P_j(J_t = i) = \int_0^t \mathbf{1}_{\{J_t = i\}} dt$$

The result now follows by combining Proposition 2.20 and (5.14) of Chapter 10 of Çinlar [7], noting that the Q_γ defined in his (2.10) coincides with our $\Phi^\gamma(0)$ \square

Remarks

- i) As $\gamma \downarrow 0$, $P_j(J_t = i) \rightarrow \tau_i$ for all i, j and we expect that $\lambda_\gamma \rightarrow \lambda_0$. Thus $C_\gamma \rightarrow C_0$ for all i , and (3) and (4) are consistent as γ decreases to zero.
- ii) Under the discounted cost criterion, the optimal hedging point depends on the initial state, denote by γ_i the optimal hedging point starting in machine state i . An alternative policy controls the system to hedging point γ_i whenever the machine state is i . Such a policy is guaranteed to result in lower cost than following a single γ . The optimal policy of Akella and Kumar [1] in a two state model is precisely of this form, however since in their model the hedging point for the breakdown state is always greater than that for the functional state, the former plays no role, and the policy is indistinguishable from one with a single hedging point. See Kimemia and Geishwin [10], Malhamé [12] and Sharifnia [16] for more on state dependent hedging points.

IV. ASYMPTOTICS FOR GENERAL DEFICIT INTERVALS

We now drop the requirement that the holding time distributions for deficit states be exponential at the expense of obtaining asymptotics rather than exact results. For the asymptotics we restrict attention to the linear cost structure in (5) and consider optimal hedging points as $c \rightarrow \infty$. The case of large penalties for unfilled demands is of practical as well as theoretical interest.

For the following recall that a distribution is nonlattice if it is not concentrated on any set of the form $\{x - 2\delta - \delta \leq x \leq 2\delta - \delta\}$.

Theorem 2 Suppose that F is nonlattice whenever $i > 0$.

- i) If $\sum \tau_i < 0$ and if $\lambda_0 > 0$ solves (2) at $c = 0$ then there is a constant $C_0 \in (0, 1)$ such that as $c \rightarrow \infty$

$$C_\gamma \sim \left(\frac{C_0(c_+ + c_-)}{c_+} \right) + o(1) \quad (22)$$

- ii) Suppose there is a unique deficit state. For any $\gamma > 0$, $\lambda_\gamma > 0$ solves (2) then there are constants C_γ , $\gamma = 1$ such that as $c \rightarrow \infty$

$$C_\gamma \sim \frac{(c_+ + c_-)}{c_+} + o(1) \quad (23)$$

Proof The argument used for Theorem 1 still applies, except that $S_{\lambda_\gamma} - I$ and $\tau_{\lambda_\gamma} - I$ no longer have exponential distributions. In the average cost setting the argument leading to (15) now shows that

$$P(\lambda_\gamma > i) = \sum \pi_j h(j) E_j [e^{-\lambda_\gamma (S_{\lambda_\gamma} - i)} / h(\Gamma_{\lambda_\gamma})] \quad (24)$$

Set $B_i = S_{\lambda_\gamma} - i$ and $\Gamma_i = \Gamma_{\lambda_\gamma}$ and consider the process $\{(B_i, \Gamma_i) : i \geq 0\}$, with i playing the role of time parameter. This process is regenerative, the regeneration points are those i for which $S_{\lambda_\gamma} = i$ and $\Gamma_{\lambda_\gamma} = j$ for some fixed j . It follows (under our nonlattice condition) that this process has a limiting distribution not depending on the initial state, let $(B_\infty, \Gamma_\infty)$ have that distribution. Then, by the very definition of convergence in distribution, the limit

$$\lim E_j [e^{-\lambda_0 (S_{\lambda_\gamma} - i)} / h(\Gamma_{\lambda_\gamma})] = E[e^{-\lambda_0 B_\infty} / h(\Gamma_\infty)]$$

exists. We have thus shown that with

$$C_0 = \sum \pi_j h(j) E[e^{-\lambda_0 B_\infty} / h(\Gamma_\infty)]$$

we have

$$P(\lambda_\gamma > i) \sim C_0 e^{-\lambda_0 i} \quad (25)$$

the symbol \sim indicating that the ratio of the two expressions converges to one as $i \rightarrow \infty$ (see also [2]). So long as the distribution of λ_γ is continuous on $(0, \infty)$, straightforward minimization of $V(-) = c_+ E[(S - \lambda_\gamma)^+] + c_- E[(\lambda_\gamma - S)^+]$ shows that the optimal hedging point satisfies

$$C_\gamma = 1 \quad (26)$$

The required continuity follows from the nonlattice assumption. But then (25) implies that

$$\frac{1}{C_\gamma} e^{-\lambda_0 i} \left(\frac{c_+}{c_+ + c_-} \right) \rightarrow 1$$

which implies (22). The proof of (23) is similar but starts from the representation

$$P(\lambda_\gamma > i) = \frac{1}{\pi} \sum_j \tau_j h(j) E_j [e^{-(\lambda_\gamma - S_{\lambda_\gamma})(\tau_{\lambda_\gamma} - i)} / h(\Gamma_{\lambda_\gamma})] \times P_j(J_t = i | T < I) e^{-\lambda_\gamma i}$$

When state 1 is the only deficit state, this reduces to

$$P(\lambda_\gamma > i) = \frac{1}{\pi} \sum_j \tau_j h(j) R h^{-1}(1) E_j [e^{-(\lambda_\gamma - S_{\lambda_\gamma})}] \times P_1(J_t = i) e^{-\lambda_\gamma i} \quad (27)$$

much as in Section III. We claim that $-\lambda_\gamma i_1 \leq 0$. Otherwise, all row sums of $\Phi(\lambda_\gamma)$ would be strictly less than one and since the maximum row sum is an upper bound on the spectral radius we would arrive at the contradiction $\rho(\lambda_\gamma) < 1$. By essentially the same regenerative argument used above for C_0 we may define

$$C_\gamma = \frac{1}{\pi} \sum_j \tau_j h(j) R h^{-1}(1) \times P_1(J_t = i) \lim_{i \rightarrow \infty} E_j [e^{-(\lambda_\gamma - S_{\lambda_\gamma})(\tau_{\lambda_\gamma} - i)}]$$

and conclude that $P_i(\lambda_\gamma > i) \sim C_\gamma e^{-\lambda_\gamma i}$. The rest of the proof is the same as part i) \square

It is possible that part ii) of this result extends to multiple deficit states. Such an extension would require convergence of $P_j(J_t = i | T < I)$ as $i \rightarrow \infty$ and a guarantee that $\tau - \lambda_\gamma i_1 \leq 0$ whenever $i_1 > 0$.

V. CONCLUDING REMARKS

- i) For simplicity, we have assumed throughout that the time spent in a machine state is independent of the next state visited. One can easily imagine settings in which it would be desirable to relax this requirement. For example, a quick repair might restore the machine to operation sooner than a thorough repair, but the resulting machine states might differ in their susceptibility to further failure. To incorporate such phenomena, one could define holding-time distributions F_{ij} corresponding to current-state i and next-state j . The matrix $\Phi(\theta)$ is defined just as in (1) but with F_i replaced by F_{ij} . The analysis goes through as before, except that in expressions like (14)

$$\frac{1}{1 + \lambda_0 r_k m_k} \sum R_k h^{-1}(i)$$

becomes

$$\sum R_{k,i} h^{-1}(i) / (1 + \lambda_0 r_k \bar{m}_{k,i})$$

with $\bar{m}_{k,i}$ the mean of $F_{k,i}$.

- ii) It also seems possible to carry out an extension in which the hedging point changes with the machine state, with one important modification. Let Z_t be the hedging point at time t , a function of \tilde{J}_t . It is possible that upon a change in the machine state the inventory level X_t exceeds the new hedging point Z_t . Under the usual operation of the system, X_t would then decrease linearly at the rate of demand until it reaches Z_t . Suppose we modify the system so that X_t is instantaneously reduced to Z_t whenever a change in machine state results in $X_t > Z_t$; physically, this corresponds to discarding excess inventory rather than waiting to sell it. With this modification, the process $Y_t = Z_t - X_t$ becomes the image under the reflection mapping of the free process $Z_t - \tilde{S}_t$, and its distribution can be analyzed through time reversal.

ACKNOWLEDGMENT

The author would like to thank P. Glynn for introducing him to measure transformations for discounted costs.

A Globally Optimal Minimax Solution for Spectral Overbounding and Factorization

Robert E. Scheid and David S. Bayard

Abstract—In this paper, an algorithm is introduced to find a minimum phase transfer function of specified order whose magnitude "tightly" overbounds a specified real-valued nonparametric function of frequency. This method has direct application to transforming nonparametric uncertainty bounds (available from system identification experiments and/or plant modeling) into parametric representations required for modern robust control design software (i.e., a minimum-phase transfer function multiplied by a norm-bounded perturbation).

I. INTRODUCTION

Assume that a discrete-time plant $P(z^{-1})$ is estimated as $\hat{P}(z^{-1})$, and let L denote the uncertainty in the estimate. For example, three common characterizations of plant uncertainty are L_A -additive uncertainty, L_I -input multiplicative uncertainty, and L_O -output multiplicative uncertainty, where [17, p. 224]

$$\begin{aligned} L_A &= P - \hat{P} \\ L_I &= \hat{P}^{-1}(P - \hat{P}) \\ L_O &= (P - \hat{P})\hat{P}^{-1} \end{aligned} \quad (1)$$

Note that multiplicative representations require a square plant. Let L denote any one of the above three quantities. Suppose, a nonparametric overbound $\ell(\omega)$ on L is known such that

$$\ell(\omega) > \bar{\sigma}(L(e^{-j\omega T})) \quad \text{for all } \omega \in [0, \pi/T] \quad (2)$$

where T is the sampling period and $\bar{\sigma}(L)$ is the maximum singular value of L . Various methods are available to find $\ell(\omega)$ from raw data (cf., [3], [11], [13], [16]). $\ell(\omega)$, however, is a nonparametric function of frequency and cannot be used directly in modern robust control software packages such as the Matlab Robust Control Toolbox [7] and μ synthesis software [2]. Instead, the uncertainty must be represented as a minimum phase transfer function matrix $\mathcal{W}(z^{-1})$ of a specified order such that

$$L(\epsilon) = \Delta \mathcal{W}(\epsilon) \quad (3)$$

where Δ is norm-bounded, i.e.,

$$\|\Delta\|_\infty < 1.$$

The choice of \mathcal{W} in (3) can be structured or unstructured. For present purposes, the simplest choice is to use a scalar matrix representation

$$\mathcal{W} = W \cdot I \quad (4)$$

where W is a single-input single-output rational function.

Manuscript received December 21, 1993. This work was supported in part by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.

The authors are with the Jet Propulsion Laboratory, California Institute of Technology, 4800 Oak Grove Drive, Pasadena, CA 91109 USA.

IEEE Log Number 9508782.

To incorporate the uncertainty bound (3) into a robust control design, a systematic method for determining the weighting W in (4) is needed. Ideally, any approach to find W should satisfy the following properties:

P1) W must overbound the uncertainty ℓ , i.e.

$$\|W(e^{-j\omega T})\| \geq \ell(\omega) \quad \text{for all } \omega \in [0, \pi/T]$$

to ensure the existence of some $\|\Delta\|_\infty < 1$ satisfying (3)

P2) W should be as tight an overbound as possible to avoid conservatism in the final robust control design

P3) W should be of specified order (in fact as low order as possible) since it will be incorporated as a weighting and increase the final controller order

P4) W should be stable and minimum phase

These requirements on W rule out using several powerful methods from the complex analysis literature. For example, interpolation methods such as Nevanlinna-Pick theory for finding rational interpolants to complex valued data [20] do not address the real valued data case and do not satisfy the above properties. For the same reasons, the extension of interpolatory methods to the noisy data case (cf. [13], [14], [12], [6], [18], etc.) are not directly applicable to the present problem. Even if interpolatory methods could be appropriately modified to overbound real valued data sets (i.e., P1)) and do so in a minimax optimal sense (i.e., P2)) the final rational fits tend to be of very high order (e.g., on the order of the number of data points) and would not satisfy properties P3) and P4) in general.

In this paper, a mathematical programming approach is used to find a W which satisfies all of the properties P1)–P4). The main idea is to reformulate the problem so as to find a spectrally factorizable rational function W^*W whose magnitude tightly overbounds the squared data $\ell^2(\omega)$. This is done in Section II by posing a minimax nonlinear optimization problem to ensure tightness of fit of a rational function having specified order, with side constraints to ensure that the data is overbounded and that the solution admits a spectral factorization. A key result in Section III is that the nonlinear optimization problem can be solved by a sequence of reweighted constrained linear problems. In particular, a globally convergent linear programming spectral overbounding and factorization (LPSOF) algorithm is presented based on solving a sequence of linear programming problems [19]. The LPSOF algorithm provides a globally optimal solution to the nonlinear problem.

II. PROBLEM FORMULATION

In this section, a nonlinear constrained optimization is posed to compute a minimum phase transfer function W of order m such that $\|W\|$ is a tight overbound on $\ell(\omega)$ for all ω . With this result, the uncertainty can be written in standard form $I = \Delta W$ where $\|\Delta\|_\infty < 1$. Forming the quantity $W(e^{-j\omega T})W^*(e^{-j\omega T})$ and evaluating on the unit circle gives an expression of the form

$$W^*W = f(\omega) \quad (5)$$

where

$$f(\omega) = f_0 + f_1 \cos(\omega T) + \dots + f_m \cos(m\omega T) \quad (6a)$$

$$\alpha(\omega) = 1 + \alpha_1 \cos(\omega T) + \dots + \alpha_m \cos(m\omega T) \quad (6b)$$

It is noted that $\alpha(\omega)$ is defined as monic without loss of generality.

A. Constraints for Overbounding

The requirement that $\|W\|$ be an overbound on $\ell(\omega)$ is equivalent to the requirement that $\|W\|^2$ is an overbound on ℓ^2 and can be

expressed as

$$\geq \ell^2(\omega) \quad \text{for all } \omega \in [0, \pi/T] \quad (7)$$

B. Constraints for Tight Overbounding

The requirement that $\|W\|^2$ be a 'tight' overbound can be expressed as

$$\min_{\delta} \delta \quad (8)$$

where

$$\delta \geq \left\{ \left(\frac{\ell^2(\omega)}{\alpha(\omega)} - \ell^2(\omega) \right) q^{-1}(\omega) \right\} \quad \text{for all } \omega \in [0, \pi/T] \quad (9)$$

Here, the criterion minimizes a worst case error δ which is frequency weighted by the quantity $q^{-1}(\omega)$.

C. Constraints for Spectral Factorizability

The requirement that the overbound f/α admits a spectral factorization can be satisfied by ensuring that (Astrom [1])

$$f(\omega)/\alpha(\omega) > 0 \quad \text{for all } \omega \in [0, \pi/T] \quad (10a)$$

$$\alpha(\omega) > 0 \quad \text{for all } \omega \in [0, \pi/T] \quad (10b)$$

Note that condition (10a) is implied by (7) and condition (10b) can be enforced explicitly by the constraint

$$\alpha(\omega) > 0 \quad \text{for all } \omega \in [0, \pi/T] \quad (11a)$$

for some small α . For technical reasons, it will be convenient to enforce a similar constraint on f as

$$f(\omega) > f_{\min} > 0 \quad \text{for all } \omega \in [0, \pi/T] \quad (11b)$$

for some small f_{\min} .

In summary, it is desired to solve the optimization problem (8), (9) for α, f subject to constraints (7) and (10a)–(10b).

III. THE LPSOF ALGORITHM

In this section, the LP spectral overbounding and factorization (LPSOF) algorithm is introduced which solves the constrained nonlinear optimization problem of Section II on grid of points $\Lambda = \{\omega_1, \dots, \omega_n\}$. Modifications to extend these results to all $\omega \in [0, \pi/T]$ will also be discussed.

The constrained optimization problem restricted to points of the set Λ can be written as

$$\min_{\delta} \delta \quad (12)$$

subject to

$$f(\omega_i) - \ell^2(\omega_i)\alpha(\omega_i) \geq 0 \quad (13a)$$

$$f(\omega_i) - \ell^2(\omega_i)\alpha(\omega_i) \leq \delta q(\omega_i)\alpha(\omega_i) \quad (13b)$$

$$f(\omega_i) \geq f_{\min}, \alpha(\omega_i) \geq \alpha_{\min} \quad (13c)$$

for all $\omega_i, i = 1, \dots, n$

where $\alpha(\omega)$ and $f(\omega)$ are defined by (6a), (6b). A key observation from (12), (13) is that for fixed δ , the optimization over α, f is simply a linear programming problem to find a feasible solution for the coefficients α, f . Hence, the joint optimization problem can be solved by a nested search procedure where an outer loop systematically decreases δ , while an inner loop finds feasible solutions in the variables α and f for fixed δ . The procedure terminates when the smallest δ is found, which admits a feasible solution. This

approach is denoted as the LP spectral overbounding and factorization (LPSOF) algorithm.

To solve problems (12) and (13), one must begin with upper and lower bounds for the optimal value δ . For example, one can choose the lower bound $\delta_- = 0$ and let the upper bound δ_+ be derived from some starting feasible suboptimal solution (an obvious choice is $\alpha = 1$, $\beta = \max_{\omega_i} t^2(\omega_i)$). Then $\hat{\delta} = (\delta_+ + \delta_-)/2$ becomes an updated value for δ_+ or δ_- depending on whether or not the inequalities (13) can be satisfied for $\delta = \hat{\delta}$ (i.e., the bisection method [8]). In this way, the LPSOF algorithm converges to the optimal value of δ geometrically (i.e., as a power of 1/2).

This process can be further accelerated by effectively linearizing about the candidate value $\hat{\delta}$. Thus, given $\hat{\delta}$, one can solve the linearized problem

$$\max_{\alpha, \beta, \delta} u \quad (14)$$

subject to

$$\beta(\omega_i) - t^2(\omega_i)\alpha(\omega_i) \geq 0 \quad (15a)$$

$$\beta(\omega_i) - t^2(\omega_i)\alpha(\omega_i) - \hat{\delta}q(\omega_i)\alpha(\omega_i) \leq -u \quad (15b)$$

$$\beta(\omega_i) \geq \underline{\beta}, \quad \alpha(\omega_i) \geq \underline{\alpha} \quad (15c)$$

for all $\omega_i, i = 1, \dots, n$.

Then $\hat{\delta}$ provides an update for δ_- or δ_+ according to whether the solution u is negative or nonnegative. In the latter case a sharper *a-posteriori* estimate for δ_+ is derived via

$$\delta_+ = \max_{\omega \in \Lambda} \left\{ \left(\frac{\beta(\omega)}{\alpha(\omega)} - t^2(\omega) \right) q^{-1}(\omega) \right\} \quad (16)$$

where $\alpha(\omega)$ and $\beta(\omega)$ are the solutions derived from (14), (15). It is also worth noting that setting $\hat{\delta} = 0$ and solving (14)–(16) provides an excellent starting value for δ_+ to initialize the algorithm.

Remark 1. It is noted that the weighting q may be chosen as certain functions of the unknown polynomials α and β without violating the linear form of the constraints. Generally $q(\omega)$ may be taken in the form

$$q(\omega) = q_0(\omega) + q_1(\omega) \frac{\beta(\omega)}{\alpha(\omega)} \quad (17)$$

where $q_0(\omega)$ and $q_1(\omega)$ are positive for $\omega \in \Lambda$ and specified before hand.

Remark 2: By the fundamental properties of linear programming [9], [10], the LPSOF algorithm is globally convergent and achieves a globally optimal solution to the discrete problem (12), (13). An excellent algorithm for spectrally factorizing polynomials β and α without solving for roots can be found in Kucera [21].

Remark 3: For each fixed value of δ the semi-infinite linear programming problem (7), (9), and (11) (i.e., for continuous-valued $\omega \in [0, \pi/T]$) can be solved as a sequence of discretized linear programming problems of the form (13) in the limit as the mesh becomes sufficiently fine (cf. [15, Section 7.2]). Thus, one can recover the solution to the semi-infinite spectral overbounding and factorization problem (7), (8), (9), and (11) using the LPSOF approach, by solving a sequence of linear programs with decreasing mesh spacing for each fixed value of δ . Decreasing the mesh spacing, however, may not be desirable in practice, and alternative methods for approximating the solution to the semi-infinite problem will be presented in Section IV.

IV. MODIFICATIONS OF THE LPSOF ALGORITHM

Strictly speaking, the LPSOF algorithm only enforces inequalities (7), (10a), (10b) at the points in the grid Λ . Hence, the inequalities may be violated in between grid points, and the solution may not

be a true overbound, and/or may not admit a spectral factor. If this happens in practice, the simplest solution, generally, is to choose a denser grid (see Remark 3) and/or increase lower bounds $\underline{\alpha}$, $\underline{\beta}$ in (13c). There may be certain cases, however, where these approaches are not desirable. Hence, in this section, systematic modifications of the LPSOF algorithm are presented to overcome this problem.

For convenience to subsequent discussion, we make the following assumptions.

Assumption 1: Let $t^2(\omega)$ be a linear spline interpolant to the points $t^2(\omega_i)$ defined on the grid $\Lambda = \{\omega_1, \dots, \omega_n\}$ with piecewise linear segments having maximum slope κ , and maximum grid size $h = \max_i \{\omega_{i+1} - \omega_i\}$.

Assumption 2: The set of vectors $\{\cos(k\omega_1 T), \dots, \cos(k\omega_n T)\} \in \mathbb{R}^n$, $k = 0, \dots, m$ are linearly independent.

Modifications of the LPSOF algorithm to ensure proper behavior between grid points, fall into two categories, *a-priori* and *a-posteriori*. These methods will be discussed separately below.

A. A-Priori Modifications

The basic idea behind the *a-priori* modifications is to enforce additional linear constraints in the LPSOF algorithm so that the derivatives $\alpha'(\omega) = \frac{d}{d\omega}(\alpha(\omega))$, $\beta'(\omega) = \frac{d}{d\omega}(\beta(\omega))$ and $(\beta/\alpha)' = \frac{d}{d\omega}(\beta/\alpha)$ are suitably bounded for all $\omega \in [0, \pi/T]$. This clearly restricts the excursions of α , β , and β/α in between grid points, so that under Assumption 1, and specification of lower bounds $\underline{\alpha}$, $\underline{\beta}$ in (13c), the desired inequalities (7), (10a), (10b) can be satisfied.

Some useful definitions are in order: A function $x(\omega)$ defined on the interval $\omega \in \Omega$ is said to be uniformly bounded from above if $|x(\omega)| \leq C' < \infty$ for all $\omega \in \Omega$. Here, the quantity C' is denoted as the uniform upper bound. Similarly, the function $x(\omega)$ is said to be uniformly bounded from below if $|x(\omega)| \geq c' > 0$ for all $\omega \in \Omega$. The quantity c' is denoted as the uniform lower bound.

A method to uniformly bound the aforementioned derivatives is now introduced. For some positive $\bar{\alpha}$, $\bar{\Lambda}$, K_α , and K_β , let the following linear constraints be imposed on the grid Λ

$$\alpha(\omega_i) \leq \bar{\alpha} \quad (18a)$$

$$\beta(\omega_i) \leq K_\alpha \alpha(\omega_i) \quad (18b)$$

$$|\alpha'(\omega_i)| \leq K_\alpha |\alpha(\omega_i)| \quad (18c)$$

$$|\beta'(\omega_i)| \leq K_\beta |\beta(\omega_i)| \quad (18d)$$

If linear constraints (18a)–(18d) are used to augment linear constraints (13a)–(13c) of the LPSOF algorithm, it can be shown that

$$\underline{\alpha} \leq \alpha(\omega_i) \leq \bar{\alpha} \quad (19a)$$

$$\underline{\beta} \leq \beta(\omega_i) \leq K_\alpha \bar{\alpha} \quad (19b)$$

$$|\alpha'(\omega_i)| \leq K_\alpha \bar{\alpha} \quad (19c)$$

$$|\beta'(\omega_i)| \leq K_\beta K_\alpha \bar{\alpha} \quad (19d)$$

$$d \left(\frac{\beta}{\alpha} \right) \leq K' (K_\beta + K_\alpha) \quad (19e)$$

where (19e) follows from

$$\left(\frac{\beta}{\alpha} \right)' = \frac{\beta'}{\alpha} - \frac{\alpha' \beta}{\alpha^2} = \frac{\beta'}{\alpha} \left(\frac{\beta'}{\beta} - \frac{\alpha'}{\alpha} \right). \quad (20)$$

Inequalities (19a)–(19e) imply that α , β , β/α and their derivatives are bounded on the grid Λ . Under Assumption 2, these bounds at the grid points impose bounds on the coefficients α_i , β_i (this is because the matrix of trigonometric functions which determines these coefficients has a bounded inverse, (cf. [8])). This implies that $|\alpha(\omega)|$, $|\beta(\omega)|$, $|\alpha'(\omega)|$ and $|\beta'(\omega)|$ are uniformly bounded from above since they are bounded functions of the bounded coefficients

α_i, β_i . If the uniform upper bounds on $|\alpha'(\omega)|$ and $|\beta'(\omega)|$ are sufficiently small, constraints (13c) on the grid points imply the existence of uniform (nonzero) lower bounds on $|\alpha(\omega)|, |\beta(\omega)|$. Hence, by systematically decreasing the values of K_i and K_{ii} (with the other constraints fixed), one can make $|\alpha'(\omega)|$ and $|\beta'(\omega)|$ arbitrarily small, and there will always be some point at which inequalities (10a), (10b) are satisfied uniformly in ω . Given that (10a), (10b) is satisfied in this manner, it follows from (20) that $|(j/\alpha)'|$ is bounded uniformly from above. Using (13a) and Assumption 1, it follows that (7) is satisfied when this uniform upper bound on $|(j/\alpha)'|$ falls below the value of κ defined in Assumption 1.

In summary, by augmenting the linear constraints (13a)–(13c) of the LPSOF algorithm by linear constraints (18a)–(18d), and solving a sequence of problems where K_i and K_{ii} are systematically decreased, there will be a point at which (7) (10a), (10b) are satisfied, ensuring that β/α is an overbound on t^2 for all $\omega \in [0, \pi/T]$ and spectrally factorizable.

B. A-Posteriori Modifications

The basic idea behind *a-posteriori* modifications is to slightly perturb the unmodified LPSOF solution so that inequalities (7), (10a), (10b) are satisfied uniformly in ω . For grid Λ sufficiently fine, a small perturbation can always be found which does the job. To see this, note that the solution to problems (12), (13) will always satisfy bounds of the form (19), if the quantities α, K, K_{ii} , and K_i are computed *a-posteriori*. As noted in the previous discussion, Assumption 2 guarantees corresponding bounds for the coefficients α_i, β_i which in turn impose uniform upper bounds on $|\alpha(\omega)|, |\beta(\omega)|, |\alpha'(\omega)|$ and $|\beta'(\omega)|$. Then, for a sufficiently small grid size h , uniform constraints (7), (10a), (10b) can be satisfied by means of an $O(h)$ perturbation of $\alpha(\omega), \beta(\omega)$, and δ .

The construction above implicitly assumes that α, K, K_{ii} , and K_i are reasonably sized. If not, these quantities can be explicitly constrained *a-priori*, as done earlier.

V. NUMERICAL EXAMPLE

In this section, the LPSOF algorithm is used to determine spectrally factorizable overbounds on additive uncertainty estimates obtained from large space structure identification experiments [5]. Raw additive uncertainty data $t^2(\omega_i)$ adapted from [5] is shown in Fig. 1, depicted by the symbol ** , on the grid $\Lambda = \{\omega_i = i\pi/(128T), i = 1, \dots, 128\}$, where $T = .05$ seconds. In addition to the raw data set, the envelope \bar{t}^2 is depicted in Fig. 1. The envelope \bar{t}^2 is a smoothed nonparametric overbound on the raw data t^2 .

In all subsequent examples, the LPSOF algorithm of Section III is used in sequential linearized form (14), (15), with underbounds $\alpha_i = \beta_i = 0$ and frequency weighting $q(\omega) = q_0 + q_1 \beta(\omega)/\alpha(\omega)$, where $q_1 = 1$ and q_0 remains to be specified (see (17)). The dual rather than primal form of the underlying LP problems [9], [10] is implemented to considerably reduce the number of constraint equations. In all runs, 10 to 15 iterations were sufficient to ensure convergence of δ to six significant digits.

A. Overbounding Raw Data

In this section, the raw data t^2 of Fig. 1 is overbounded using the LPSOF algorithm of Section III.

The first set of runs is generated by fixing $m = 4$ and $q_1 = 1$ and varying weighting factor q_0 as $q_0 = 0, .01, .1, 1$. The results are summarized in Fig. 2, where the raw data t^2 is depicted by the symbol ** . It is seen that the overbound associated with $q_0 = 0$ does a reasonably good job of overbounding the data, but tends to sacrifice some accuracy in the peaks for accuracy in the troughs (e.g., there

Fig. 1 Raw additive uncertainty data (t^2 (denoted by **) and envelope data (\bar{t}^2 (denoted by *)) defined on 128 point grid.

Fig. 2 Spectrally factorizable overbounds β/α on raw data t^2 (denoted by **) using unmodified LPSOF algorithm ($\alpha_i = \beta_i = 0, q_1 = 1, m = 4$) obtained by varying weighting factor $q_0 = 0, .01, .1, 1$

is about an 8 db overshoot of the main peak). Methods to improve the results become apparent.

Method 1: Deemphasize the weighting of trough data by increasing q_0 .

Method 2: Reduce oscillatory behavior of the data by overbounding the envelope \bar{t}^2 rather than raw data t^2 .

Method 1 motivates the remaining runs of Fig. 2 which are generated by increasing q_0 . (Method 2 motivates using envelope data rather than raw data, which will be discussed later.) It is seen from Fig. 2, that increasing q_0 from 0 to .01 improves the accuracy of the overbound by several db in the vicinity of the peaks at the cost of accuracy in the troughs. Increasing q_0 further to .1 and 1 continues this trend. Hence, the user can choose from the family of curves in Fig. 2, to trade-off accuracy in the peaks for accuracy in the troughs.

The second set of runs is generated by fixing $q_1 = 1, q_0 = 1$ and varying the order m as $m = 2, 4, 6$. The results are summarized in Fig. 3. It is seen that the successive overbounds improve uniformly as the order is increased. In particular, the peaks are fitted reasonably well by bounds of all orders (this is a consequence of using $q_0 = 1$ for all runs) while most of the improvement from increasing order comes from fitting the troughs.

Fig 3 Spectrally factorizable overbounds $1/\alpha$ on raw data l^2 (denoted by '*') using unmodified LPSOF algorithm ($\alpha = \beta = 0$, $q_0 = 1$, $q_1 = 1$) obtained by varying bound order $m = 2, 4, 6$

Fig 4 Spectrally factorizable overbounds $1/\alpha$ on envelope data \tilde{l}^2 (denoted by '*') using unmodified LPSOF algorithm ($\alpha = \beta = 0$, $q_0 = 0$, $q_1 = 1$) obtained by varying bound order $m = 2, 4, 6$

B Overbounding Envelope Data

In this study (in accordance with Method 2 outlined above), oscillatory data is avoided by overbounding the envelope data \tilde{l}^2 rather than raw data l^2 (see Fig 1).

The runs of Fig 4 are generated by fixing $q_0 = 0$, $q_1 = 1$ and varying the order m as $m = 2, 4, 6$. The envelope data \tilde{l}^2 is depicted by the symbol '*'. It is seen that the overbounds for $m = 4$ and $m = 6$ are excellent, and in fact the latter nearly interpolates the data.

VI. CONCLUSION

A systematic method, denoted as the LPSOF algorithm, has been developed for finding a minimum-phase transfer function of specified order whose magnitude "tightly" overbounds a specified nonparametric real-valued function of frequency. The main idea is to find a spectrally factorizable rational function which tightly overbounds the data "squared." This leads to a nonlinear constrained optimization problem which can be solved by a sequence of linear programming problems.

The original motivation behind the development of the LPSOF algorithm was to systematically replace the graphical overbounding method used in [4] for determining robust control weightings. The algorithm is, however, generally useful for determining spectral factors from raw PSD data and can be useful in such applications as deconvolution, disturbance identification, blind channel equalization, and estimation of noise coloring filters.

A Lower Bound for Limiting Time Delay for Closed-Loop Stability of an Arbitrary SISO Plant

R. Devanathan

Abstract—This correspondence is concerned with the time delay margin for closed-loop stability of a single input, single output plant with time delay uncertainty. Since no restriction is placed on the stabilizing controller, the limiting value of time delay depends on the plant transfer function only. The approach, using a modified form of classical Nevanlinna–Pick interpolation theory, provides a lower bound for the limiting time delay given the plant open-loop poles and zeros only.

NOTATION

\mathbb{C} = {Complex plane}
 $A = \{s \in \mathbb{C}, \text{Re}(s) > 0\}$
 $\bar{A} = \{s \in \mathbb{C}, \text{Re}(s) \geq 0\}$
 $\hat{A} = \bar{A} \cup \{\infty\}$
 $U = \{s \in \mathbb{C}, |s| < 1\}$
 $\bar{U} = \{s \in \mathbb{C}, |s| \leq 1\}$

I. INTRODUCTION

The closed-loop stability of single-input single-output (SISO) systems with time delay uncertainty is considered in this paper. Walton and Marshall [1] have given a direct method for stability analysis of time delay systems. Consider the closed-loop system of Fig. 1. Let the process transfer function be given by

$$p(s) = p_0(s) \exp(-T_d s), \quad T_d \geq 0 \quad (1.1)$$

where $p_0(s)$ corresponds to the nominal transfer function and T_d corresponds to the time delay uncertainty. Walton and Marshall [1] consider the following problem. Given $p_0(s)$ and the controller transfer function $c(s)$, what is the limiting (minimum) value of time delay T_d below which the closed-loop system of Fig. 1 is stable? El-Sakkary [2] has given a partial solution to this problem.

Suppose we now ask: Consider the closed-loop system of Fig. 1 where the plant $p(s)$ can be any transfer function of the form of (1.1). What is the largest value of the limiting (minimum) time delay, call it $T_{d\max}$, below which there exists a controller stabilising the closed-loop system of Fig. 1? This is known as the optimum time delay margin problem. In this paper, we attempt to characterize a lower bound for $T_{d\max}$.

II. BACKGROUND

Let the nominal real rational transfer function $p_0(s)$ correspond to m finite zeros, $q_i, i = 1, 2, \dots, m$, multiplicities included, and n poles, $p_j, j = 1, 2, \dots, n$, multiplicities included, in the right half of the complex plane including the imaginary axis, i.e., in \bar{A} . The problem is well posed [3] when $p_0(s)$ is strictly proper.

Let the zero at infinity of $p_0(s)$ be denoted by q_∞ , of multiplicity $(n - m)$. Let $E(s)$ be such that

$$E(s) = p_0(s) c(s) / \{1 + p_0(s) c(s)\}. \quad (2.1)$$

Given $E(s)$, (2.1) can be used to find $c(s)$. The closed-loop system of Fig. 1 corresponding to the nominal system is stable if and only if [4]

- i) $E(s)$ is analytic in \bar{A}

Fig. 1. Closed-loop system.

- ii) $E(q_i) = 0, i = 1, 2, \dots, m$, multiplicities included
- iii) $E(q_\infty) = 0$, multiplicities included
- iv) $E(p_j) = 1, j = 1, 2, \dots, n$, multiplicities included.

(2.2)

Consider the conformal mapping [5] as shown in Fig. 2. \bar{U} is the closed unit disk while U corresponds to the open unit disk. G can be any simply connected region in $\mathbb{C} \cup \{\infty\}$ containing the points 0 and 1.

ϕ is a mapping such that

$$\phi: G \rightarrow U \quad (2.3)$$

and

$$\phi(0) = 0. \quad (2.4)$$

The conditions ii), iii), and iv) of (2.2) correspond to

- i) $E(\infty) = 0, i = 1, 2, \dots, m$, multiplicities included
- ii) $E(z_{q_\infty}) = 0$, multiplicities included
- iii) $E(\infty) = \phi(1), j = 1, 2, \dots, n$, multiplicities included

(2.5)

where

$$E: \bar{U} \rightarrow U \quad (2.6)$$

$$\psi: \bar{A} \rightarrow \bar{U} \quad (2.7)$$

$$z_{q_i} = \psi(q_i), \quad i = 1, 2, \dots, m \quad (2.8)$$

$$z_{q_\infty} = \psi(q_\infty) \quad (2.9)$$

$$z_{p_j} = \psi(p_j), \quad j = 1, 2, \dots, n. \quad (2.10)$$

Following [5], consider the mapping E of (2.6) such that

$$\bar{E}(z_t) = \alpha b_t, \quad t = 1, 2, \dots, 2n, \quad \alpha \geq 0 \quad (2.11)$$

where

$$z_t = \infty, t = 1, 2, \dots, m, \text{ and } t = 1, 2, \dots, m, \text{ respectively,} \quad (2.12)$$

$$z_t = z_{q_\infty}, t = m + 1, \dots, n \quad (2.13)$$

$$z_t = z_{p_j}, t = n + 1, \dots, 2n \text{ and } j = 1, 2, \dots, n, \text{ respectively,} \quad (2.14)$$

$$b_t = 0, t = 1, 2, \dots, n \quad (2.15)$$

$$b_t = 1, t = n + 1, \dots, 2n \quad (2.16)$$

\bar{E} exists if and only if

$$\alpha \leq \alpha_{\max} \quad (2.17)$$

where α_{\max} is an invariant defined on the interpolation data $\{z_t, b_t\}$ specified as in (2.12)–(2.16) above. Further, the mapping $E(s)$ given in Fig. 2 (where G is any arbitrary simply connected region) satisfying the condition given by (2.2) exists, if and only if

$$|\phi(1)| < \alpha_{\max}. \quad (2.18)$$

Fig. 2. Conformal mapping relationships.

Fig. 3. η -plane

III. TIME DELAY UNCERTAINTY

Consider the characteristic equation for the system of Fig. 1, viz.

$$1 + p_0(s) c(s) \exp(-T_d s) = 0, s \in \tilde{A}. \quad (3.1)$$

Using (2.1), (3.1) can be rearranged as

$$\eta(s) = \eta\{E(s)\} = \{1 - E(s)\}/E(s) = -\exp(-T_d s), s \in \tilde{A}. \quad (3.2)$$

The function η maps the E -plane into the η -plane. For $s = j\omega$, $\omega \geq 0$, the right-hand side (RHS) of (3.2) maps the $j\omega$ -axis in the s -plane onto the unit circle centre origin, in the η -plane as shown in Fig. 3.

Notice that

$$\eta(1) = 0 \quad (3.3)$$

and

$$\eta(0) = \infty. \quad (3.4)$$

Consider a simply connected region G' (containing the points 0 and 1) in the E -plane such that its image G'' (containing points ∞ and 0, respectively) under the mapping η corresponds to the η -plane minus the hatched arc as shown in Fig. 3. Using (3.2), if we define the mapping φ such that

$$\varphi\{\eta(s)\} = 1/\{1 + \eta(s)\} = E(s) \quad (3.5)$$

then G can be obtained by mapping G'' under φ . If G' can now be conformally mapped [6] in to the open unit disk U' by the mapping ϕ' such that

$$\phi'(\infty) = 0 \quad (3.6)$$

then the mapping $\phi: G \rightarrow U'$ of Fig. 2 will have been implemented (compare (2.4) with (3.4) and (3.6)) such that

$$\phi = \phi' \cdot \eta. \quad (3.7)$$

Let the mapping ϕ' be given by the function

$$\phi'(y) = \frac{\sqrt{\{(y-q)/(y-q')\} \exp(j\gamma)} - \exp(j\gamma/2)}{\sqrt{\{(y-q)/(y-q')\} \exp(j\gamma)} + \exp(-j\gamma/2)}$$

Fig. 4. ϕ' -plane.

$$\times [\exp\{j(\pi - \gamma)/2\}] \quad (3.8)$$

where

$$y = \eta\{E(s)\}$$

q and q' in the η -plane are conjugates of each other and

$$q = \exp\{j(\pi - \gamma)\} \quad (3.9)$$

γ is the angle as shown in Fig. 3. Also, from (3.3) and (3.7)

$$\phi(1) = \phi'(0). \quad (3.10)$$

The image of G' in Fig. 3 under the mapping ϕ' is as shown in Fig. 4. The hatched portion in the η -plane is mapped onto the unit circle in the ϕ' -plane. The arc $qq''q'$ in the η -plane is transformed into the arc $u'bu$ in the ϕ' -plane. Also, the origin in the η -plane is mapped on to the point v in the ϕ' -plane. Simple calculation shows that

$$\phi(1) = \phi'(0) = ov = \sin(\gamma/2), 0 < \gamma < \pi \quad (3.11)$$

and that

$$ob = \tan(\gamma/4). \quad (3.12)$$

Let

$$\tilde{E} = E \cdot v. \quad (3.13)$$

The function $\tilde{E}(s)$ can be computed from Fig. 2, (3.7) and (3.13) as

$$\tilde{E}(s) = \tilde{E}(s) \cdot v^{-1} = \frac{\{\tilde{E}(s) \sin(\gamma/2) - 1\} \{\tilde{E}(s)\}}{[\sin(\gamma/2) \{\tilde{E}(s)\}^2 - 1]} \quad (3.14)$$

and the corresponding controller $c(s)$ can be determined using (2.1) as

$$c(s) = \frac{[\{\tilde{E}(s) \sin(\gamma/2) - 1\} \{\tilde{E}(s)\}]}{p_0(s) [\{\tilde{E}(s)\} - \sin(\gamma/2)]} \quad (3.15)$$

The following result can now be stated.

Theorem 1. Consider the conformal mapping of Fig. 2. Let the simply connected region G be such that η maps G on to G'' where G'' corresponds to the η -plane minus the hatched arc on the unit circle defined by angle γ ($0 < \gamma < \pi$) as shown in Fig. 3 such that the mapping ϕ' is defined in terms of γ through (3.8) and (3.9). The mapping E satisfying the condition (2.2), then exists if and only if

$$\gamma < 2 \sin^{-1}(\alpha_{\max}). \quad (3.16)$$

The function $E(s)$ is given by (3.14).

Proof: From the result of [5], (2.18) follows. Since $\sin(\gamma/2)$ is positive for $0 < \gamma < \pi$, it then follows from (3.11) and (2.18) that

$$\sin(\gamma/2) < \alpha_{\max}.$$

Hence (3.16) follows. This ensures that $\tilde{E}(s)$ exists as per [5] based on the modified Nevanlinna-Pick theory. The procedure for finding $\tilde{E}(s)$ is well known [7], [8] through the formation of the Fejervary array corresponding to the mapping $\tilde{U} \rightarrow U'$. $\tilde{E}(s)$ is found from (3.13). Hence $E(s)$ is given by (3.14). Hence the result.

Fig. 5. Detailed conformal mappings.

IV. TIME DELAY MARGIN

Consider the transformation

$$v_1(s) = v = \{k(s - t)\}/(s + t), \quad 0 < k < 1, \quad t > 0 \quad (4.1)$$

such that

$$v_1: \tilde{A} \rightarrow \tilde{U}. \quad (4.2)$$

Further consider the transformation

$$v_2(v) = z = (v - k)/(1 - vk) \quad (4.3)$$

such that

$$v_2: \tilde{U} \rightarrow \tilde{U}. \quad (4.4)$$

Let

$$v = v_2 \circ v_1 \quad (4.5)$$

such that

$$v: \tilde{A} \rightarrow \tilde{U}. \quad (4.6)$$

The $j\omega$ -axis of the complex plane \tilde{C} together with the point at infinity is mapped by v_1 on to the circle (call it $c1$) centre origin and radius k which in turn is mapped by v_2 onto the circle (call it $c2$) on a diameter whose extreme points correspond to $\{-2k/(1+k^2)\}$ and the origin. Notice that

$$v(\infty) = v_2\{v_1(\infty)\} = 0. \quad (4.7)$$

Referring to Fig. 2, if the zero at infinity of E is of order $m' (=n-m)$ then so is the zero of \tilde{E} at the origin. Since \tilde{E} is analytic in \tilde{U} , it follows by Schwarz's lemma [9] that

$$\{|\tilde{E}(z)|\} < |z|^{m'}, \quad |z| < 1. \quad (4.8)$$

Fig. 5 shows the detailed mapping as discussed so far.

Representing an arbitrary point on the circle $c1$ as

$$v = v_1 = k \exp(j\theta), \quad 0 \leq \theta \leq 2\pi. \quad (4.9)$$

Consideration of the mapping v_1 will show that

$$\tan(\theta/2) = t/\omega. \quad (4.10)$$

Further, considering the mapping v_2 , it can be shown that

$$\begin{aligned} |z| &= |z_1| = f_1(\omega) \\ &= \frac{2kt}{\sqrt{(1-k^2)^2\omega^2 + (1+k^2)^2t^2}}, \quad \omega \geq 0 \end{aligned} \quad (4.11)$$

where

$$z_1 = v_2(v_1). \quad (4.12)$$

Define

$$\rho(\gamma) = \{\tan(\gamma/4)\}^{1/m'}. \quad (4.13)$$

Let ω be such that

$$f_1(\omega) < \rho(\gamma). \quad (4.14)$$

Substituting for $f_1(\omega)$ from (4.11), (4.14) can be expressed as

$$\omega > \omega_0 = \frac{t}{(1-k^2)} \sqrt{\frac{4k^2}{\rho^2(\gamma)} - (1+k^2)^2}. \quad (4.15)$$

We can now state the following result.

Theorem 2. Assume that the condition of Theorem 1 is met and that initially the nominal system is stable. Then the closed-loop system is stable under the time delay uncertainty provided T_d satisfies the inequality

$$T_d < \gamma/\omega_0 \quad (4.16)$$

where ω_0 is given by the RHS of (4.15).

Proof: Following generally the approach due to Walton and Marshall [3], since the control system of Fig. 1 is nominally stable, under time delay uncertainty, the closed-loop poles first need to cross the imaginary axis in the complex plane before the system becomes unstable. The zeros of the characteristic (3.1) are also necessarily solutions of

$$p_0(j\omega) p_0(-j\omega) e(j\omega) e(-j\omega) = 1, \quad \omega \geq 0 \quad (4.17)$$

since (3.1) is real. The number of ω 's (they are all finite) which correspond to the solution of (4.17) are finite in number. Let the largest of them be denoted by ω_m .

A necessary condition for the roots of the characteristic (3.1) to cross the imaginary axis is when the gain condition of (3.2) (equivalent to (3.1)) is satisfied for $s = j\omega$. The RHS of (3.2), when $s = j\omega$ corresponds to points on the unit circle in the η -plane. Since the points on the hatched portion of the unit circle are left out by design from the η -mapping, solutions to (3.2) can only exist corresponding to points on the arc $qq''q'$ in the η -plane (see Fig. 3). The mapping ϕ' maps the arc $qq''q'$ on to the arc $u'hu$ (see Fig. 4) as explained in Section III. The smallest distance from the origin to points on the arc $u'hu$ corresponds to the length of the line segment ob (see Fig. 4) which is given by (3.12).

Considering the mapping of the $j\omega$ -axis via the transformation $\{E \circ v\}$ (see Fig. 2) onto the open unit disk U' and using (4.8) through (4.12), it follows that

$$E(z_1) < |z_1|^{m'} = \{f_1(\omega)\}^{m'}. \quad (4.18)$$

Equation (4.14) then ensures that the mapping of the $j\omega$ -axis via the transformation $\{E \circ v\}$ on to the unit open disk U' (see Fig. 4) falls short of the arc $u'hu$, from magnitude considerations alone for all $\omega > \omega_0$ where ω_0 is given by the RHS of (4.15). Since the arc $u'hu$ is the image under the mapping ϕ' of the arc $qq''q'$ corresponding to feasible ω -solutions of (3.2), it follows that (3.2) cannot have a solution for $\omega > \omega_0$. It then follows that

$$\omega_0 \geq \omega_m.$$

Since the angle subtended by the circular arc between any point on the arc $qq''q'$ and the (-1) point in Fig. 3 at the origin, can be considered (see RHS of (3.2) as corresponding to the product $\{\omega T_d\}$, the smallest such angle corresponds to the point q , the angle being γ as shown in Fig. 3. Since no solution to (3.2) exists for $\omega > \omega_0$, the same is true for

$$T_d < \gamma/\omega_0$$

and hence the closed-loop stability is assured. Hence the result.

Remark 1: The analysis leading to Theorem 2 is based on the conformal mapping $v_1(s)$ (see (4.1)) for $0 < k < 1$. The strict inequality, viz., $k < 1$ is necessary to include the case of zeros of $p_0(s)$, lying on the $j\omega$ -axis and at infinity, being mapped to zero in our analysis. This is due to the well-known result [10] that the

Möbius transformation [represented by (4.3) in our case] can only map points on the circumference on the unit circle on to itself. A provision to the effect of $k < 1$ is also assumed while considering the boundary interpolation case in theorem 1.5 of [5]. Moreover, in our case, as will be shown in Theorem 3, a lower bound for T_{\max} is optimized in a certain sense over k , $0 < k < 1$.

Remark 2: The ratio γ/ω_0 represents a lower bound for T_{\max}

$$\gamma/\omega_0 \leq T_{\max}.$$

For a given β and k , the ratio (γ/ω_0) is maximized by choosing γ as large as possible subject to the constraint of inequality (3.16). Now it remains to optimize (maximize) the lower bound, in a certain sense, by choosing k appropriately. This is taken up next.

In the sequel, k is treated as a variable, $0 < k < 1$, and all the parameters, such as, α_{\max} , γ , ω_0 , ρ and others are all dependent on k .

Theorem 3 Consider the lower bound, viz., the ratio (γ/ω_0) for the time delay margin T_{\max} as given in Theorem 2. For $0 < k < 1$, a maximum exists for this ratio if

$$\rho(k) < (1/a)\{2k/(1+k^2)\}, \quad 0 < k < 1, a > 1 \quad (4.19)$$

and this maximum corresponds to the value of k such that the following conditions are satisfied

$$\begin{aligned} (d\gamma/dk) \rho \{1k^2 - (1+k^2)^2 \rho^2\} + (d\rho/dk) 4k^3 \\ = 4\gamma k \rho \{(1+k^2)/(1-k^2)\}(1-\rho^2), \quad 0 < k < 1 \end{aligned} \quad (4.20)$$

$$(1/\omega_0)(d^2\omega_0/dk^2) > (1/\gamma)(d^2\gamma/dk^2) \quad (4.21)$$

where

$$\begin{aligned} d^2\omega_0/dk^2 = H(k)\{B(k) + L(k)(d\rho/dk) \\ + D(k)(d\rho/dk)^2 + F(k)(d^2\rho/dk^2)\} \end{aligned} \quad (4.22)$$

$$H(k) = [4\beta/\{(1-k^2)^3\rho^6\}][(4k^2/\rho^2) - (1+k^2)^2]^{-1/2} \quad (4.23)$$

$$\begin{aligned} B(k) = -12k^3(1-k^2)^2\rho + 8k^3(3+k^2)\rho^2 \\ + 3k(1-k^2)^2\rho^3 \\ - (1+6k^2+36k^4+18k^6+3k^8)\rho^4 \\ + (1+k^2)^3(1+3k^2)\rho^5 \end{aligned} \quad (4.24)$$

$$\begin{aligned} L(k) = (1-k^2)\{12k^4(1-k^2) + \rho(4k^3)(1-5k^2) \\ - \rho^2(1+k^2)^2(1-k^2)(3k^2) \\ + \rho^3(1+k^2)k(1+7k^4)\} \end{aligned} \quad (4.25)$$

$$D(k) = -(1-k^2)^2(4k^4) \quad (4.26)$$

$$F(k) = -\{4k^2 - \rho^2(1+k^2)^2\}(1-k^2)^2k^2\rho \quad (4.27)$$

and for clarity, the argument k is dropped from $\rho(k)$ and written as ρ only.

Proof Using (4.19), the RHS of (4.15) can be written as

$$\omega_0 > \omega_1 = [\beta\{1/(1+k^2)\}/(1-k^2)]\{\sqrt{a^2-1}\}. \quad (4.28)$$

Since $\beta > 0$ and $a > 1$ are constants, it follows that

$$\omega_1 \rightarrow \beta\sqrt{a^2-1} > 0, \quad k \rightarrow 0. \quad (4.29)$$

Also, for k in the range $0 < k < 1$, since the interpolation data $\{z_l, b_l\}$, $l = n+1, \dots, 2n$, $n \neq 0$ (specified in (2.14) and (2.16)) is confined to the region enclosed by the circle ϵ_2 in \tilde{t}^* (the image of \tilde{A} under the mapping ψ), it follows by Schwarz's Lemma (applied to the analytical map \tilde{E} given by (2.11)) that necessarily

$$\alpha_{\max} < \{2k/(1+k^2)\}^{m'}, \quad m' \geq 1. \quad (4.30)$$

Due to (3.16) and (4.30)

$$\alpha_{\max} \rightarrow 0 \text{ and } \gamma \rightarrow 0, \text{ as } k \rightarrow 0. \quad (4.31)$$

Hence using (4.28), (4.29) and (4.31)

$$(\gamma/\omega_0) < (\gamma/\omega_1) \rightarrow 0, \text{ as } k \rightarrow 0. \quad (4.32)$$

Also, as $k \rightarrow 1$, $\omega_1 \rightarrow \infty$. With $0 < \gamma < \pi$

$$(\gamma/\omega_0) < (\gamma/\omega_1) \rightarrow 0, \text{ as } k \rightarrow 1. \quad (4.33)$$

Notice that ω_0 given by RHS of (4.15) is such that $\omega_0 > 0$, $0 < k < 1$ since $\rho < 1$. That $\rho < 1$ can be seen from the inequalities (4.34) and (4.35) below

$$\begin{aligned} \tan(\gamma/4) < \sin(\gamma/2) < \alpha_{\max} \leq \{2k/(1+k^2)\}^{m'}, \\ m' \geq 1, 0 < \gamma < \pi \end{aligned} \quad (4.34)$$

$$\begin{aligned} \rho = \{\tan(\gamma/4)\}^{1/m'} < 2k/(1+k^2) < 1, \\ 0 < k < 1. \end{aligned} \quad (4.35)$$

With $\gamma > 0$, then the ratio $(\gamma/\omega_0) > 0$. (4.32) and (4.33) thus reveal that at least a maximum value for the ratio (γ/ω_0) exists in the range $0 < k < 1$.

Differentiating the ratio (γ/ω_0) with respect to k (with ω_0 given by RHS of (4.15)) and equating it to zero yields, after simplification, (4.20). To ensure that (4.20) corresponds to a maximum condition, one needs to check whether

$$d^2(\gamma/\omega_0)/dk^2 < 0. \quad (4.36)$$

Direct differentiation of the RHS of inequality (4.16) with respect to k yields (4.21). Equation (4.22)–(4.27) are obtained by some simplification of the direct differentiation of ω_0 given by the RHS of inequality (4.15) with respect to k . Hence the result of Theorem 3.

Remark 3 That the condition given in the inequality (4.19) is only a mild one can be seen by comparing the constraint on $\rho(k)$ due to the inequalities (4.19) and (4.35).

V. EXAMPLE

Let

$$\begin{aligned} p_0(s) &= 1/(s-2) \\ \beta &= 1, \quad m' = 1. \end{aligned}$$

Assuming k as a variable, using (4.1) and (4.3)

$$v_1(2) = v_1 = k/3$$

$$v_1(\infty) = v_2 = k$$

and

$$z_1 = v_2(v_1) = -2k/(3-k^2)$$

$$z_2 = v_2(v_2) = 0.$$

For the interpolation data of $(z_1, 1)$ and $(z_2, 0)$ for the mapping $\tilde{t}^* \rightarrow \tilde{t}$

$$\alpha_{\max} = 2k/(3-k^2).$$

Since $\sin(\gamma/2)$ can be arbitrarily close to α_{\max} , put

$$\sin(\gamma/2) = \alpha_{\max}.$$

$$\gamma = 2\sin^{-1}\{2k/(3-k^2)\}$$

$$\begin{aligned} \rho &= \tan(\gamma/4) = \{1 - \sqrt{1 - \alpha_{\max}^2}\}/\alpha_{\max} \\ &= \{(3-k^2) - \sqrt{(9-k^2)(1-k^2)}\}/(2k) \end{aligned}$$

$$d\rho/dk = (3+k^2)\rho/\{k\sqrt{(9-k^2)(1-k^2)}\}$$

$$d\gamma/dk = 4(3+k^2)/\{(3-k^2)\sqrt{(9-k^2)(1-k^2)}\}.$$

Equation (4.20) is satisfied in the range $0 < k < 1$, for $k = 0.781$ only. Also, using (4.22)–(4.27), (4.21) has been verified to be true at $k = 0.781$. The ratio γ/ω_0 is maximized for $k = 0.781$ and a lower bound for T_d is obtained as

$$T_{d\max} \geq \gamma/\omega_0 = 1.424519519/9.942663337 \\ = 0.143273434.$$

VI. CONCLUSION

Given a plant transfer function with time delay uncertainty, the question arises as to the maximum limiting time delay below which a controller exists such that the closed-loop system remains stable. Since no restriction is placed on the controller, it is expected that the maximum limiting time delay should be a function of the plant transfer function only. This paper has provided a solution to this problem in terms of a lower bound for the limiting time delay. The result will be helpful in determining the time delay margin below which the closed-loop stability of a given plant is guaranteed with the existence of a stabilising controller which can be determined in a straight forward way.

A New Reduction Technique for a Class of Singularly Perturbed Optimal Control Problems

Vladimir Gaitsgory

Abstract—We consider a class of singularly perturbed optimal control problems which may not be approximated by the reduced problems constructed via the formal replacement of the fast variables by the states of equilibrium of the "fast" subsystem considered with "frozen" slow variables and controls. We construct a reduced optimal control problem which provides a true approximation for the problems under consideration and write down necessary and sufficient optimality conditions for this reduced problem.

I. INTRODUCTION

Singularly perturbed optimal control problems have been intensively studied in the literature (see the overviews in [1], [7]–[9] and also more recent works [5], [6], [10]–[12]). As follows from the quoted overviews, a common approach to singularly perturbed optimal control problems is based on their replacement by some reduced order problems obtained via equating of the singular perturbation parameter to zero.

Recently in [5], [6], [11], and [12], it was shown that there are classes of problems which do not allow such an approach. That is, equating the parameter to zero leads, of course, to a simpler problem but the solution of this problem does not approximate the solution of the original singularly perturbed one with an arbitrarily small but nonzero value of the parameter.

In [11] and [12], it was noticed that such a situation may appear in H^∞ -optimal control problems. In [5] and [6], it was established that it may appear in the standard optimal control setting if the system is nonlinear and/or the cost function is nonconvex.

Our consideration in this paper is connected with results in [5] about an approximation of singularly perturbed optimal control problems by problems of optimization of some differential inclusions. In contrast to [5], where the main goal was to construct an approximating problem, in this paper we are interested in how this problem can be solved. We study here an interesting special case where the approximating optimization problem allows a simple representation as a "classic" optimal control problem which we call an extended reduced problem. We construct necessary and sufficient optimality conditions for this problem and describe how it is related to the reduced problem obtained in a traditional way (that is, via equating the small parameter to zero).

II. EXTENDED REDUCED PROBLEM

We shall restrict ourselves to consideration of a class of singularly perturbed (SP) optimal control problems written in the form

$$\text{minimize } G(z(1)) \quad (1)$$

subject to

$$\dot{z}(t) = Q(z(t)) + A(z(t))g(y(t), u(t)), \quad (2)$$

$$\epsilon \dot{y}(t) = f(y(t), u(t)), \quad y(0) = y \quad (3)$$

$$u(t) \in U, \quad \forall t \in [0, 1]. \quad (4)$$

Here ϵ is a small parameter. $Q(\cdot)$, $g(\cdot)$, $f(\cdot)$ are vector functions taking their values in R^k , R^l and R^n , respectively, and $A(\cdot)$ is a $k \times l$ matrix function. The functions $G(\cdot)$, $Q(\cdot)$, and $A(\cdot)$ are supposed to satisfy local Lipschitz conditions in z and the functions $g(y, u)$, $f(y, u)$ are supposed to be continuous and satisfy local Lipschitz conditions in y with a constant which does not depend on $u \in U$. The minimization is executed on the set of admissible controls which is defined as the set of measurable functions $u(t)$ satisfying the inclusion (4), where U is a compact subset of R^m .

We shall suppose that subsystem (3) being written in the "stretched" time scale $\tau = t\epsilon^{-1}$

$$\dot{y}(\tau) = f(y(\tau), u(\tau)) \quad (5)$$

satisfies the following two assumptions.

Assumption 1: There exists a compact set $P \subset R^n$ and a function $\eta(\tau)$

$$\lim_{\tau \rightarrow \infty} \eta(\tau) = 0, \quad \int_0^\infty \eta(\tau) d\tau < \infty$$

such that for any $y' \in P$, $i = 1, 2$ and for any admissible control $u(\tau)$: $\|y(\tau, u(\cdot), y^1) - y(\tau, u(\cdot), y^2)\| \leq \eta(\tau) \|y^1 - y^2\|$, where $y(\tau, u(\cdot), y)$ stands for the solution of (5) obtained with the control $u(\tau)$ and with the initial values $y(0) = y$.

Assumption 2: There exists a compact set $\Omega \subset P$ such that for any admissible control $u(\tau)$ and for any initial values $y \in \Omega$, the solution of (5) does not leave P .

Along with these two we also need an assumption about the trajectories of the SP system (2)–(4).

Assumption 3: There exist compact sets D and W , $D \subset W \subset R^n$, such that for any admissible control $u(t)$ and for any initial values $(z, y) \in D \times \Omega$ the trajectories of (2)–(4) do not leave $W \times P$.

Under Assumptions 1–3 from Theorems 3.2 and 4.1 in [5] it follows that the z -components of the trajectories of (2)–(4) are approximated by the solutions of the differential inclusion with the right-hand side defined for all $z \in W$ as the closure $\text{cl}\{Q(z) + A(z)V_p\}$, where the set $V_p \subset R^l$ is the union

$$V_p = \bigcup_{T>0} \bigcup_{u(\cdot)} \left\{ T^{-1} \int_0^T g(y(\tau), u(\tau)) d\tau \right\} \quad (6)$$

taken over all admissible controls $u(\tau)$ defined on the interval $[0, T]$, and also over all $T > 0$, with $y(\tau)$ being the solution of (5) obtained with the control $u(\tau)$ and satisfying the periodicity condition

$$y(0) = y(T) \in P. \quad (7)$$

Since $\text{cl}\{Q(z) + A(z)V_p\} = Q(z) + A(z)\text{cl}\{V_p\}$ and since the closure $\text{cl}\{V_p\}$, which we denote as \bar{V} , is compact and convex [5, Theorems 3.1 and 3.2], the set of the solutions of the above mentioned differential inclusion coincides with the set of trajectories of the system

$$\dot{z}(t) = Q(z(t)) + A(z(t))v(t) \quad z(0) = z \quad (8)$$

with the admissible controls $v(t)$ being defined as the measurable functions satisfying the inclusion

$$v(t) \in \bar{V}, \quad \forall t \in [0, 1]. \quad (9)$$

The problem of minimization of the cost function (1) on the trajectories of system (8) with the admissible controls defined as above will be called the extended reduced (ER) problem.

An application of Theorem 4.1 of [5] leads now to the following statements about the connections between the SP and ER problems: There exists a function $\mu(\epsilon)$ tending to zero as ϵ tends to zero such that:

- 1) The optimal value function $W^*(s, z, y)$ of the SP problem and the optimal value function $W^*(s, z)$ of the ER problem (that is, the optimal values of the cost achieved in the SP and ER problems subject to that the motions begin from the moment $s \in [0, 1]$ with the initial values $(z(s), y(s)) = (z, y)$ and $z(s) = z$, respectively) satisfy the inequality

$$|W^*(s, z, y) - W^*(s, z)| \leq \mu(\epsilon),$$

$$\forall (s, z, y) \in [0, 1] \times D \times \Omega.$$

- 2) Let $\delta \geq 0$ be an arbitrary number and $v^\delta(t)$ be an admissible control in the ER problem such that

$$G(z^\delta(1)) \leq W^*(0, z) + \delta \quad (10)$$

where $z^\delta(t)$ is the trajectory of (8) obtained with the control $v^\delta(t)$ and with initial values $z^\delta(0) = z \in D$, that is, $v^\delta(t)$ is δ -suboptimal in the ER problem. Then using this control one may find a control $u^\delta(t)$ which is asymptotically δ -suboptimal in the SP problem. That is, it satisfies (4) and when using in (2), (3) with the initial values $(z^\delta(0), y^\delta(0)) = (z, y)$, $y \in \Omega$ it generates the trajectory $(z^\delta(t), y^\delta(t))$ satisfying the inequality

$$G(z^\delta(1)) \leq W^*(0, z, y) + \delta + O(\mu(\epsilon)).$$

Notice that in a general case the ER problem is not equivalent to the reduced (R) problem obtained via equating ϵ to zero in (1)–(4). The latter, as can be easily shown on the basis of Filipov's Lemma [3], is equivalent to the problem of minimization of cost function (1) on the trajectories of system (8) with admissible controls $v(t)$ being measurable functions satisfying the inclusion

$$v(t) \in V_{\epsilon} \quad (11)$$

where $V_{\epsilon} = \bigcup_{u \in U} \{g(v(u), u)\}$ and $v(u)$ is the root of the equation: $f(y, u) = 0$. Since, by Theorem 3.2 [5], $\text{conv} V_{\epsilon} \subset \bar{V}$ and this inclusion can be proper, all the trajectories which are admissible in the R problem are also admissible in the ER problem but not vice versa.

III. NECESSARY AND SUFFICIENT CONDITIONS OF OPTIMALITY FOR THE ER PROBLEM

Let us introduce the following periodic optimization PO problem

$$\sup_{u(\cdot)} \left\{ T^{-1} \int_0^T \lambda^T A(z) g(y(\tau), u(\tau)) d\tau \right\} = h(z, \lambda). \quad (12)$$

Here sup is sought over the length T of the time interval, over the admissible controls $u(\tau) \in U$ defined on $[0, T]$ and over the corresponding solutions $y(\tau)$ of system (5) satisfying periodicity conditions (7). The optimal value of the problem depends on the values of the parameters z , λ and the function defining this dependence is denoted as $h(z, \lambda)$.

Let $(v^0(t), z^0(t))$ be an optimal control and the corresponding trajectory of the ER problem. Since, by definition, $v^0(t) \in \bar{V}$, $\forall t \in [0, 1]$ and \bar{V} is the closure of the set V_p introduced in (6), corresponding to each $t \in [0, 1]$ there exist a sequence of positive numbers T_i^t , a sequence of controls $u_i^t(\tau) \in U$ defined on the intervals $[0, T_i^t]$ and a sequence of the solutions $y_i^t(\tau)$ of system (5) satisfying the periodicity conditions: $y_i^t(0) = y_i^t(T_i^t) \in P$, $i = 1, 2, \dots$, such that

$$v^0(t) = \lim_{i \rightarrow \infty} (T_i^t)^{-1} \int_0^{T_i^t} g(y_i^t(\tau), u_i^t(\tau)) d\tau. \quad (13)$$

Theorem 1 Let Assumptions 1–3 hold and let $G(z)$, $Q(\cdot)$, and $A(\cdot)$ have continuous partial derivatives with respect to the components of z . Let $\lambda(t)$ be the solution of the system

$$\dot{\lambda}(t) = -F'_z(z^0(t), v^0(t))\lambda(t), \quad \lambda(1) = -G'(z^0(1)) \quad (14)$$

where

$$\begin{aligned} F(z, v) &= Q(z) + A(z)v, \\ F'_z(z, v) &= \left\{ \frac{\partial F_i(z, v)}{\partial z_j} \right\}, \\ G'_z(z) &= \left\{ \frac{\partial G_i(z)}{\partial z_j} \right\} \end{aligned} \quad (15)$$

$F_i(z, v)$, $i = 1, \dots, k$ are the components of the vector function $F(z, v)$. Then for almost all $t \in [0, 1]$

$$\begin{aligned} \lim_{i \rightarrow \infty} (T_i^t)^{-1} \int_0^{T_i^t} \lambda^T(t) A(z^0(t)) g(y_i^t(\tau), u_i^t(\tau)) d\tau \\ = h(z^0(t), \lambda(t)). \end{aligned} \quad (16)$$

That is, the sequence of triplets $\{T^i, u^i(\tau), y^i(\tau)\}$ defined as that satisfying (13) is maximizing in PO problem (12) with $z = z^0(t)$ and $\lambda = \lambda(t)$.

Proof of the theorem is obtained via the direct application of Pontriagin's maximum principle to the ER problem.

Let us note that if for all t from some subset ω of $[0, 1]$ there exist $T^i > 0$, a control $u^i(\tau) \in U$, $\forall \tau \in [0, T^i]$, and the solution $y^i(\tau)$ of system (5) satisfying periodicity conditions: $y^i(0) = y^i(T^i) \in P$ such that

$$v^0(t) = (T^i)^{-1} \int_0^{T^i} g(y^i(\tau), u^i(\tau)) d\tau \quad (17)$$

that is, $v^0(t) \in V_p$, $\forall t \in \omega$, then for almost all such t the triple $\{T^i, u^i(\tau), y^i(\tau)\}$ is the solution of PO problem (12) with $z = z^0(t)$, $\lambda = \lambda(t)$.

Let us denote by $\{T^{-\lambda}, u^{-\lambda}(\tau), y^{-\lambda}(\tau)\}$ a solution of PO problem (12) with given z and λ and define the function $v(z, \lambda)$ as

$$(T^{-\lambda})^{-1} \int_0^{T^{-\lambda}} g(y^{-\lambda}(\tau), u^{-\lambda}(\tau)) d\tau. \quad (18)$$

Assuming that (17) takes place for all $t \in [0, 1]$, one may come to the conclusion that the optimal control $v^0(t)$ can be presented in the form

$$v^0(t) = v(z^0(t), \lambda(t)) \quad (19)$$

where $z^0(t)$, $\lambda(t)$ are determined as a solution of the following boundary-value problem

$$\begin{aligned} \dot{z}^0(t) &= Q(z^0(t)) + A(z^0(t))v(z^0(t), \lambda(t)), \quad z^0(0) = z \\ \dot{\lambda}(t) &= -F'(z^0(t), v(z^0(t), \lambda(t)))\lambda(t), \\ \lambda(1) &= -G'(z^0(1)). \end{aligned}$$

Notice that the verification of (17) and the construction of the family of the solutions of (12) depending on z and λ seem to be very problematic in the general case. The described procedure, however, maybe also applied without such a verification and with the use of a family of approximate solutions of (12) instead of the family of precise ones. In Section IV below we shall consider a special case when an estimation of "suboptimality" of the control (19) via the estimation of the approximation of the solutions of (12) is possible.

Sufficient optimality conditions for the ER problem can be constructed on the basis of the Hamilton-Jacobi-Bellman (HJB) equation written for this problem in the form

$$W'_z(s, z) + \min_{v \in V} \{ (W'_z(s, z))^T (Q(z) + A(z)v) \} = 0. \quad (20)$$

Using again the fact that \bar{V} is the closure of V_p and also the definition of $h(z, \lambda)$ as the optimal value of the PO problem (12), one may rewrite (20) in the following form

$$W'_z(s, z) + (W'_z(s, z))^T Q(z) - h(z, -W'_z(s, z)) = 0. \quad (21)$$

HJB equation (21) provides a characterization of the optimal value function of the ER problem (and, thus, an approximate characterization of the optimal value function of the SP problem). Namely, if the former is differentiable at some point $(s, z) \in R^{k+1}$, then it satisfies (29) at this point [4, Chapter IV, Theorem 4.1]. On the other hand, given some admissible trajectory $z^0(t)$ of the ER problem (that is, a trajectory of (8) obtained with some admissible control $v^0(t)$), its optimality can be verified on the basis of the following sufficient optimality conditions.

Theorem 2: If under Assumptions 1-3 there exists a function $W(s, z)$ defined and having continuous partial derivatives in some δ -tube, Γ_δ , around $z^0(t)$

$$\Gamma_\delta = \{(t, z) \mid t \in [0, 1], \|z - z^0(t)\| < \delta\}, \quad \delta > 0$$

and also satisfying there (21) with the following boundary conditions

$$\begin{aligned} W(1, z) &= G(z), \quad \forall z \in \{z^1 \mid \|z^1 - z^0(1)\| < \delta\}; \\ W(0, z^0(0)) &\geq G(z^0(0)) \end{aligned}$$

then $(v^0(t), z^0(t))$ is a local solution of the ER problem, that is, for all admissible trajectories $z(t)$ such that $(t, z(t)) \in \Gamma_\delta$

$$G(z^0(1)) \leq G(z(1)).$$

Proof: The theorem is a reformulation of Proposition 3.7.2 in [2] and, thus, it is implied by the proof of this proposition.

In a general case the optimal value function of the ER problem is not differentiable at all points, although it can be shown to satisfy local Lipschitz conditions and, thus, it is differentiable almost everywhere [4, Chapter IV, Theorem 4.2]. Similarly to Theorem 2, sufficient (and also necessary) conditions for the admissible trajectory of the ER problem to be locally optimal can be constructed on the basis of some generalized version of the GJB equation introduced in [2]. This is

$$\min \{ \alpha + \beta^T Q(z) - h(z, -\beta), \quad (\alpha, \beta) \in \partial W(s, z) \}$$

where $\partial W(s, z)$ is the generalized Clarke gradient. The formulation and the proof of the corresponding statement can be adapted from [2, Theorem 3.7.6]. \square

IV. ASYMPTOTIC LINEARIZATION OF THE SP PROBLEM

Let us consider a class of SP problems which are linear in the slow variables. That is, assume that cost function (1) and slow subsystem (2) are written as

$$\inf_{u \in U} \int_0^1 z^T(t) dt \quad (22)$$

and

$$\dot{z}(t) = Qz(t) + Ag(y(t), u(t)), \quad z(0) = z \quad (23)$$

respectively, where $Q(k \times k)$ and $A(k \times l)$ are constant matrices. In this case the system (8) becomes linear

$$\dot{z}(t) = Qz(t) + Av(t), \quad z(0) = z \quad (24)$$

and, thus, by Theorem 1, nonlinear SP problem (22), (23), (3), (4) is approximated by linear ER problem (22), (24), (9).

The linearity of the ER problem makes Pontriagin's maximum principle not only a necessary but also a sufficient condition of optimality in this problem. More than that, the following statement is known to be true.

Let $\lambda(t)$ be defined as the solution of system (14) which, by (22) and (24) takes the form

$$\dot{\lambda}(t) = -Q^T \lambda(t), \quad \lambda(1) = -c \Leftrightarrow \lambda(t) = -e^{Q^T(1-t)} c \quad (25)$$

and let an admissible control $v^\delta(t)$ satisfies the inequality

$$\lambda^T(t)Av^\delta(t) \geq h(\lambda(t)) - \eta(t), \quad \eta(t) \geq 0$$

for almost all $t \in [0, 1]$. Here

$$h(\lambda) = \max \{ \lambda^T A v \mid v \in \bar{V} \} \quad (26)$$

and $\eta(t)$ is some integrable function.

Then the trajectory $z^\delta(t)$ of (24) obtained when using this control satisfies (10) with $\delta = \int_0^1 \eta(t) dt$. That is, $v^\delta(t)$ is δ -suboptimal in the ER problem.

The validity of this statement follows from the fact that the value of the cost function (22) obtained when applying the control $v^\delta(t)$ on the interval $[s, 1]$ with the initial values $z(s) = z$ is equal to

$$c^T z^\delta(1) = -\lambda^T(s)z - \int_s^1 \lambda^T(t)A v^\delta(t)dt$$

whereas the optimal cost function value is equal to

$$W(s, z) = -\lambda^T(s)z - \int_s^1 h(\lambda(t))dt. \quad (27)$$

Notice that

$$\max\{\lambda^T v \mid v \in \bar{V}\} = \sup\{\lambda^T v \mid v \in V_p\}$$

and, thus, $h(\lambda)$ coincides with the optimal value of the PO problem (12), with the dependence on z disappearing since the matrix $A(z)$ is supposed to be constant. This allows us to reformulate the statement above as follows.

Let T^λ be a positive number, $u^\lambda(\tau) \in U$ be a control defined on $[0, T^\lambda]$ and $y^\lambda(\tau)$ be the solution of (5) corresponding to this control satisfying the periodicity condition: $y^\lambda(0) = y^\lambda(T^\lambda) \in P$ such that

$$\begin{aligned} (T^\lambda)^{-1} \int_0^{T^\lambda} \lambda^T A g(y^\lambda(\tau), u^\lambda(\tau)) d\tau \\ \geq h(\lambda) - \eta(\lambda), \quad \eta(\lambda) \geq 0 \end{aligned}$$

and let

$$v(\lambda) = (T^\lambda)^{-1} \int_0^{T^\lambda} g(y^\lambda(\tau), u^\lambda(\tau)) d\tau.$$

Suppose that the family of triplets $\{T^\lambda, u^\lambda(\tau), y^\lambda(\tau)\}$ and, thus, also $v(\lambda)$ are defined for all $\lambda \in \Lambda$, with Λ containing $\lambda(t), \forall t \in [0, 1]$. Then the control $v^\delta(t) = v(\lambda(t))$ is δ -suboptimal in the ER problem with $\delta = \int_0^1 \eta(\lambda(t))dt$.

V. CONNECTIONS BETWEEN THE ER AND R PROBLEMS

As we have already noticed, the sets of controls and trajectories admissible in the ER problem are in the general case more rich than those in the R one and, hence, the optimal value functions of these two problems, $W(s, z)$ and, respectively, $F(s, z)$, satisfy the inequality

$$F(s, z) \geq W(s, z) \quad \forall (s, z) \in [0, 1] \times R^k.$$

In case the SP problem is linear in z , that is (22), (23) are valid, the difference between $F(s, z)$ and $W(s, z)$ allows an explicit representation.

Let us define $h_{st}(\lambda)$ as the optimal value of the steady state optimization SSO problem corresponding to PO problem (12)

$$\begin{aligned} h_{st}(\lambda) &= \max\{\lambda^T A g(v(u), u) \mid u \in U\} \\ &= \max\{\lambda^T A g(y, u) \mid g(y, u) = 0, u \in U, y \in P\} \end{aligned}$$

where again, as above, the dependence of the optimal value on z disappears since A is not dependent on z .

Theorem 3: Suppose that Assumptions 1-3 and (22), (23) are true. Then

$$F(s, z) - W(s, z) = \int_s^1 (h(\lambda(t)) - h_{st}(\lambda(t))) dt \quad (28)$$

where $\lambda(t)$ is defined in (25).

Proof: In the case under consideration the R problem takes the form (22), (24), (11). That is, it is linear and, hence, its optimal value function is given by the expression

$$F(s, z) = -\lambda^T(s)z - \int_s^1 \max\{\lambda^T(t)A v \mid v \in V_{st}\} dt.$$

Comparing this with (27) and taking into account that

$$\max\{\lambda^T A v \mid v \in V_{st}\} = h_{st}(\lambda)$$

one obtains (28). \square

Corollary: Under the assumptions of Theorem 3 the optimal value function of the SP problem converges to the optimal value function of the R problem

$$\lim_{\delta \rightarrow 0} W(s, z, y) = F(s, z) \quad \forall (s, z, y) \in [0, 1] \times D \times \Omega \quad (29)$$

if and only if for almost all $t \in [0, 1]$

$$h(\lambda(t)) = h_{st}(\lambda(t)). \quad (30)$$

Notice that in a general case $h(\lambda) \geq h_{st}(\lambda)$ and a number of tests allowing one to verify whether this inequality is the strict one or it takes the form of the equality were developed in periodic optimization theory (see references in [5], [6]). Notice also that if this inequality takes the form of the equality for all λ (that is, (30) is true for all λ and not only for $\lambda = \lambda(t)$), then as it follows from Theorems 3.2 and 4.2 in [5], the convergence (29) can be guaranteed for SP problems of a much more general structure than that we are dealing with in this paper.

VI. CONCLUSION

We have proposed a new method to deal with the class of SP problems described. The method consists of an approximation of the solution of the SP problem by the solution of the ER problem and of characterization of the latter by necessary and sufficient optimality conditions. For SP problems linear in the slow variables the method allows the complete answer to the question about the efficiency of the traditional reduction technique.

Pole Assignment with Robust Stability

Mark E. Halpern, Robin J. Evans, and Robin D. Hill

Abstract—This paper uses convex analysis for the pole assignment design of discrete-time SISO systems incorporating robust stability against norm bounded parametric perturbations in the plant transfer function. The method involves designing an overparameterized pole assignment controller for the nominal plant with the overparameterization chosen to reduce the size of changes in the closed-loop characteristic equation which result from plant perturbations. Sufficiency bounds on the l_p norm of the perturbation guaranteeing stability are obtained.

I. INTRODUCTION

For most real control problems, the behavior of the plant does not match exactly that of an assumed finite order linear time-invariant dynamic model. This is because the true plant usually has complicated dynamics which may be nonlinear and of high order.

This motivates the design of robust controllers, that is compensators which achieve acceptable performance in some sense for a range of plants. This then can allow for uncertainties in the plant model. Uncertainties are usually considered to fit into two broad categories, namely structured and unstructured uncertainties depending on the specificity of the knowledge of the perturbations with respect to the plant model structure. For example, uncertainties in the frequency response of a plant are unstructured because they relate to the plant as a whole. On the other hand, uncertainties in a parametric description of a plant are structured. The two main aspects of robustness are stability robustness and performance robustness. In this work we focus on design for stability robustness in the presence of structured parametric uncertainty in the plant.

Previous related work is described in [1]–[9]. Dahleh [1] used the small gain theorem to obtain necessary and sufficient conditions for closed-loop stability in the presence of l_∞ induced norm bounded coprime factor perturbations to the plant. In [2], Soh and Evans applied Kharitonov results [3] to characterize allowable perturbations of an interval plant in closed loop with a pole placement compensator. Kharitonov-type extreme point results do not hold, however, for a stability region which is a circle at the origin of the complex plane so they are not easily used for testing discrete-time stability so a bilinear transform was used in [2].

An approach which handles general stability regions and, thus allows the treatment of discrete-time systems, involves treating the vector of coefficients of an n th order closed-loop characteristic equation as a point in n -dimensional parameter space. Fam and Meditch [4] have determined the stability boundary for discrete-time systems in this space of coefficients and have shown it to be bounded by three hypersurfaces. Soh *et al.* [5] have found the largest hypersphere centered at a specified stable point and containing the coefficients of only stable polynomials.

Using this type of framework, Biernacki *et al.* [6], and Keel *et al.* [7] have proposed continuous-time compensator synthesis approaches for uncertain multivariable plants. They regard the compensator as a

mapping from plant parameter space to closed-loop coefficient space and design the compensator to restrict the closed-loop coefficients to the interior of a stable region in this space. The compensator design involves a nonconvex numerical optimization.

Berger [8], [9] has proposed an approach for the synthesis of robust control systems using overparameterized pole assignment controllers. In that work, the overparameterization is used to minimize the variance of the closed-loop characteristic polynomial due to plant parameter uncertainties described by the covariance matrix of the plant parameter estimates as obtained by a recursive least squares estimator.

In this paper we present an approach to the design of overparameterized pole assignment compensators for SISO discrete-time systems which maintain stability in the presence of norm bounded structured parametric uncertainty in the plant model. The work is in a similar spirit to that in [7], but our use of norms is different and we design for nominal pole assignment. This gives a design which uses a convex optimization and allows some closed form results to be obtained.

II. PROBLEM FORMULATION

The z transform, \hat{h} , of a sequence, $\{h_i\}_{i=0}^\infty$, is defined by $\hat{h} = \sum_{i=0}^\infty h_i z^{-i}$. With this definition, a stable transfer function has all of its poles inside the unit disc of the complex plane. The symbol z^{-1} denotes the unit delay and polynomial, $X(z)$, of order n , is given by $X(z) = \sum_{i=0}^n x_i z^{-i}$.

In this work we consider the vector of coefficients of a polynomial as an element in an l_p normed space. We denote the vector of coefficients of $X(z)$ as x , with the l_p norm of a vector $x = \{x_i\}_{i=0}^\infty$ denoted as $\|x\|_p$, defined as

$$\|x\|_p = \left| \sum |x_i|^p \right|^{1/p}$$

for $1 \leq p < \infty$ with

$$\|x\|_\infty = \sup |x_i|$$

Consider a SISO discrete-time plant given by

$$\hat{y}_p = \frac{B(z)}{A(z)} \hat{u}_p$$

where \hat{y}_p is the plant output, u_p is its input, and $B(z)$ and $A(z)$ are coprime polynomials with $b_0 = 0$ and $a_0 = 1$. The plant has n_a finite poles $t_1, t_2, \dots, t_{n_a} \neq 0$. The plant is in a feedback control system with \hat{u}_p given by

$$\hat{u}_p = \frac{G(z)}{(1 - z^{-1})F(z)} w - \hat{y}_p$$

where w is the reference input and $G(z)$ and $F(z)$ are compensator polynomials. Note that for convenience a one degree of freedom (1-DOF) compensator is considered here, however the robustness results obtained apply equally for 2-DOF systems.

The system closed-loop poles are the roots of $V(z) = 0$, where

$$A(z)(1 - z^{-1})F(z) + B(z)G(z) = V(z). \quad (1)$$

For the usual pole-assignment controller design, the designer specifies $V(z)$ with all its roots stable and then solves (1) for the compensator polynomials, $F(z)$ and $G(z)$. The $F(z)$ and $G(z)$ which satisfy (1) are not unique but are parameterized as follows. If $F^0(z)$ and $G^0(z)$

IEEE Log Number 9408780

are a particular solution to (1), then all $F(z)$ and $G(z)$ which give the same $V(z)$ are given by

$$F(z) = F^0(-) + B(-) V(-) \quad (2)$$

and

$$G(-) = G^0(-) - (1 - z^{-1}) A(-) V(-) \quad (3)$$

where $V(-)$ is an arbitrary polynomial

Usually, $F^0(-)$ and $G^0(-)$ are chosen to be the minimum order unique polynomials satisfying (1), and $V(-)$ is incorporated to give some sort of performance improvement, through overparameterization of the compensator. Such a procedure gives proper controllers.

In the work presented here, $V(-)$ is chosen to reduce the effects of parametric plant perturbations on $V(-)$. We consider the plant as a nominal plant $\frac{B^0(-)}{A^0(-)}$ modified by perturbation polynomials $\Delta B(-)$ with coefficient vector $\Delta b = (0 \ \Delta b_1 \ \dots \ \Delta b_{n_{\Delta b}})$ and $\Delta A(-)$ with coefficient vector $\Delta a = (0 \ \Delta a_1 \ \dots \ \Delta a_{n_{\Delta a}})$ so that the perturbed plant is

$$\frac{B(-)}{A(-)} = \frac{B^0(-) + \Delta B(-)}{A^0(-) + \Delta A(-)}$$

The orders of $\Delta B(-)$ and $\Delta A(-)$ may be larger than those of $B^0(z)$ which has order n_{B^0} and $A^0(-)$ with order n_{A^0} . The order of the perturbed plant polynomials is

$$n_l = \max\{n_{b_l}, n_{\Delta b_l}\}$$

and

$$n_r = \max\{n_{r_0}, n_{\Delta r_l}\}$$

If the perturbed plant is used in conjunction with a compensator designed to give characteristic polynomial $V^0(-)$ with the nominal plant $B^0(-)/A^0(-)$, the closed-loop characteristic equation will be

$$V^0(-) + \Delta V(-) = 0$$

where from (1)

$$\Delta V(-) = G(-)\Delta B(-) + (1 - z^{-1})F(-)\Delta A(-) \quad (4)$$

Our approach involves designing the compensator to reduce the effect of $\Delta B(-)$ and $\Delta A(-)$ on the size of $\Delta V(-)$ thereby allowing larger plant perturbations while preserving stability.

III. ROBUSTNESS AGAINST A CLASS OF PLANT PERTURBATIONS

We consider the coefficient vectors of $\Delta B(-)$ and $\Delta A(-)$ as fixed but unknown elements in an l_p normed space.

Initially, we examine the case with $\Delta A(-) = 0$. In this case (4) reduces to

$$\Delta V(-) = G(-)\Delta B(-)$$

In terms of coefficients we then have

$$\Delta v_i = \sum_{j=0}^l q_j \Delta b_{i-j}, \quad i = 1, 2, \dots, n_r + n_{\Delta b_l}$$

so that Hölder's Inequality gives

$$\|\Delta v\|_\infty \leq \|q\|_l \|\Delta b\|_l \quad (5)$$

for all $p, q \in [1, \infty)$ satisfying $1/p + 1/q = 1$

We define γ to be the largest number such that

$$\|\Delta v\|_\infty < \gamma \Rightarrow V^0(-) + \Delta V(-) \text{ is stable}$$

A sufficient condition for stability of the perturbed system is $\|\Delta v\|_\infty < \gamma$. A sufficient condition for $\|\Delta v\|_\infty < \gamma$ is that for some $p, q \in [1, \infty)$ satisfying $1/p + 1/q = 1$ we have $\|q\|_l \|\Delta b\|_l < \gamma$.

This yields a key result which is a sufficiency test for stability if for some $p, q \in [1, \infty)$ satisfying $1/p + 1/q = 1$ we have

$$\|\Delta b\|_l < \gamma \quad (6)$$

then the perturbed system remains stable.

If "degree dropping," where the perturbations cause certain of the b_i to become zero, occurs, this does not invalidate (6).

We may interpret γ geometrically as half the length of side of the largest hypercube centered at v^0 , the vector of coefficients of the nominal closed-loop characteristic polynomial, and containing only stable polynomials. The value of γ depends only on v^0 and on n , the order of the perturbed closed-loop characteristic polynomial given by

$$n = \max\{n_b + n_r, n_r + n_l + 1\}$$

Vicino [10] has shown how to calculate γ . For the particular case where the nominal system is deadbeat with order n we have from Soh [11] that $\gamma = 1/n$.

Thus from (6) we can design a controller with robust stability against l_l perturbations to the plant numerator by minimizing $\|q\|_l$.

This minimization may be performed in several ways. One way is by calculating $G(-) = G^0(-) - (1 - z^{-1}) V^0(-) V(-)$ in terms of the unknown coefficients of $V(-)$ and then minimizing $\|q\|_l$ with respect to these coefficients. If $p = 1$ or $p = \infty$ the minimization is a linear program. If $p = 2$ there is a closed form solution.

Alternatively the minimization of $\|q\|_l$ may be formulated as the minimization of a norm subject to a set of linear interpolation constraints as follows

$$(7)$$

subject to

$$\sum_{i=1}^n q_i t_i = \frac{V^0(t_i)}{B^0(t_i)}, \quad i = 1, 2, \dots, n \quad (8)$$

and to

$$\sum_{i=0}^n q_i = \frac{V^0(1)}{B^0(1)} \quad (9)$$

where (9) is for an integrator pole. Here the t_i 's are the plant poles which are all known. They may be stable or unstable.

Writing the minimization in this form (7)–(9) yields the insight that "adding" more poles to the plant restricts the feasible set for the minimization and thus increases the value of $(\|q\|_l)_{\min}$, thereby tending to decrease the robustness to uncertainty in the plant numerator. In this respect the integrator imposed for performance, has the same kind of effect as an extra plant pole.

As the order of the system is increased through overparameterization of the compensator the values of both γ and of $(\|q\|_l)_{\min}$ become smaller. It is thus necessary to check that their quotient increases with overparameterization.

Another benefit of expressing the minimization as in (7)–(9) is that it enables the construction of a dual maximization problem, which we may use in some special cases to obtain an analytical solution to the minimization (7)–(9).

The maximization, dual to the primal minimization of (7)–(9), is given by

$$(\|q\|_l)_{\min} = \max_{\alpha, \beta} \left| \sum_{i=1}^n \alpha_i \frac{V^0(t_i)}{B^0(t_i)} + \alpha \frac{V^0(1)}{B^0(1)} \right|$$

subject to

$$\|q^*\|_l \leq 1$$

where

$$g_i^* = \sum_{j=1}^{n_g} \alpha_j t_j^{-i} + \alpha_{n_g+1}; \quad i = 0, \dots, n_g.$$

A. Closed Form Solutions

In this section we derive analytical expressions for $(\|\Delta b\|_q)_{\max}$ for a nominal deadbeat closed-loop system where the plant has only one pole $t_1 \in (-\infty, \infty)$ with $t_1 \neq 0$ and where there is no integrator in the loop.

For the problem of minimizing the l_p norm of a vector $x \in l_p$ subject to one linear constraint $\sum_{i=0}^{\infty} e_i x_i = m$ (which we write as $e \cdot x = m$), Hölder's Inequality yields

$$\begin{aligned} \min \|x\|_p &= \\ \text{s.t. } e \cdot x &= m \end{aligned} \quad (10)$$

where $p, q \in [1, \infty)$ and $1/p + 1/q = 1$.

Applying this result to the minimization problem of (7) gives

$$(\|g\|_p)_{\min} = \frac{1}{|B^0(t_1)| \|t_1^{(n_g)}\|_q}$$

where

$$= (1, t_1^{-1}, t_1^{-2}, \dots, t_1^{-n_g})$$

Since the closed-loop system is deadbeat, we have

$$\gamma = \frac{1}{n} = \frac{1}{n_b + n_g}$$

so that

$$(\|\Delta b\|_q)_{\max} = \frac{|B^0(t_1)| \|t_1^{(n_g)}\|_q}{n_b + n_g} \quad (11)$$

With $q = 1$, (11) gives

$$(\|\Delta b\|_1)_{\max} = \frac{|B^0(t_1)|}{(n_b + n_g)} \frac{(1 - |t_1|^{-(n_g+1)})}{(1 - |t_1|^{-1})}. \quad (12)$$

With $q = 2$, (11) gives

$$(\|\Delta b\|_2)_{\max} = \frac{|B^0(t_1)|}{n_b + n_g} |1 - t_1^{-(2n_g+2)}|^{1/2} \quad (13)$$

With $q = \infty$, (11) gives

if $|t_1| > 1$,

$$(\|\Delta b\|_{\infty})_{\max} = \frac{|B^0(t_1)|}{n_b + n_g} \quad (14)$$

and if $|t_1| \leq 1$,

$$(\|\Delta b\|_{\infty})_{\max} = \frac{|t_1^{-n_g} B^0(t_1)|}{n_b + n_g} \quad (15)$$

Here with no overparameterization, $n_g = 0$.

Equation (11) indicates that if the plant is stable, that is if $(|t_1| < 1)$, then the nominal deadbeat system can be made closed-loop stable against arbitrarily large perturbations of arbitrarily high order in the plant numerator by overparameterizing. We can also see this by inspecting (8), noting that the coefficients on the left-hand side of the constraint (8) may be made arbitrarily large by overparameterizing. This clearly holds for a plant with any number of only stable poles.

These closed form solutions (11)–(15) for $(\|\Delta b\|)_{\max}$ are each proportional to $B^0(t_1)$. A value of $B^0(t_1) = 0$ indicates a plant pole-zero cancellation. An unstable root common to $B^0(z)$ and $A^0(z)$ clearly means that the nominal plant is not stabilizable but a stable common root has no such effect. The closed form solutions are obtained on the basis of deadbeat pole placement, and this is not possible if there is a plant pole-zero cancellation.

B. Selection of Norms

Performing the design requires choosing the l_p norm of the compensator coefficient vector to be minimized. This should be done based on knowledge of the distribution of perturbation coefficient magnitudes to allow larger perturbations without losing a guarantee of stability. We do this by incorporating a scaling factor c into the perturbation so that

$$\Delta B(z) = c\delta(z).$$

This does not uniquely define c but if we keep $\delta(z)$ constant, we may usefully try to make c large. We then define $c_{(q)}$ according to

$$\|\Delta b\|_q = (\|\Delta b\|_q)_{\max} \Rightarrow c = c_{(q)}$$

and then attempt to find the value of q which maximizes $c_{(q)}$.

We consider only l_1, l_2 , and l_{∞} norms because these are the easiest to calculate. The results extend for the more general case of l_q norms with $q \in [1, \infty)$.

An important result behind the selection is that

$$(\|g\|_{\infty})_{\min} \leq (\|g\|_2)_{\min} \leq (\|g\|_1)_{\min}.$$

From (6) then we have that

$$(\|\Delta b\|_1)_{\max} \geq (\|\Delta b\|_2)_{\max} \geq (\|\Delta b\|_{\infty})_{\max}. \quad (16)$$

We illustrate the norm selection process by considering two extreme distributions of perturbation coefficient magnitudes. The first arises from a perturbation with only one nonzero coefficient, that is $\Delta B(z) = c z^{-k}$ where k is an unknown integer in the range $[1, n_{\Delta b}]$.

We wish to choose the l_p norm such that minimizing $\|g\|_p$ gives the largest value of $|c|$ with guaranteed stability. For this perturbation

$$\|\Delta b\|_1 = \|\Delta b\|_2 = \|\Delta b\|_{\infty} = |c|$$

so that

$$\|\Delta b\|_1 = (\|\Delta b\|_1)_{\max} \Rightarrow c_{(1)} = (\|\Delta b\|_1)_{\max},$$

$$\|\Delta b\|_2 = (\|\Delta b\|_2)_{\max} \Rightarrow c_{(2)} = (\|\Delta b\|_2)_{\max}$$

and

$$\|\Delta b\|_{\infty} = (\|\Delta b\|_{\infty})_{\max} \Rightarrow c_{(\infty)} = (\|\Delta b\|_{\infty})_{\max}.$$

Equation (16) implies that we obtain the largest value of $|c|$ by choosing $q = 1$ and $p = \infty$, that is we design by minimizing $\|g\|_{\infty}$.

At the other extreme, if the perturbation is such that $|\Delta b_i| = c$ for $i = 1, \dots, n_{\Delta b}$, then $\|\Delta b\|_1 = c n_{\Delta b}$, $\|\Delta b\|_2 = c \sqrt{n_{\Delta b}}$ and $\|\Delta b\|_{\infty} = c$ so that we have

$$\|\Delta b\|_1 = (\|\Delta b\|_1)_{\max} \Rightarrow c_{(1)} = \frac{(\|\Delta b\|_1)_{\max}}{n_{\Delta b}},$$

$$\|\Delta b\|_2 = (\|\Delta b\|_2)_{\max} \Rightarrow c_{(2)} = \frac{(\|\Delta b\|_2)_{\max}}{\sqrt{n_{\Delta b}}}$$

and

$$\|\Delta b\|_{\infty} = (\|\Delta b\|_{\infty})_{\max} \Rightarrow c_{(\infty)} = (\|\Delta b\|_{\infty})_{\max}.$$

For the simple case where the plant has only one pole $t_1 \in (-\infty, \infty)$ with $t_1 \neq 0$ and where the nominal closed-loop pole set is deadbeat, we can substitute for $(\|\Delta b\|_q)_{\max}$ from (7)–(9) to obtain

$$\begin{aligned} c_{(1)} &= \frac{|B^0(t_1)|}{(n_b + n_g)} \frac{(1 - |t_1|^{-(n_g+1)})}{(1 - |t_1|^{-1})} \frac{1}{n_{\Delta b}}, \\ c_{(2)} &= \frac{|B^0(t_1)|}{(n_b + n_g)} \frac{1 - t_1^{-(2n_g+2)}}{1 - t_1^{-2}} \frac{1}{\sqrt{n_{\Delta b}}} \end{aligned}$$

TABLE I
EFFECT OF OVERPARAMETERIZATION OF COMPENSATORS

Order of $G(z)$	$(\ L\ _1)_{\min}$	γ	$(\ \Delta b\ _1)_{\max}$
1	4.08654	1/3	0.0816
2	1.72476	0.25	0.1449
3	1.10385	0.2	0.1812
4	0.7871	1/6	0.2117

and

$$c_{(\infty)} = \frac{|B^0(t_1)|}{(n_b + n_q)}.$$

For $n_{\Delta b} \geq 2$, $n_g \geq 1$ and $|t_1| > 1$, we have $c_{(\infty)} > c_{(2)} > c_{(1)}$ and therefore can guarantee closed-loop stability for a larger value of γ if we minimize $\|g\|_1$.

C. Example

In this example we demonstrate how overparameterizing the compensator can increase the value of $(\|\Delta b\|_1)_{\max}$.

The nominal plant is

$$\frac{B^0(z)}{A^0(z)} = \frac{0.1333z^{-1} - 0.6667z^{-2}}{1 - 0.6667z^{-1}}$$

and so has a delay, a nonminimum phase zero and a stable pole. The nominal closed-loop pole set is to be deadbeat, and there is an integrator in the loop so (11) does not apply. The order $n_{\Delta b}$ of the perturbation is chosen to be $n_{\Delta b} = 2$ so that $n_b = \max(n_{b0}, n_{\Delta b}) = \max(2, 2) = 2$. Increasing the value of $n_{\Delta b}$ reduces the value of γ by increasing the value of n_b in the formula $\gamma = 1/(n_b + n_q)$ for a nominal deadbeat system. Table I shows the effect of overparameterization for this example. This table shows how the l_1 norm of the guaranteed safe perturbation on the plant numerator increases as the compensator is overparameterized.

D. Other Plant Perturbations

A similar approach can be taken for plant perturbations with $\Delta B(z) = 0$ and $\Delta A(z) \neq 0$.

For both $\Delta A(z)$, $\Delta B(z) \neq 0$ we may prefer on the basis of the distribution of perturbation coefficient magnitudes to consider Δb and Δa to be elements of different l_p normed spaces. We take $\Delta b \in l_{p_B}$ and $\Delta a \in l_{p_A}$ where $p_A, p_B \in [1, \infty)$. We then have, by a simple extension of (5) that

$$\|\Delta v\|_{\infty} \leq \|f\|_{p_A} \|\Delta a\|_{q_A} + \|g\|_{p_B} \|\Delta b\|_{q_B}$$

for all $p_A, q_A, p_B, q_B \in [1, \infty)$ satisfying $1/p_A + 1/q_A = 1$ and $1/p_B + 1/q_B = 1$.

Here, for convenience of notation, f is the coefficient vector of $(1 - z^{-1})F(z)$.

A sufficient condition for stability of the perturbed system is that

$$\|f\|_{p_A} \|\Delta a\|_{q_A} + \|g\|_{p_B} \|\Delta b\|_{q_B} < 1 \quad (17)$$

for some $p_A, q_A, p_B, q_B \in [1, \infty)$ satisfying $1/p_A + 1/q_A = 1$ and $1/p_B + 1/q_B = 1$.

The design approach then is to make $\|g\|_1$ and $\|f\|_1$ small in order to reduce the "gain" from each perturbation to Δv .

We cannot minimize both $\|g\|_1$ and $\|f\|_1$ independently with respect to $X(z)$ since the same value of $X(z)$ must be incorporated in both $G(z)$ and $F(z)$ as in (2) and (3). To design a compensator

to reduce the "gain" from each perturbation to Δv , we need to share the minimization effort between reducing $\|g\|_1$ and $\|f\|_1$.

There are a number of ways of doing this. One way is to formulate the compensator design as the minimization of a weighted sum of $\|f\|_1$ and $\|g\|_1$ with respect to $X(z)$ subject to the set of linear equality constraints obtained by equating like powers of z in

$$A^0(z)(1 - z^{-1})F^0(z) + B^0(z)G^0(z) = V^0(z). \quad (18)$$

Another way is to specify a numerical upper bound for either $\|g\|_1$ or $\|f\|_1$ (of course the value specified must be large enough to be achievable) and then to formulate the design as the minimization of an l_p norm of the other coefficient vector, subject to the constraints (18) and to that on the specified value of the norm of the first coefficient vector.

If only l_1 and l_{∞} norms are used in the previously mentioned schemes, the optimizations are linear programs.

By whatever means the minimization effort is apportioned, the perturbed system will be stable if (17) holds.

If either of the perturbations is of high order, it will reduce γ thereby reducing the maximum allowable value of the other perturbation.

IV. REMARK

In this paper we have calculated allowable bounds on the l_p norms of plant parameter perturbations such that $\|\Delta v\|_{\infty} < \gamma$ where γ has been chosen to guarantee stability. We could have selected a smaller value of γ sufficient to ensure that the perturbed closed-loop poles do not cross chosen regions surrounding the nominal closed loop poles. The approach could then be considered as design for robust pole assignment. Of course reducing the value of γ reduces allowable bounds on plant perturbations.

V. CONCLUSION

We have presented a framework which uses convex optimization to design overparameterized pole assignment compensators with guaranteed stability against l_p norm bounded plant parameter perturbations. The framework is flexible and a number of design problems may be formulated within it, depending on the nature of the parametric perturbations.

The Carathéodory–Fejér Problem and $\mathcal{H}_\infty/\ell_1$ Identification: A Time Domain Approach

Jie Chen and Carl N. Nett

Abstract—In this paper we study a worse-case, robust control oriented identification problem. This problem is in the framework of \mathcal{H}_∞ identification but the formulation here is more general. The available *a priori* information in our problem consists of a lower bound on the relative stability of the plant, an upper bound on a certain gain associated with the plant, and an upper bound on the noise level. The plant to be identified is assumed to lie in a certain subset in the space of \mathcal{H}_∞ , characterized by the assumed *a priori* information. The available experimental information consists of a corrupt finite output time series obtained in response to a known nonzero but otherwise arbitrary input. Our objective is to identify from the given *a priori* and experimental information an uncertain model which consists of a nominal model in \mathcal{H}_∞ and a bound on the modeling error measured in \mathcal{H}_∞ norm. We present both an identification algorithm and several explicit lower and upper bounds on the identification error. The proposed algorithm is in the class of interpolatory algorithms which are known to possess desirable optimality properties in reducing the identification error. This algorithm is obtained by solving an extended Carathéodory–Fejér problem via standard convex programming methods. Both the algorithm and error bounds can be applied to ℓ_1 identification problems as well.

I. INTRODUCTION

Recently, there has been a considerable amount of interest in system identification from a worst-case robust control oriented approach (see, e.g., [14], [34] and the references therein). A specific example is the \mathcal{H}_∞ identification problem initiated in [14]. In this problem, one typically needs to apply a sequence of complex sinusoidal inputs to estimate a sequence of point frequency samples of the plant transfer function, and one then seeks to identify, from the estimated frequency samples and certain assumed *a priori* information, an uncertain model. This problem has been studied extensively (cf. [14], [11], [12], [26], [27], [2], [21], [6]), and much of the research has been focused on identifying from a given sequence of corrupted point frequency samples a model consistent with \mathcal{H}_∞ control design.

Another problem that is closely related to that of the \mathcal{H}_∞ identification is more concerned with the task of identifying an uncertain model compatible with the ℓ_1 design methodology. This problem has been generally referred to as identification in ℓ_1 and has been studied in, e.g., [5], [16], [17], [20], [7], [32], [29]. In this problem, one typically assumes certain prior knowledge of the plant impulse response, and the identification procedure then proceeds with a sequence of time domain data.

In the present paper, we consider a variant to the \mathcal{H}_∞ and ℓ_1 identification problems alluded to above. This problem is formulated in such a way that the assumed plant *a priori* information is identical to that in the framework of [14], while the assumed experimental information is more similar to those utilized in [5], [16], [20]. Our objective is to identify an uncertain model in \mathcal{H}_∞ which includes a nominal model in \mathcal{H}_∞ and a bound on the modeling error measured in \mathcal{H}_∞ norm. As such, this problem may be considered as a hybrid of the \mathcal{H}_∞ and ℓ_1 identification problems or merely a more general formulation of \mathcal{H}_∞ identification problems. We shall present both an interpolatory identification algorithm [31], [5], [6] and several explicit lower and upper bounds on identification error for this problem. Though our results are derived in the \mathcal{H}_∞ framework, they can be applied equally well to ℓ_1 identification problems.

The main difference between our approach and that initiated in [14] lies in that the identification here is conducted entirely in time domain. This has a number of implications. First, unlike in [14], there is no need in the present approach to transform the time response data to frequency samples. A more important merit with this approach is that the proposed interpolatory algorithm has a guaranteed optimality property for the overall identification problem. In contrast, the previously known interpolatory algorithms [6], [13] in the framework of [14] are suboptimal with respect to only the step of identification from point frequency samples; the overall optimality properties, however, are lost due to the transformation from the time response data to the frequency samples. Moreover, the main difference between this work and that of ℓ_1 identification [5], [16], [20], [32] lies in the assumed plant *a priori* information. Unlike that in ℓ_1 identification, the plant *a priori* information in this approach is assumed for the plant transfer function. Though it is possible to transform this *a priori* information to one on the plant impulse response (e.g., via Cauchy estimates) and hence to apply the ℓ_1 identification approach, the transformation will necessarily lead to undesirable conservatism and thus result in a loss of optimality properties. From these perspectives, it appears that the algorithm presented in this paper is the first algorithm with a guaranteed optimality property for the problem of \mathcal{H}_∞ identification. Finally, though our technique in deriving the algorithm is very similar to that of [28] (see also [33]), the two problems are clearly different in that the goal in this paper is to identify an uncertain model from certain given *a priori* information and experimental data, while the problem in [28] amounts to verifying the consistency of a given uncertain model to data.

A preliminary version of this paper has appeared previously as [4].

A. Organization

In Section II, we formulate the problem and provide a brief review on relevant notions in information-based complexity (IBC) [31]. In Section III, we present our identification algorithm. This algorithm relies on the solution of a related problem termed the consistency between the data and *a priori* information, which is concerned with the issue of validating the assumed *a priori* information and is reduced to a convex optimization problem. The construction of the algorithm together with the consistency problem amounts to solving an extended Carathéodory–Fejér [18] interpolation problem. Finally, explicit lower and upper bounds on the identification error are derived in Section IV, and the convergence properties of the proposed identification algorithm are established. The paper is concluded in Section V.

B. Notation

We shall use the following notations throughout this paper. Let \mathbf{Z} denote the set of integers, $\mathbf{Z}_+ := \{k \in \mathbf{Z} : k \geq 0\}$, and $\mathbf{Z}_{+,n} := \{k \in \mathbf{Z}_+ : k < n\}$. Let \mathbf{R} denote the set of real numbers, and \mathbf{R}^n the space of n dimensional real vectors. Moreover, let $\mathbf{R}_+ := \{x \in \mathbf{R} : x \geq 0\}$. The symbol $\bar{\sigma}(A)$ denotes the largest singular value of the matrix $A \in \mathbf{R}^{n \times n}$, and if A is a symmetric matrix, $\bar{\lambda}(A)$ denotes its largest eigenvalue. The transpose of $A \in \mathbf{R}^{n \times n}$ is denoted by A^T . For any positive $\rho \in \mathbf{R}_+$, let $\mathbf{D}_\rho := \{z \in \mathbf{C} : |z| < \rho\}$ and define the normed space

$$\mathcal{H}_{\infty,\rho} := \left\{ f: \mathbf{D}_\rho \rightarrow \mathbf{C} \mid f \text{ analytic in } \mathbf{D}_\rho \text{ and } \|f\|_{\infty,\rho} := \sup_{z \in \mathbf{D}_\rho} |f(z)| < \infty \right\}.$$

Furthermore, when $\rho = 1$, we shall replace \mathbf{D}_1 by \mathbf{D} , and $\mathcal{H}_{\infty,1}$ by \mathcal{H}_∞ , and so on. Note that the union of $\mathcal{H}_{\infty,\rho}$ for all $\rho > 1$ constitutes a linear space. We denote this linear space by $\mathcal{H}_+ := \bigcup_{\rho>1} \mathcal{H}_{\infty,\rho} \subset \mathcal{H}_\infty$. Recall also the normed spaces ℓ_∞ and ℓ_1 (see, e.g., [8]). We shall use the symbol $\|\cdot\|_\infty$ to denote the norm associated with each of the spaces ℓ_∞ and \mathcal{H}_∞ ; however, each of these uses should be clear from context. For each of the normed spaces $(X, \|\cdot\|_X)$ given above, we shall define $\bar{B}X(M) := \{x \in X : \|x\|_X \leq M\}$. Finally, for each $n \in \mathbf{Z}_+, n \geq 1$, we define a projection operator by $P_n: \ell_\infty \rightarrow \mathbf{C}^n$ such that $(P_n f)_k := f_k$ for all $k \in \mathbf{Z}_{+,n}$. Furthermore, we define the operator $T: \mathbf{C}^n \rightarrow \mathbf{C}^{n \times n}$ by

$$T(c_0, \dots, c_{n-1}) = \begin{bmatrix} c_0 & 0 & \cdots & 0 \\ & c_1 & c_0 & \cdots & 0 \\ & & c_{n-1} & c_{n-2} & \cdots & c_0 \end{bmatrix}$$

where $c := [c_0 \ \cdots \ c_{n-1}] \in \mathbf{R}^n$. Often, to simplify the notation, for a vector denoted by a lowercase letter, we shall use its capital version to denote the corresponding lower triangular Toeplitz matrix generated by T , i.e., $C := T(c_0, \dots, c_{n-1})$.

II. PROBLEM STATEMENT AND PRELIMINARY BACKGROUND

We consider the class of causal, linear, shift-invariant, exponentially stable, distributed parameter systems. This class of systems is identified with the linear space \mathcal{H}_+ . The plant to be identified is represented by an $h \in \mathcal{H}_+$ which is the standard z -Transform of the plant impulse response evaluated at $1/z$:

$$h(z) := \sum h_k z^k. \quad (2.1)$$

The plant *a priori* information consists of two positive constants $M > 0$ and $\rho > 1$, and the system to be identified is assumed to be an element of $\bar{B}\mathcal{H}_{\infty,\rho}(M)$. Note that the plant set $\bar{B}\mathcal{H}_{\infty,\rho}(M)$ is precisely the same as that considered in [14], [11], [12], [26], and [6], and interpretations on M and ρ may be found in [14].

The experimental procedure considered herein is similar to those in [16], [20], [5]. Specifically, the experimental data is obtained by applying an arbitrary nonzero input $u \in \ell_\infty$ to the plant $h \in \bar{B}\mathcal{H}_{\infty,\rho}(M)$, which generates an output $h * u$ as the convolution product of h and u . The output measurement is assumed to be corrupted by an additive bounded noise v , and the corrupted output is observed over a finite duration n . This experiment can be precisely described using the experiment operator

$$E_n(h, v) := P_n((h * u) + v)$$

where $v \in \bar{B}\ell_\infty(\epsilon)$, and $\epsilon > 0$ is a prescribed bound, and it represents the full *a priori* information on the output noise. Denote

$U := T(u_0, \dots, u_{n-1})$. Then, each data record $y \in \mathbf{R}^n$, where $y_k := (E_n(h, v))_k$, can be expressed as $y = U P_n h + P_n v$. The set of all possible data which may be generated from the experiment is

$$\mathcal{Y} := \{y \in \mathbf{R}^n : y = U P_n h + P_n v \text{ for some } (h, v) \in \bar{B}\mathcal{H}_{\infty,\rho}(M) \times \bar{B}\ell_\infty(\epsilon)\}.$$

For each $y \in \mathcal{Y}$, we define the set of indistinguishable systems (cf. [31], [22], [6]) by

$$\mathcal{P}(y) := \{h \in \bar{B}\mathcal{H}_{\infty,\rho}(M) : y = U P_n h + P_n v \text{ for some } v \in \bar{B}\ell_\infty(\epsilon)\}.$$

Given the above *a priori* and experimental information, our primary goal in this paper is to develop an uncertain model that is consistent with the \mathcal{H}_∞ design framework. This goal will be achieved by constructing an identification algorithm and by quantifying a corresponding identification error. An identification algorithm is a mapping¹ $A_n: \mathbf{R}^n \rightarrow \mathcal{H}_+$ which operates on the data record and produces an element $A_n(y) \in \mathcal{H}_+$. The local and global identification errors associated with an algorithm A_n are defined, as usual (cf. [31], [6]), by

$$e(A_n; \rho, M, \epsilon; y) := \sup_{h \in \mathcal{P}(y)} \|h - A_n(y)\|_\infty$$

and

$$c(A_n; \rho, M, \epsilon) := \sup_{y \in \mathcal{Y}} e(A_n; \rho, M, \epsilon; y)$$

respectively. Note that the global error provides a universal bound on the modeling error regardless of data records. Additionally, as in [14], [11], [12], [26], it will be used to define convergence property of identification algorithms. An Algorithm A_n is said to be convergent if it satisfies the property

$$\lim_{\substack{n \rightarrow \infty \\ \epsilon \rightarrow 0}} c(A_n; \rho, M, \epsilon) = 0.$$

We shall be particularly interested in a class of algorithms which are termed interpolatory algorithms (cf. [31], [23], [5], [6]). An algorithm A_n is said to be interpolatory if for any $y \in \mathcal{Y}$, $A_n(y) \in \mathcal{P}(y)$. Algorithms of interpolatory class are known to possess many desirable properties, among which is its optimality properties in reducing the identification error. To precisely state these properties, we introduce the concepts of the radius and diameter [31] for the set $\mathcal{P}(y)$, defined by

$$r(\mathcal{P}(y)) := \inf_{h \in \mathcal{H}_+} \sup_{p \in \mathcal{P}(y)} \|h - p\|_\infty$$

and

$$d(\mathcal{P}(y)) := \sup_{h, p \in \mathcal{P}(y)} \|h - p\|_\infty$$

respectively. More specifically, the quantities $r(\mathcal{P}(y))$ and $d(\mathcal{P}(y))$ are called local radius and diameter, and their global counterparts are defined by $r^* := \sup_{y \in \mathcal{Y}} r(\mathcal{P}(y))$ and $d^* := \sup_{y \in \mathcal{Y}} d(\mathcal{P}(y))$, respectively. It is well known that the radius $r(\mathcal{P}(y))$ coincides with the minimal possible, or optimal identification error [31], [22], [5], [6]. It is also well known that if $A_n(y) \in \mathcal{P}(y)$, then

$$r(\mathcal{P}(y)) \leq e(A_n; \rho, M, \epsilon; y) \leq d(\mathcal{P}(y)) \leq 2r(\mathcal{P}(y)). \quad (2.2)$$

¹In a broader sense, an identification algorithm acts on the input-output data pair (u, y) . To simplify the notation, we omit the dependence of all the relevant notions (e.g., $\mathcal{P}(y)$, $A_n(y)$, etc.) on the input and the *a priori* information.

In this sense, an interpolatory algorithm is said to be optimal to within a factor of two. Finally, let

$$s^* := \sup_{\substack{h \in \tilde{B}\mathcal{H}_{\infty, \rho}(M) \\ \|U^* P_n h\|_{\infty} \leq \epsilon}} \|h(z)\|_{\infty} = \sup_{h \in P(0)} \|h(z)\|_{\infty}. \quad (2.3)$$

Then, as in [6], [31], it can be shown that the global radius and diameter satisfy the inequalities

$$s^* \leq r^* \leq d^* = 2s^*. \quad (2.4)$$

Note that the above quantity s^* (defined with respect to \mathcal{H}_{∞} norm) constitutes also a lower bound for the global radius even when it is measured in l_1 norm.

III. AN IDENTIFICATION ALGORITHM

A. Consistency of Data and *a priori* Information

In the preceding definition of identification error, we have assumed implicitly that the set $P(y)$ is nonempty; otherwise, the identification error will become unbounded. Whether this assumption holds is concerned with the issue whether the given data record and the assumed *a priori* information are consistent. Precisely, the notion of the consistency between the data and *a priori* information is defined as follows.

Definition 3.1: Given the plant *a priori* information $(\rho, M) \in [1, \infty) \times [0, \infty)$ and the noise *a priori* information $\epsilon \in [0, \infty)$. A data record $y \in \mathbf{R}^n$ is said to be consistent with the plant and noise *a priori* information (ρ, M, ϵ) if $P(y) \neq \emptyset$.

In other words, the consistency between y and (ρ, M, ϵ) is equivalent to the existence of a model-noise pair $(h, v) \in B\mathcal{H}_{\infty, \rho}(M) \times B l_{\infty}(\epsilon)$ such that for this pair the data $y \in \mathbf{R}^n$ may be generated from the experiment $E_n(h, v)$. As such, the consistency problem amounts to establishing the existence of an analytic function $h \in B\mathcal{H}_{\infty, \rho}(M)$ whose first n Taylor coefficients satisfy the relation $y = U^* P_n h + P_n v$ for some $v \in B l_{\infty}(\epsilon)$. This characteristic bears a close resemblance to that of the Carathéodory-Fejér problem (cf. [9], [18]) and thus suggests the following necessary and sufficient condition.

Lemma 3.1: Let $(\rho, M) \in [1, \infty) \times [0, \infty)$ and $\epsilon \in [0, \infty)$. Then, $y \in \mathbf{R}^n$ is consistent with (ρ, M, ϵ) if and only if there exists a $v \in B l_{\infty}(\epsilon)$ such that

$$(Y^* - V^*)(Y^* - V^*)^T \leq M^2 U^* R^{-2} U^T \quad (3.1)$$

where $R := \text{diag}(1/\rho \cdots \rho^{n-1})$.

Proof: Let $f(z) := (1/M)h(z)$. Then, $f \in \tilde{B}\mathcal{H}_{\infty}(1)$ if and only if $h \in \tilde{B}\mathcal{H}_{\infty, \rho}(M)$. Note that for any $z \in \mathbf{D}$, $h(z) = \sum_{k=0}^{\infty} h_k \rho^k z^k$. Hence, $f(z)$ can be expanded as $f(z) = \sum_{k=0}^{\infty} f_k z^k$ with $f_k = (1/M)\rho^k h_k$ for all $k \in \mathbf{Z}_+$. It follows that $P_n f = (1/M)R P_n h$, and that $y = U^* P_n h + P_n v$ if and only if $y = M U^* R^{-1} P_n f + P_n v$. Therefore, $P(y) \neq \emptyset$ if and only if there exists a function $f \in \tilde{B}\mathcal{H}_{\infty}(1)$ such that $y = M U^* R^{-1} P_n f + P_n v$ for some $v \in B l_{\infty}(\epsilon)$. The result then follows from utilizing an extended Carathéodory-Fejér theorem given in [30, p. 26]. \square

Based upon Lemma 3.1, we give below two equivalent necessary and sufficient conditions that can be readily computed. To simplify our presentation, we shall assume, with no loss of generality, that $u_0 \neq 0$. Under this assumption, U is invertible and its inverse is also a lower triangular Toeplitz matrix [5].

Theorem 3.1: Let $(\rho, M) \in [1, \infty) \times [0, \infty)$ and $\epsilon \in [0, \infty)$. Assume also that $u_0 \neq 0$. Then, $y \in \mathbf{R}^n$ is consistent with (ρ, M, ϵ) if and only if

$$\min_{v \in B l_{\infty}(\epsilon)} \bar{\sigma}(R U^{-1}(Y^* - V^*)) \leq M. \quad (3.2)$$

Proof: Since U is invertible, condition (3.1) is equivalent to that

$$(R U^{-1}(Y^* - V^*))(R U^{-1}(Y^* - V^*))^T \leq M^2 I. \quad (3.3)$$

This, however, is equivalent to that $\bar{\sigma}(R U^{-1}(Y^* - V^*)) \leq M$. Hence, the proof is completed. \square

Similar to the results given in [6], [28], Theorem 3.1 shows that the consistency problem can be solved as a convex program. This is clear by noting the fact that the largest singular value $\bar{\sigma}(A)$ is a convex function of A , and that the matrix $R U^{-1}(Y^* - V^*)$ is an affine function of $v_k, k \in \mathbf{Z}_{n+}$. As in [6], it is easy to derive necessary or sufficient conditions from this result.

Theorem 3.2: Let $(\rho, M) \in [1, \infty) \times [0, \infty)$ and $\epsilon \in [0, \infty)$. Furthermore, denote

$$A(v) := \begin{bmatrix} -M^2 U^* R^{-2} U^T & -(Y^* - V^*) \\ -(Y^* - V^*)^T & -I \end{bmatrix}.$$

Then, $y \in \mathbf{R}^n$ is consistent with (ρ, M, ϵ) if and only if

$$\min_{v \in B l_{\infty}(\epsilon)} \lambda(A(v)) \leq 0. \quad (3.4)$$

Proof: By Lemma 3.1 and a well-known fact concerning the Schur complement (see, e.g., [15]), we assert that (3.1) is equivalent to the condition

$$\begin{bmatrix} M^2 U^* R^{-2} U^T & (Y^* - V^*) \\ (Y^* - V^*)^T & I \end{bmatrix} > 0.$$

The latter condition, however, is equivalent to that $\lambda(A(v)) \leq 0$. Hence, the proof is completed. \square

Minimization problem (3.4) can also be solved as a convex program. This follows from the fact that the largest eigenvalue $\lambda(A)$ of a symmetric matrix A is a convex function of A (see, e.g., [15]), and that the matrix $A(v)$ is an affine function of $v_k, k \in \mathbf{Z}_{n+}$. Each of problems (3.2) and (3.4) belongs to the class of constrained nondifferentiable convex programs. Numerically, problem (3.4) is more amenable to implementation, as it possesses the standard form for this class of problems, for which the techniques developed in e.g., [3], [25] can be directly applied. Note also that in this result, the assumption $u_0 \neq 0$ is dropped.

Finally, as in [5], [6], we comment on the problems of computing the minimal *a priori* information levels that are required for the *a priori* information and data record to be consistent. The utility of these minimal information levels lies in that they help build up one's confidence in the assumed *a priori* information, particularly when the computed levels are significantly lower than those assumed. Toward this end, one problem is compute, given ρ and ϵ

$$M^* := \min\{M: P(y) \neq \emptyset\}. \quad (3.5)$$

Clearly, as a by-product of the data consistency problem, M^* is solved as

$$M^* = \min_{v \in B l_{\infty}(\epsilon)} \bar{\sigma}(R U^{-1}(Y^* - V^*)).$$

Another problem is to compute, given M and ρ

$$\epsilon^* = \min\{\epsilon: P(y) \neq \emptyset\}. \quad (3.6)$$

This quantity may be computed by solving a convex program analogous to (3.4)

$$\epsilon^* = \min\{\epsilon: A(v) \leq 0, \quad |v_k| \leq \epsilon, \quad k \in \mathbf{Z}_{n+}\}.$$

Alternatively, it can be solved by computing $\epsilon^* = \min\{\epsilon: f(\epsilon) \leq M\}$; where $f(\cdot): \mathbf{R}_+ \rightarrow \mathbf{R}_+$ is defined by

$$f(\epsilon) := \min_{v \in B l_{\infty}(\epsilon)} \bar{\sigma}(R U^{-1}(Y^* - V^*)).$$

As in [6], it can be readily shown that $f(\cdot)$ is continuous and nonincreasing. Hence, ϵ^* may be computed easily by using, e.g., the bisection method, given the fact that $f(\epsilon)$ may be solved for each $\epsilon \in \mathbf{R}_+$. Finally, it is also of interest to compute, given M and ϵ

$$\rho^* := \max\{\rho: \mathcal{P}(y) \neq \emptyset\} \quad (3.7)$$

which can be solved by computing $\rho^* = \max\{\rho: g(\rho) \leq M\}$, where $g(\cdot): [1, \infty) \rightarrow \mathbf{R}_+$ is defined by

$$g(\rho) := \max_{v \in H(\infty, \epsilon)} \bar{\sigma}(R U^{-1}(Y - V)).$$

Clearly, $g(\cdot)$ is continuous. It is also easy to show that $g(\cdot)$ is nondecreasing. Indeed, let $\rho_1 \leq \rho_2$, and denote $R_1 := \text{diag}(1/\rho_1 \cdots 1/\rho_1^{n-1})$ and $R_2 := \text{diag}(1/\rho_2 \cdots 1/\rho_2^{n-1})$. Then, for any $v \in \bar{B}(\infty, \epsilon)$

$$\begin{aligned} \bar{\sigma}(R_1 U^{-1}(Y - V)) &= \bar{\sigma}(R_1 R_2^{-1} R_2 U^{-1}(Y - V)) \\ &\leq \bar{\sigma}(R_1 R_2^{-1}) \bar{\sigma}(R_2 U^{-1}(Y - V)) \\ &= \bar{\sigma}(R_2 U^{-1}(Y - V)). \end{aligned}$$

This implies that $g(\rho_1) \leq g(\rho_2)$. Since $g(\cdot)$ is continuous and nondecreasing, problem (3.7) may be solved by using the bisection method as well.

B. An Interpolatory Algorithm

As an immediate consequence, the solution of the data consistency problem yields as a by-product an interpolatory algorithm. Indeed, once the consistency problem is solved, we may construct immediately an "interpolating" function $h \in B\mathcal{H}_{\infty, \rho}(M)$ using the Schur algorithm [9] or a procedure of [1] (see also [18]), such that its first n Taylor coefficients satisfy the relation $y = U P_n h + P_n v^*$ with v^* being the solution of the consistency problem. Clearly, such an interpolating function lies in the set $\mathcal{P}(y)$, and it can be constructed using the following interpolatory algorithm.

Algorithm 3.1

- **Step 1:** Solve minimization problem (3.4). Let the minimizer be denoted by

and the minimum be denoted by λ^* . Accordingly, write $V^* := T(v_0^*, \dots, v_{n-1}^*)$. If $\lambda^* > 0$, stop. The data and *a priori* information are not consistent. Otherwise go to Step 2.

- **Step 2:** Compute the matrix $H^* := (1/M) R U^{-1}(Y - V^*)$. If $\lambda^* < 0$, go to Step 3a. Otherwise compute the rank of $I - H^* H^{*T}$ and go to Step 3b.
- **Step 3a:** Compute the polynomials

$$\begin{aligned} p(z) &:= \begin{bmatrix} 0 & 0 & 1 \end{bmatrix} T(1, \dots, z^{n-1}) (I - H^* H^{*T})^{-1} \\ &\quad \begin{bmatrix} 0 \\ 1 \end{bmatrix} \\ &\quad \vdots \\ &\quad 0 \\ &\quad 1 \end{aligned} \quad (3.8) \end{aligned}$$

$$\begin{aligned} q(z) &:= \begin{bmatrix} 0 & 0 & 1 \end{bmatrix} T(p_{n-1}(z), \dots, p_0(z)) \\ &\quad \begin{bmatrix} 0 \\ 1 \end{bmatrix} \\ &\quad \times (I - H^* H^{*T})^{-1} \end{aligned} \quad (3.9)$$

where $p_k(z) := \sum_{i=0}^k h_i z^{k-i}$ for all $k \in \mathbf{Z}_{+,n}$, and $P_n h^* := U^{-1}(y - P_n v^*)$. The proposed algorithm A_n is given by

$$A_n(y)(z) := M \frac{(\frac{z}{\rho})^n p(\frac{z}{\rho})c + (\frac{z}{\rho})^{n-1} q(\frac{z}{\rho})}{(\frac{z}{\rho})^n q(\frac{z}{\rho})c + p(\frac{z}{\rho})}$$

where $|c| \leq 1$ is an arbitrary real constant.

Step 3b: Let $\text{rank}(I - H^* H^{*T}) = m$. Also, let I be the $(m+1) \times (m+1)$ identity matrix and

$$H := [I \ 0] H^* \begin{bmatrix} I \\ 0 \end{bmatrix}.$$

Solve a vector $c^T = [c_0 \cdots c_m]$ from the equation $(I - H H^T)c = 0$. The proposed algorithm A_n is given by

$$A_n(y)(z) := M \frac{c_0 \rho^m + c_1 \rho^{m-1} z + \cdots + c_m z^m}{c_m \rho^m + c_{m-1} \rho^{m-1} z + \cdots + c_0 z^m}.$$

The above algorithm, as those developed in [6], consists of two parts which solve a consistency problem first and a standard Carathéodory–Fejér problem subsequently. The key to the algorithm is clearly Step 1, which determines whether the measured data and the assumed *a priori* information are consistent. When $\lambda^* > 0$, the consistency problem admits no solution and the algorithm stops. When $\lambda^* \leq 0$, the data and *a priori* information are consistent and the algorithm proceeds to find an interpolating function $f \in \bar{B}\mathcal{H}_{\infty}(1)$. This function is found in either Step 3a or Step 3b and is then transformed to an interpolating function $h \in \bar{B}\mathcal{H}_{\infty, \rho}(M)$ via the transformation $h(z) := M f(z/\rho)$. When $\lambda^* = 0$, the interpolating function is unique [18] and is found in Step 3b. The algorithm produces a real rational transfer function with an order of m . When $\lambda^* < 0$, the interpolating function is nonunique [18] and can be parameterized by an analytic function in $B\mathcal{H}_{\infty}(1)$. Step 3a gives one specific choice of such functions by selecting the free parameter as a real constant c , which yields a real rational transfer function with an order of n . The construction in Step 3a and Step 3b follows from a modified procedure based on [1]. Note that the algorithm may be numerically ill-conditioned when $I - H^* H^{*T}$ is nearly singular. This, however, should not pose a serious problem for a well-conditioned algorithm may be obtained by resorting to an alternative procedure given in [1].

IV. BOUNDS ON IDENTIFICATION ERROR

In this section we provide several explicit lower and upper bounds for the identification error associated with the interpolatory algorithm proposed above. These bounds are derived for the global radius and diameter of the set $\mathcal{P}(y)$; therefore, they are applicable to any interpolatory algorithms. Our first result is a lower bound upon the global radius of $\mathcal{P}(y)$. As noted at the close of Section II, this result also serves as a lower bound for the corresponding ℓ_1 identification problem.

Theorem 4.1 Let $\|P_n u\|_{\infty} \neq 0$. Then

$$r^* \geq \min \left\{ M, \frac{\epsilon}{\|P_n u\|_{\infty}} \right\}. \quad (4.1)$$

Furthermore, if $\epsilon/\|P_n u\|_{\infty} < M$, then

$$> \frac{(M/\rho^n) + (\epsilon/\|P_n u\|_{\infty})}{1 + (1/M\rho^n)(\epsilon/\|P_n u\|_{\infty})}. \quad (4.2)$$

Proof: To establish Part i), consider the function

$$h(z) := \min \left\{ M, \frac{\epsilon}{\|P_n u\|_{\infty}} \right\}.$$

Clearly, $h \in B\mathcal{H}_{\infty, \rho}(M)$. Note also that $\|U P_n h\|_{\infty} \leq \max_{k \in \mathbf{Z}_{+,n}} (|u_k|/\|P_n u\|_{\infty}) \epsilon = \epsilon$. Hence $h \in \mathcal{P}(0)$. The result then follows by using (2.4). Suppose now that $(\epsilon/\|P_n u\|_{\infty}) < M$ and consider the function

$$h(z) := M \frac{(z^n/\rho^n) + (\epsilon/\|P_n u\|_{\infty})(1/M)}{1 + (z^n/\rho^n)(\epsilon/\|P_n u\|_{\infty})(1/M)}.$$

Since $(\epsilon/\|P_n u\|_{\infty}) < M$, h is analytic in \mathbf{D}_{ρ} . Furthermore, we have $|h(z)| \leq M$ for any $z \in \mathbf{D}_{\rho}$. The latter assertion follows from the

well-known fact that for any $a, b \in \mathbf{D}$ the inequality (see, e.g., [10, p. 4])

$$\frac{a-b}{1-ba} \leq \frac{|a|+|b|}{1+|a| \cdot |b|} \leq 1. \quad (4.3)$$

holds. As a result, $h \in \bar{B}\mathcal{H}_{\infty, \rho}(M)$. Note now that h can be expanded in Taylor series as

$$h(z) = \frac{\epsilon}{\|P_n u\|_{\infty}} + M \left(1 - \left(\frac{\epsilon}{M\|P_n u\|_{\infty}} \right)^2 \right) \frac{z^n}{\rho^n} - \dots$$

It follows that $\|U P_n h\|_{\infty} = \max_{k \in \mathbf{Z}_{+,n}} (|u_k|/\|P_n u\|_{\infty})\epsilon = \epsilon$. Hence again, $h \in \mathcal{P}(0)$. To complete the proof, we claim that

$$= \frac{(M/\rho^n) + (\epsilon/\|P_n u\|_{\infty})}{1 + (1/\rho^n)(\epsilon/\|P_n u\|_{\infty})(1/M)}.$$

Indeed, according to (4.3), we have

$$\|h(z)\|_{\infty} \leq \frac{(M/\rho^n) + (\epsilon/\|P_n u\|_{\infty})}{1 + (1/\rho^n)(\epsilon/\|P_n u\|_{\infty})(1/M)}.$$

The upper bound, however, is attained at $z = 1$. The proof for Part ii) is now completed by using (2.4). \square

The significance of the lower bound (4.1) lies in that it provides an irreducible level of identification error in terms of the quantity $\epsilon/\|P_n u\|_{\infty}$, which, as in [14], may be interpreted as a noise-to-signal ratio. The lower bound (4.2) provides an estimate tighter than (4.1) when $(\epsilon/\|P_n u\|_{\infty}) < M$. Note that in the noise free case ($\epsilon = 0$), this lower bound reduces to $r^* \geq M/\rho^n$, which together with a result of [24] yields

$$\frac{M}{\rho^n} \leq r^* \leq d^* \leq \frac{2M}{\rho^n}.$$

This inequality and (4.2) suggest that the global identification error will be inherently large when M is large and ρ is close to one.

We now present an upper bound for the global diameter of the set $\mathcal{P}(y)$. As in [14], [6], this bound is also useful for establishing the convergence property of Algorithm 3.1 in \mathcal{H}_{∞} . Furthermore, it shows that the algorithm is convergent in ℓ_1 , and when combined with the error bound, it leads to an uncertain model consistent with ℓ_1 design as well. We shall assume that $u_0 \neq 0$. Hence, we may write $W := T(u_0, \dots, w_{n-1}) = U^{-1}$. Note that the vector $w := [w_0 \dots w_{n-1}]^T$ can be calculated explicitly from U^{-1} .

Theorem 4.2: Assume that $u_0 \neq 0$. Let $l \in \mathbf{Z}_+$ be the largest integer k such that

$$\sum_{i=0}^l |w_i| \leq \frac{M}{\rho^l}. \quad (4.4)$$

Denote further that $l^* := \min\{l, n\}$. Then

$$d^* \leq 2 \left(\epsilon \sum_{k=0}^{l^*} (l^* + 1 - k) |w_k| + \frac{M}{\rho^{l^*-1}(\rho - 1)} \right). \quad (4.5)$$

In addition, any interpolatory algorithm is convergent.

Proof: For any $h \in \mathcal{P}(0)$, it can be expressed as $h = \sum_{k=0}^{\infty} h_k z^k$, where h_k satisfies the condition $U P_n h = P_n v$ for some $v \in \bar{B}\ell_{\infty}(\epsilon)$. It follows that $h_k = \sum_{i=0}^{\infty} w_{k-i} v_i$ for all $k \in \mathbf{Z}_{+,n}$. Additionally, by Cauchy's estimates (see, e.g., [19], p. 137), we have $|h_k| \leq M/\rho^k$ for all $k \in \mathbf{Z}_+$, since $h \in \bar{B}\mathcal{H}_{\infty, \rho}(M)$. Therefore,

it follows that

$$\begin{aligned} & \sup_{n \in \mathcal{P}(0)} \|h(z)\|_1 \\ &= \max \left\{ \|h\|_1; P_n h = U^{-1} P_n v, \right. \\ & \quad \left. |h_k| \leq M/\rho^k, k \in \mathbf{Z}_+, v \in \bar{B}\ell_{\infty}(\epsilon) \right\} \\ &= \max \left\{ \|W^* P_n v\|_1, \sum_{k=0}^l w_{k-i} v_i \leq \frac{M}{\rho^k}, \right. \\ & \quad \left. k \in \mathbf{Z}_{+,n}, v \in \bar{B}\ell_{\infty}(\epsilon) \right\} + \sum_{k=n}^{\infty} \frac{M}{\rho^k} \\ &\leq \sum_{k=0}^{n-1} \min \left\{ \epsilon \sum_{i=0}^k |w_i|, \frac{M}{\rho^k} \right\} + \sum_{k=n}^{\infty} \frac{M}{\rho^k} \\ &= \epsilon \sum \sum |w_i| + \sum_{k=l^*+1}^{\infty} \frac{M}{\rho^k} \\ &= \epsilon \sum_{k=0}^{l^*} (l^* + 1 - k) |w_k| + \frac{M}{\rho^{l^*}(\rho - 1)}. \end{aligned}$$

By a well-known fact [8], however, $\|h\|_{\infty} \leq \|h\|_1$. Consequently, the upper bound (4.5) may be established by using (2.4). To verify the convergence property of interpolatory algorithms, we show that $d^* \rightarrow 0$ as $n \rightarrow \infty$ and $\epsilon \rightarrow 0$. Indeed, it follows from the above proof that

$$\begin{aligned} d^* &\leq 2 \left(\sum_{k=0}^{n-1} \min \left\{ \epsilon \sum_{i=0}^k |w_i|, \frac{M}{\rho^k} \right\} + \sum_{k=n}^{\infty} \frac{M}{\rho^k} \right) \\ &\leq 2 \left(l^* \frac{M}{\rho^{l^*}} + \frac{M}{\rho^{l^*}(\rho - 1)} \right) \end{aligned}$$

where the last upper bound converges to zero when $l^* \rightarrow \infty$. Since $l^* = \min\{l, n\}$, and since $\epsilon \sum_{i=0}^{l^*} |w_i| > M/\rho^{l^*+1}$, it follows that $l^* \rightarrow \infty$ as $n \rightarrow \infty$ and $\epsilon \rightarrow 0$. Therefore, $d^* \rightarrow 0$ as $n \rightarrow \infty$ and $\epsilon \rightarrow 0$. This completes our proof. \square

In the remainder of this section we present an additional upper bound for the global diameter d^* . This result may be combined with Theorem 4.2 to yield an improved estimate of the global identification error in the \mathcal{H}_{∞} (but not in ℓ_1) case. Note that if $u_0 \neq 0$ and $\epsilon/|u_0| \geq M$, then d^* can always be bounded by $d^* \leq 2M \leq 2(\epsilon/|u_0|)$. This follows by examining the quantity s^* defined by (2.3), and by noting the fact that $s^* \leq \sup_{h \in \mathcal{H}_{\infty, \rho}(M)} \|h\|_{\infty} = M$. Hence, it suffices to consider the case $\epsilon/|u_0| < M$. The following lemma, given in [6], is useful in our derivation.

Lemma 4.1: Let $f: [0, 1] \times [0, 1] \rightarrow \mathbf{R}_+$ be defined by

$$f(x, y) := \frac{x+y}{1+xy}.$$

Then, $f(x, y)$ is monotonically increasing with respect to both x and y .

Theorem 4.3: Assume that $u_0 \neq 0$ and $\epsilon/|u_0| < M$. Then

$$d^* \leq 2 \frac{(\epsilon/|u_0|) + M(\gamma/\rho)}{1 + (\epsilon/M|u_0|)(\gamma/\rho)} \quad (4.6)$$

where

$$\gamma := \sum_{k=0}^{n-2} \min \left\{ \alpha_k, \frac{1}{\rho^k} \right\} + \frac{1}{\rho^{n-2}(\rho - 1)}$$

and for $k \in \mathbf{Z}_{+,n-1}$, α_k can be computed iteratively as

$$\alpha_k := \epsilon \frac{\rho M \sum_{i=0}^{k+1} |w_i| + (\epsilon/|u_0|) \sum_{i=1}^k \alpha_{k-i} \sum_{j=1}^i |w_j|}{M^2 - (\epsilon/|u_0|)^2}.$$

Proof Consider any $h \in \mathcal{P}(0)$. Then, $h \in \bar{\mathcal{B}}\mathcal{H}_{\infty, \rho}(M)$ and it satisfies the condition $h_k = \sum_{i=0}^k u_{k-i} \rho^i$, $k \in \mathbb{Z}_{+, n}$ for some $\rho \in \bar{\mathcal{B}}\mathcal{H}_{\infty}(\epsilon)$. Let f be defined by $f(\cdot) = (1/M)h(\rho\cdot)$. It follows that $f \in \bar{\mathcal{B}}\mathcal{H}_{\infty}(1)$ and $f_k = (1/M)\rho^k h_k$ for $k \in \mathbb{Z}_{+, n}$. Since h interpolates h_k , $k \in \mathbb{Z}_{+, n}$ in $\bar{\mathcal{B}}\mathcal{H}_{\infty, \rho}(M)$, f interpolates f_k , $k \in \mathbb{Z}_{+, n}$ in $\bar{\mathcal{B}}\mathcal{H}_{\infty}(1)$. Furthermore, since $\epsilon/|u_0| < M$, we have $|f_0| = (1/M)|h_0| = (1/M)|u_0 \rho^0| = (1/M)|u_0|/\rho \leq \epsilon/(M|u_0|) < 1$. Therefore, by Schur's algorithm (see, e.g., [9]), f may be expressed as

$$f(\cdot) = \frac{f_0 + \rho g(\cdot)}{1 + f_0 \rho g(\cdot)}$$

where $g \in \bar{\mathcal{B}}\mathcal{H}_{\infty}(1)$ satisfies the condition

$$g_k = \frac{f_{k+1} + f_0 \sum_{i=1}^k g_{k-i}}{1 - |f_0|^2}, \quad k \in \mathbb{Z}_+$$

By inequality (4.3) it follows that for any $z \in \mathcal{D}$ $|f(\cdot)| \leq (|f_0| + |\rho g(\cdot)|)/(1 + |f_0 \rho g(\cdot)|)$. This implies that for any $\cdot \in \mathcal{D}_\rho$

$$|h(\cdot)| = M|f(\cdot/\rho)| \leq M \frac{|f_0| + |\rho g(\cdot/\rho)|}{1 + |f_0| |\rho g(\cdot/\rho)|}$$

Therefore, by Lemma 4.1, we have

$$\begin{aligned} \gamma^* &= \sup_{f \in \mathcal{P}(0)} \|h(\cdot)\|_{\infty} \\ &\leq M \frac{(\epsilon/|Mu_0|) + (1/\rho) \sup_{g \in \Omega} \|g(\cdot)\|_{\infty}}{1 + (\epsilon/|Mu_0|)(1/\rho) \sup_{g \in \Omega} \|g(\cdot)\|_{\infty}} \end{aligned}$$

where $g(\cdot) = g(\cdot/\rho) \in \bar{\mathcal{B}}\mathcal{H}_{\infty, \rho}(1)$ and $\Omega = \{g \in \bar{\mathcal{B}}\mathcal{H}_{\infty, \rho}(1) : g_k = q_k/\rho^k, k \in \mathbb{Z}_{+, n-1}, \rho \in \bar{\mathcal{B}}\mathcal{H}_{\infty}(\epsilon)\}$. As a result, for any $g \in \Omega$, we have

$$\begin{aligned} q_k &= (1/\rho^k) \frac{f_{k+1} + f_0 \sum_{i=1}^k g_{k-i}}{1 - |f_0|^2} \\ &= \frac{\rho M h_{k+1} + h_0 \sum_{i=1}^k q_{k-i}}{M^2 - |h_0|^2} \end{aligned}$$

It is clear that $|q_0| \leq \alpha_0$. Suppose that $|q_i| \leq \alpha_i$ for $i \in \mathbb{Z}_{+, n-1}$. Then, we have

$$\begin{aligned} |q_k| &\leq \epsilon \frac{\rho M \sum_{i=0}^{k+1} |u_i| + (\epsilon/|u_0|) \sum_{i=1}^k |q_{k-i}| \sum_{j=1}^k |u_j|}{M^2 - (\epsilon/|u_0|)^2} \\ &\leq \epsilon \frac{\rho M \sum_{i=0}^{k+1} |u_i| + (\epsilon/|u_0|) \sum_{i=1}^k \alpha_{k-i} \sum_{j=1}^k |u_j|}{M^2 - (\epsilon/|u_0|)^2} \\ &= \alpha_k \end{aligned}$$

Therefore, we conclude that $|q_k| \leq \alpha_k$ for all $k \in \mathbb{Z}_{+, n-1}$. It follows as in the proof of Theorem 4.2 that

$$\sup_{g \in \Omega} \|g(\cdot)\|_{\infty} \leq \sum_{k=0}^{n-2} \min \left\{ |q_k|, \frac{1}{\rho^k} \right\} + \frac{1}{\rho^{n-2}(\rho-1)} \leq \gamma$$

Hence again, by Lemma 4.1, we conclude that

$$\gamma^* \leq \frac{(\epsilon/|u_0|) + M(\gamma/\rho)}{1 + (\epsilon/|Mu_0|)(\gamma/\rho)}$$

The proof may now be completed by applying (2.4). \square

Note that the upper bound in (4.6) also indicates that any interpolatory algorithm is convergent. Indeed, a technique similar to the proof of Theorem 4.2 may be employed to show that γ approaches to zero when $n \rightarrow \infty$ and $\epsilon \rightarrow 0$. This upper bound is derived by combining the Schur's iterative algorithm [9] and the technique used in the proof of Theorem 4.2, which essentially involves approximating a function $h \in \mathcal{P}(0)$ via a first order rational function.

V CONCLUSION

We have presented an identification algorithm for a worst-case \mathcal{H}_{∞} identification problem. The main feature about this algorithm is that it is an interpolatory algorithm constructed based on time domain data. A direct consequence of this feature is that the algorithm is optimal to within a factor of two. This property is not shared by the previously available algorithms for \mathcal{H}_{∞} identification problems. Note also that the algorithm is interpolatory for the corresponding ℓ_1 identification problem as well.

A main disadvantage of this algorithm is that it requires solving a convex optimization problem with a size equal to the number of data. This may be computationally demanding. By trading off the optimality properties, it is possible to lessen this computational complexity. How to achieve a judicious trade-off between the optimality and complexity is a difficult issue and appears to be a worthy research topic. Future problems also exist in the aspects of, e.g., derivation of lower order models, identification for multivariable systems and issues related to input design and sample complexity [7], [29], [17].

Pole Assignment for Linear Periodic Systems by Memoryless Output Feedback

Dirk Aeyels and Jacques L. Willems

Abstract—We consider linear periodic discrete-time systems. We are interested in the problem of placing the poles of the monodromy map by means of periodic output feedback of the same or multiple period. It is well known that, in general, the poles of time-invariant systems cannot be assigned by constant output feedback. This is in contrast with what can be obtained in the context of time-variant systems. The main contribution of this paper is that periodic output feedback suffices for pole placement of periodic systems.

I. STABILIZATION AND POLE ASSIGNMENT FOR LINEAR SYSTEMS

The purpose of closed-loop control is to monitor the behavior of a dynamical system by means of a well-chosen feedback to achieve a prescribed goal. The design of appropriate feedback laws to obtain stability or a preassigned location of the poles, as well as the study of the limitations imposed by constraints on the possible feedback strategies, represent major research areas in control theory. For

linear time-invariant systems, the closed-loop poles can be assigned arbitrarily¹ by state feedback, provided the system is controllable. On the other hand, controllability and observability imply the existence of a state reconstructor, such that the poles of the closed-loop system can be assigned arbitrarily by dynamic output feedback.

It is well known, however, that in general pole assignment is not possible by means of linear time-invariant memoryless output feedback. In some recent papers [2], [3] the authors have shown that—under some technical conditions—for controllable and observable linear time-invariant discrete-time systems, exact pole assignment is possible by means of memoryless linear periodic output feedback. It seems natural to examine the possibilities of periodic feedback control when the original system itself is periodic. A first result, concerned with low-order systems, has appeared in [4]. In the present paper we extend these results to the general case of discrete-time systems. To our knowledge the problem has only received limited attention in the literature except for a recent paper that addresses the same question [7]. Our results are essentially different, e.g., there is no restriction on the dimension of the system with respect to the number of inputs and outputs.

II. MEMORYLESS PERIODIC OUTPUT FEEDBACK CONTROL FOR PERIODIC LINEAR SYSTEMS

A. Problem Statement

Consider a linear periodic discrete-time system with scalar input and scalar output

$$x_{i+1} = A_i x_i + b_i u_i, \quad y_i = c_i x_i \quad (1)$$

where $x_i \in R^n$, $u_i \in R$, $y_i \in R$, $i \in Z$. The matrices A_i , b_i , c_i have appropriate dimensions. The system is assumed to be periodic with period T

$$A_{i+T} = A_i, \quad b_{i+T} = b_i, \quad c_{i+T} = c_i.$$

The fundamental question that arises is to what extent the pole assignment problem can be solved by introducing time-varying (but memoryless) output feedback. In particular we assume that the time dependent feedback gain is periodic with the same period as the system. Consider the system (1) with periodic feedback

$$u_{i+T} = k_r y_{i+T}$$

with $r \in Z$ and $i \in \{0, 1, \dots, T-1\}$. With this periodic feedback the closed-loop system is also a periodic linear system of period T . This system can be considered as a time-invariant system over a time interval equal to the period T

$$\begin{aligned} x_{(i+1)T} &= (A_{T-1} + k_{T-1} b_{T-1} c_{T-1}) \\ &\times (A_{T-2} + k_{T-2} b_{T-2} c_{T-2}) \cdots (A_0 + k_0 b_0 c_0) x_{iT}. \end{aligned} \quad (2)$$

The eigenvalues of the system matrix

$$\begin{aligned} A_{cl} &= (A_{T-1} + k_{T-1} b_{T-1} c_{T-1}) \\ &\times (A_{T-2} + k_{T-2} b_{T-2} c_{T-2}) \cdots (A_0 + k_0 b_0 c_0) \end{aligned}$$

of (2)—from now on also called the poles of the periodic system—determine the dynamics of the periodic system. We recall here that the eigenvalues of A_{cl} are invariant under cyclic permutation

¹Obviously the complex poles must occur in complex conjugate pairs.

of its defining factors: this implies that the poles are identical for every system matrix that describes the closed-loop system considered over a period T . The original problem of pole assignment can then be restated as selecting feedback gains k_{T-1}, \dots, k_0 such that the eigenvalues of the closed-loop system matrix A_{cl} are the roots of a given polynomial:

$$\alpha(z) = z^n + \alpha_{n-1}z^{n-1} + \dots + \alpha_1z + \alpha_0. \quad (3)$$

B. Reformulation of the Problem

After introducing the notation

$$\Pi = (A_{T-2} + k_{T-2}b_{T-2}c_{T-2}) \cdots (A_0 + k_0b_0c_0) \\ A_{eq} = A_{T-1}\Pi, \quad c_{eq} = c_{T-1}\Pi, \quad b_{eq} = b_{T-1}$$

system (2) is represented as

$$\xi_{r+1} = A_{eq}\xi_r + b_{eq}v_r, \quad z_r = c_{eq}\xi_r \quad (4)$$

with $\xi_r = x_{r,T}$ and $v_r = k_{T-1}z_r$. The question is whether the eigenvalues of

$$A_{cl} = A_{eq} + k_{T-1}b_{eq}c_{eq} \quad (5)$$

can be arbitrarily assigned by the feedback gains. This question is treated in the Appendix. The analysis leads to the result stated and discussed in the next sections.

C. Main Result

The analysis of the appendixes yields the pole assignment property for systems with period T equal to $n+1$. Only this particular case is considered in the present section. The general case is referred to the discussion in Section II-D. For the sake of the presentation a number of assumptions are formulated before the theorem statement is given.

Assumption 1: The matrices A_i for $i = 0, \dots, n$, are nonsingular.

Assumption 2: The n vectors

$$\begin{bmatrix} c_1 \\ c_2 A_1 \\ \vdots \\ c_{n-1} A_{n-2} A_{n-3} \cdots A_1 \\ c_n A_{n-1} A_{n-2} \cdots A_1 \end{bmatrix}$$

are linearly independent.

Assumption 3: The n vectors

$$\begin{bmatrix} c_0 A_0^{-1} \\ c_1 \\ c_2 A_1 \\ \vdots \\ c_{n-1} A_{n-2} A_{n-3} \cdots A_1 \end{bmatrix}$$

are linearly independent.

Assumption 4:

$$\text{rank}[b_{eq} \quad A_{eq}b_{eq} \quad \cdots \quad A_{eq}^{n-1}b_{eq}] = n \quad (6)$$

for the values of the gains k_i , for $i = 1, \dots, n-1$, given by (18), and for k_0 equal to $k_0^0 = -1/c_0 A_0^{-1} b_0$.

Assumption 5:

$$\text{rank}[b_{eq} \quad A_{eq}b_{eq} \quad \cdots \quad A_{eq}^{n-2}b_{eq} \quad A_0^{-1}b_0] = n \quad (7)$$

for the values of the gains k_i , for $i = 1, \dots, n-1$, given by (18), and for k_0 equal to $k_0^0 = -1/c_0 A_0^{-1} b_0$.

Assumption 6: The parameters of system (1) satisfy

$$c_0 A_0^{-1} b_0 \neq 0.$$

The denominators of the gains k_i^0 , for $i = 1, \dots, n-1$, defined by (18), are nonzero

$$1 + k_i^0 c_i A_i^{-1} b_i \neq 0 \quad \text{for } i = 1, \dots, n-1.$$

Theorem 1: Consider the periodic single input single output system (1) with period $n+1$. Then under Assumptions 1)–6), the poles of the system can arbitrarily be assigned except at the origin by a periodic output feedback strategy with period equal to $n+1$.

D. Discussion

- A noteworthy aspect of Theorem 1 is that the feedback law has the same period $n+1$ as the system itself. Hence the system structure is not altered by the feedback, in contrast with the result for time-invariant systems [3], where the time-invariant system is transformed to a periodic system by the feedback. Systems with period T not equal to $n+1$ can readily be dealt with:

—If the period T is larger than $n+1$, then the result can still be used. Indeed if, e.g., at $rT+1, r \in \mathbb{Z}$, the input is set equal to zero, then

$$x_{rT+2} = A_1 A_0 x_{rT} + A_1 b_0 u_{rT}.$$

This reduces the period by one, considering $rT, rT+2, rT+3, \dots$ as sampling instants, $A_1 A_0$ as the new plant matrix, and $A_1 b_0$ as the new input matrix at rT . Repeating this procedure (if necessary), one finally obtains a system of period $n+1$ to which Theorem 2 can be applied. This periodic feedback actually $n+1$ corresponds to a feedback of period T in the original system.

Another approach would be to consider more variables k_i in the analysis of the appendixes, such that some of the variables can be chosen (almost) arbitrarily.

—If the period T is less than $n+1$, then the system can also be seen as a periodic system with period $2T, 3T$, or in general kT , with $k \in \mathbb{Z}$. In this way a period equal to $n+1$ or larger can easily be obtained, and the problem is reduced to either the case considered above, or the case considered in Theorem 1 itself.

- We briefly discuss the assumptions of the theorem. Assumption 1 on the nonsingularity of the system matrices is necessary for the analysis in the Appendix. This assumption, if not true, may be realized by an *a priori* output feedback; this feedback may be combined with the periodic output feedback obtained from the analysis of the Appendix resulting in a periodic output feedback that solves the pole assignment problem. If, however, Assumption 1 cannot be realized in this way, system (2) has a zero eigenvalue for all output feedback coefficients and pole assignment is certainly not possible by linear periodic output feedback. Assumptions 2–3 correspond to observability of the system. Assumptions 4–6 are weak conditions that are a consequence of the technical approach. It is also assumed that the desired pole pattern does not contain one or more closed-loop poles at the origin. This restriction is again a consequence of the technique and can most probably be waived. Some of the restrictions implied by the assumptions of Theorem 1 can be avoided by a cyclic permutation of the time indexes $0, 1, 2, \dots, T-1$. Also it can readily be seen that Assumptions 1–6 reduce to the assumptions obtained in [3] in case the original system is time-invariant.
- The result of Theorem 1 can be generalized to MIMO systems; see [3] for details.
- It seems important to emphasize that the result of Theorem 1 is more than a statement on the genericity of pole assignability by periodic memoryless output feedback. The theorem provides explicit sufficient conditions on the parameters under which the pole assignability problem is solvable. These conditions are

clearly generically satisfied since they require that the parameters do not satisfy a set of algebraic equations.

- The problem of pole assignment is basically one of solving a set of nonlinear algebraic equations. These equations are explicitly derived in Appendix B. We have given a number of verifiable conditions under which this problem is solvable.
- An important feature of the result of Theorem 1 is that no minimum number of inputs or outputs is imposed, distinguishing it from the result of Yan and Bitmead [7] who relate the number of inputs and outputs to the order of the system. Notice also that we are considering exact pole assignment, not almost pole assignment.

E. Illustrative Example

As an example, consider a periodic system of second order with period 3. The system data are

$$A_0 = \begin{bmatrix} 0 & 1 \\ 1 & 2 \end{bmatrix}, A_1 = \begin{bmatrix} 0 & 1 \\ 2 & 1 \end{bmatrix}$$

$$c_1 = c_2 = [-1 \quad 1]$$

We want to find output feedback gains such that for the system considered over one period the closed-loop poles are $-0.5 \pm 0.5j$. It is directly verified that the assumptions of the main theorem are satisfied. By the techniques explained in the appendixes the gains k_0 and k_1 must be determined from (13) and k_2 follows from Ackermann's formula. For this specific example (13) is

$$2(k_1 - 1)(k_0 - 3)(2k_1 k_0 + 4k_0 + 10) + (k_1 k_0 + k_0 - k_1 + 1) = 0.$$

The nominal choice for k_0 is here $k_0^0 = 3$. Following the perturbation analysis we choose $k_0 = 2$, and we obtain $k_1 = 1.0915$. From Ackermann's formula we obtain $k_2 = -3.4665$. This leads to

$$A_1 = [A_2 + k_2 b_2 c_2][A_1 + k_1 b_1 c_1][A_0 + k_0 b_0 c_0]$$

$$= \begin{bmatrix} 3.0915 & 6.0915 \\ -2.1585 & -1.0915 \end{bmatrix}$$

with the required eigenvalues.

III. CONCLUSION

After a discussion of the pole assignment problem for time-invariant discrete-time systems by memoryless output feedback we have posed the same problem for periodic systems. The main part of the paper is concerned with establishing the following result: it is possible in general to assign the poles of a linear periodic discrete-time system by linear periodic output feedback of the same or multiple period.

APPENDIX A

VAN DER WOUDE'S LEMMA

In Section II-B it was shown that the problem is reduced to finding the feedback gains such that the eigenvalues of (5) are the roots of a given characteristic polynomial (3). A result derived by Van der Woude [6] is well suited to analyze this condition. It is formulated below applied to the problem formulated in Section II-B.

As a general rule we will indicate in the course of the technical developments where the assumptions of the main theorem come in. This is done by explicitly making reference to them.

Lemma 1: If the pair $A_{i,q}, b_{i,q}$ is controllable (Assumption 4), there exists an output feedback

(8)

for system (4) such that the polynomial $\alpha(\cdot)$, given by (3), is the characteristic polynomial of (5), if and only if

$$\alpha(A_{i,q})\ker(c_{i,q}) \subset \text{im}[b_{i,q} \quad A_{i,q}b_{i,q} \quad \dots \quad A_{i,q}^{T-1}b_{i,q}] \quad (9)$$

The problem is hence to ensure, if possible, that (9) can be satisfied by a suitable choice of real k_{T-2}, \dots, k_0 . Notice that both sides of (9) depend on k_{T-2}, \dots, k_0 through A_{eq} and c_{eq} . Once k_{T-2}, \dots, k_0 have been computed, it must be checked that the pair A_{eq}, b_{eq} is controllable. The control, given by (8), must then be determined such that

$$\alpha(\cdot) = \det[zI - (A_{eq} - k_{T-1}b_{eq}c_{eq})].$$

The existence of the control follows from Lemma 1. One approach for determining k_{T-1} is to use Ackermann's formula [1], [5]. The original problem is then reduced to ensure that the feedback constants can be chosen such that (9) holds and such that the controllability matrix has full rank

$$\text{rank}[b_{eq} \quad A_{eq}b_{eq} \quad \dots \quad A_{eq}^{T-1}b_{eq}] \quad (10)$$

The following appendixes are dedicated to an in depth analysis of relations (9) and (10). The main line of the analysis is as follows. First (9) is reformulated as an algebraic equation in k_{T-2}, \dots, k_0 . This equation is explicitly solved in Appendix B for a special choice of k_0 which is denoted by k_0^0 ; the obtained solutions are denoted as k_{T-2}^0, \dots, k_1^0 . These solutions are not acceptable, however, since the choice of k_0 violates one of the conditions imposed. Therefore a perturbation analysis is performed in Appendix C to show that for k_0 close to k_0^0 the equation can also be solved and the solutions can be accepted. The analysis requires some weak restrictions on the system data, which are introduced as the discussion proceeds.

APPENDIX B

THE DETERMINATION OF THE NOMINAL FEEDBACK GAINS

In the analysis of the present and the next appendix, the period T is set equal to $n+1$. This is in accordance with the results obtained for the time-invariant case [3]. In the sequel we assume that all matrices A_i are nonsingular (Assumption 1).

To solve (9), the equation is transformed into a more tractable expression under the additional assumption that the matrices $A_i + k_i b_i c_i$, for $i = 0, \dots, n-1$, are nonsingular. Then

$$\ker(c_{i,q}) = \ker(c_n \Pi) = \Pi^{-1} \ker(c_n) \quad (11)$$

and (9) is equivalent with

$$\alpha(A_{i,q})\Pi^{-1} \ker(c_n) \subset \text{im}[b_n \quad A_n \Pi b_n \quad \dots \quad (A_n \Pi)^{n-2} b_n] \quad (12)$$

Of course it must be checked *a posteriori* that the nonsingularity conditions are satisfied for the obtained solutions.

Assume that the controllability condition (10) is satisfied and let v^+ be a row vector (dependent on k_i) perpendicular to the $n-1$ independent vectors

$$b_n, A_n \Pi b_n, (A_n \Pi)^2 b_n, \dots, (A_n \Pi)^{n-2} b_n.$$

Let $c_1^+, c_2^+, \dots, c_{n-1}^+$ be a basis of column vectors spanning the null space of c_n (i.e., perpendicular to c_n). Then (12) is equivalent with the set of $n-1$ equations in the n variables k_0, k_1, \dots, k_{n-1}

$$v^+ \alpha(A_{eq}) \Pi^{-1} c_i^+ = 0$$

for $i = 1, \dots, n-1$. Explicitly these equations are

$$v^+ (A_{eq}^{n-1} A_n + \dots + \alpha_1 A_n) c_i^+ + \alpha_0 v^+ (A_0 + k_0 b_0 c_0)^{-1} \dots (A_{n-1} + k_{n-1} b_{n-1} c_{n-1})^{-1} c_i^+ = 0. \quad (13)$$

The Woodbury formula [5] yields

$$(A + kbc)^{-1} = (1 + kcA^{-1}b)^{-1}[(1 + kcA^{-1}b)A^{-1} - kA^{-1}bcA^{-1}].$$

Then (13) is equivalent with

$$\begin{aligned} & (1 + k_0 c_0 A_0^{-1} b_0) v^+ \\ & \times (A_{n-1}^{-1} A_n + \alpha_{n-1} A_{n-1}^{-2} A_n + \cdots + \alpha_1 A_n) c_i^+ \\ & + \alpha_0 v^+ [(1 + k_0 c_0 A_0^{-1} b_0) A_0^{-1} - k_0 A_0^{-1} b_0 c_0 A_0^{-1}] \\ & \times (A_1 + k_1 b_1 c_1)^{-1} \cdots (A_{n-1} + k_{n-1} b_{n-1} c_{n-1})^{-1} c_i^+ = 0 \end{aligned} \quad (14)$$

for $i = 1, \dots, n-1$. Recall that the desired gains k_i must be such that the matrices $A_i + k_i b_i c_i$, with $i = 0, \dots, n-1$, are nonsingular. Note that (14) consists of $n-1$ equations with n variables k_i ; hence in general one of the gains may be chosen and the others computed from the equations. We assume that $c_0 A_0^{-1} b_0$ does not vanish (Assumption 6). Although we have required that the matrices $A_i + k_i b_i c_i$ are nonsingular, we first solve (14) under the assumption that k_0 is equal to $-1/c_0 A_0^{-1} b_0$, denoted as k_0^0 . Appendix C is devoted to solving (14) for k_0 different from that value.

The gains k_i satisfying (14) for the particular choice of k_0 are called the nominal solutions; they are denoted by k_i^0 . It is assumed that α_0 is nonzero. This implies that the desired closed-loop system has no poles at the origin. Furthermore we assume that $v^+ A_0^{-1} b_0 \neq 0$. This condition holds due to Assumptions 4 and 5. Then (14) yields

$$c_0 A_0^{-1} (A_1 + k_1 b_1 c_1)^{-1} \cdots (A_{n-1} + k_{n-1} b_{n-1} c_{n-1})^{-1} v^+ = 0. \quad (15)$$

This is equivalent with

$$c_0 A_0^{-1} \div c_n (A_{n-1} + k_{n-1} b_{n-1} c_{n-1}) \cdots (A_1 + k_1 b_1 c_1) \quad (16)$$

where the symbol \div stands for proportionality.

Although the above set of equations for the gains k_1, \dots, k_{n-1} is nonlinear, it is shown below that it can be brought in a triangular form and explicitly solved. Assume that the vectors

$$v_n = c_n A_{n-1} A_{n-2} \cdots A_1$$

are linearly independent (Assumption 2). This is actually an observability condition, requiring that the state can be reconstructed from n successive output measurements. Then $c_0 A_0^{-1}$ can be expressed as

$$c_0 A_0^{-1} = a_1 v_1 + a_2 v_2 + \cdots + a_n v_n, \quad (17)$$

The constant a_n is assumed to be nonzero (this is Assumption 3); it determines the proportionality factor in (16). The solutions k_i for $i = 1, \dots, n-1$ can readily be calculated from (16); the solution k_i^0 is expressed as a function of k_{i+1}^0, \dots, k_n^0 :

$$k_i^0 = \frac{a_i}{a_n c_n (A_{n-1} + k_{n-1}^0 b_{n-1} c_{n-1}) \cdots (A_{i+1} + k_{i+1}^0 b_{i+1} c_{i+1}) b_i},$$

where the denominators are assumed to be nonzero. More explicitly for $i = 1, \dots, n-1$

$$k_i^0 = \frac{a_i}{a_n c_n A_{n-1} \cdots A_{i+1} b_i + \cdots + a_{i+1} c_{i+1} b_i}, \quad (18)$$

APPENDIX C PERTURBATION ANALYSIS

In Appendix B we obtained a set of expressions (18) determining the constants k_i^0 ($i = 1, \dots, n$) satisfying relation (12) for a choice of k_0 equal to k_0^0 . This value cannot be accepted as was explained in Appendix B. Therefore, relation (12) is reconsidered for $k_0 = k_0^0 + \epsilon$, with ϵ small. It is shown below that for this choice of k_0 there exist solutions k_i ($i = 1, \dots, n-1$) of (12) or equivalently (14).

The application of the Woodbury formula to all matrices $(A_i + k_i b_i c_i)^{-1}$ in (14) yields

$$\begin{aligned} & (1 + k_0 c_0 A_0^{-1} b_0) (1 + k_1 c_1 A_1^{-1} b_1) \\ & \cdots (1 + k_{n-1} c_{n-1} A_{n-1}^{-1} b_{n-1}) \\ & \times v^+ (A_{n-1}^{-1} A_n + \alpha_{n-1} A_{n-1}^{-2} A_n + \cdots + \alpha_1 A_n) c_i^+ \\ & + \alpha_0 v^+ [(1 + k_0 c_0 A_0^{-1} b_0) A_0^{-1} - k_0 A_0^{-1} b_0 c_0 A_0^{-1}] \\ & \times [(1 + k_{n-1} c_{n-1} A_{n-1}^{-1} b_{n-1}) A_{n-1}^{-1} \\ & - k_{n-1} A_{n-1}^{-1} b_{n-1} c_{n-1} A_{n-1}^{-1}] c_i^+ = 0 \end{aligned} \quad (19)$$

for $i = 1, \dots, n-1$. The vectors c_i^+ constitute a basis of $\ker(c_n)$. We take the following particular choice. Consider the set of vectors

$$w_i = v_i A_1^{-1} A_2^{-1} \cdots A_{n-1}^{-1}$$

for $i = 1, \dots, n$. These vectors are independent because of the observability assumption introduced in Appendix B. Notice that

$$w_i = v_i A_1^{-1} A_2^{-1} \cdots A_{n-1}^{-1} = v_i A_i^{-1} A_{i+1}^{-1} \cdots A_{n-1}^{-1}$$

for $i = 1, \dots, n-1$, and

The vectors c_i^+ are chosen such that c_i^+ is orthogonal to all w_j , for $j \neq i$. Each vector is unambiguously defined up to a scalar.

In an obvious notation each equation in (19) is written as

$$\Phi_i(k_0, \dots, k_{n-1}) + \alpha_0 g_i(k_0, \dots, k_{n-1}) = 0 \quad (20)$$

for $i = 1, \dots, n-1$. Let k^0 denote the vector of the nominal gains k_0^0, \dots, k_{n-1}^0 . Below it is shown that the Jacobian matrix

$$\frac{\partial(\Phi_i + \alpha_0 g_i)}{\partial k_j} \quad (21)$$

with $i, j = 1, \dots, n-1$, evaluated at k^0 is nonsingular. This establishes by the implicit function theorem that there exists a solution to (19) also for $k_0 = k_0^0 + \epsilon$ with ϵ sufficiently small. The corresponding solutions k_i are smoothly dependent on ϵ and equal to k_i^0 for ϵ equal to zero. Assume (Assumption 6)

$$k_i^0 c_i A_i^{-1} b_i \neq -1 \quad \text{for } i = 1, \dots, n-1. \quad (22)$$

Then the solutions k_i also satisfy $1 + k_i c_i A_i^{-1} b_i \neq 0$ for small ϵ .

We now prove the nonsingularity of the Jacobian matrix. First notice that evaluated at k^0 , we have

$$\frac{\partial(\Phi_i + \alpha_0 g_i)}{\partial k_j} = \alpha_0 \frac{\partial g_i}{\partial k_j} \quad (23)$$

for $i, j = 1, \dots, n-1$, since each Φ_i contains the factor $1 + k_0 c_0 A_0^{-1} b_0$ which vanishes at k^0 . For $k_0 = k_0^0$ the function g_i can be written as follows

$$\frac{1}{c_0 A_0^{-1} b_0} f_i$$

with

$$\begin{aligned} f_i &= c_0 A_0^{-1} [(1 + k_1 c_1 A_1^{-1} b_1) A_1^{-1} - k_1 A_1^{-1} b_1 c_1 A_1^{-1}] \\ & \times [(1 + k_{n-1} c_{n-1} A_{n-1}^{-1} b_{n-1}) A_{n-1}^{-1} \\ & - k_{n-1} A_{n-1}^{-1} b_{n-1} c_{n-1} A_{n-1}^{-1}] c_i^+, \end{aligned}$$

From (15) it follows that f_i vanishes at k^0 . Therefore

$$\alpha_0 \frac{\partial f_i}{\partial k_j} = \alpha_0 \frac{v^+ A_0^{-1} b_0}{c_0 A_0^{-1} b_0} \frac{\partial f_i}{\partial k_j}. \quad (24)$$

Notice that with the particular choice of the vectors c_1^+ the function f_1 has the following form

$$\begin{aligned} f_1 &= (1 + k_2 c_2 A_2^{-1} b_2) \cdots (1 + k_{n-1} c_{n-1} A_{n-1}^{-1} b_{n-1}) \\ &\quad \times c_0 A_0^{-1} [A_1^{-1} (1 + k_1 c_1 A_1^{-1} b_1) \\ &\quad - k_1 A_1^{-1} b_1 c_1 A_1^{-1}] A_2^{-1} A_3^{-1} \cdots A_{n-2}^{-1} A_{n-1}^{-1} c_1^+. \end{aligned}$$

With the particular choice of c_1^+ and invoking (17) one obtains

$$c_0 A_0^{-1} A_1^{-1} \cdots A_{n-1}^{-1} c_1^+ = a_1 c_1 A_1^{-1} A_2^{-1} \cdots A_{n-1}^{-1} c_1^+.$$

Hence

$$\begin{aligned} f_1 &= (1 + k_2 c_2 A_2^{-1} b_2) \cdots (1 + k_{n-1} c_{n-1} A_{n-1}^{-1} b_{n-1}) \\ &\quad \times [a_1 (1 + k_1 c_1 A_1^{-1} b_1) - k_1 c_0 A_0^{-1} A_1^{-1} b_1] \\ &\quad \times c_1 A_1^{-1} \cdots A_{n-1}^{-1} c_1^+. \end{aligned}$$

With

$$c_0 A_0^{-1} = a_1 c_1 + a_2 c_2 A_1 + \cdots + a_n c_n A_{n-1} \cdots A_1 \quad (25)$$

one obtains

$$\begin{aligned} f_1 &= (1 + k_2 c_2 A_2^{-1} b_2) \cdots (1 + k_{n-1} c_{n-1} A_{n-1}^{-1} b_{n-1}) \\ &\quad \times c_1 A_1^{-1} \cdots A_{n-1}^{-1} c_1^+ [a_1 - k_1 (a_2 c_2 + a_3 c_3 A_2 \\ &\quad + \cdots + a_n c_n A_{n-1} A_{n-2} \cdots A_2) b_1]. \end{aligned}$$

From the explicit expressions (18) of k_i^0 we conclude that all elements (except for the diagonal element) of the first row of the Jacobian matrix (21) vanish when they are evaluated at k^0

$$\frac{\partial f_1}{\partial k_j}(k^0) = 0$$

for $j > 1$.

Consider the first diagonal element: one obtains

$$\begin{aligned} \frac{\partial f_1}{\partial k_1}(k^0) &= -(1 + k_2^0 c_2 A_2^{-1} b_2) \cdots (1 + k_{n-1}^0 c_{n-1} A_{n-1}^{-1} b_{n-1}) \\ &\quad \times c_1 A_1^{-1} \cdots A_{n-1}^{-1} c_1^+ (a_2 c_2 + a_3 c_3 A_2 \\ &\quad + \cdots + a_n c_n A_{n-1} A_{n-2} \cdots A_2) b_1. \end{aligned}$$

This expression is different from zero since (22) holds and the nominal k_i^0 exist (i.e., the denominators are not equal to zero).

Consider now the second row of the Jacobian matrix (21): the expression of f_2 is rewritten, using the definition of c_2^+

$$\begin{aligned} f_2 &= (1 + k_1 c_1 A_1^{-1} b_1) \cdots (1 + k_{n-1} c_{n-1} A_{n-1}^{-1} b_{n-1}) \\ &\quad \times c_0 A_0^{-1} [(1 + k_1 c_1 A_1^{-1} b_1) A_1^{-1} - k_1 A_1^{-1} b_1 c_1 A_1^{-1}] \\ &\quad \times [(1 + k_2 c_2 A_2^{-1} b_2) A_2^{-1} - k_2 A_2^{-1} b_2 c_2 A_2^{-1}] \\ &\quad \times A_3^{-1} \cdots A_{n-2}^{-1} A_{n-1}^{-1} c_2^+. \end{aligned}$$

Invoking (17) and the definition of c_2^+ , one obtains

$$\begin{aligned} f_2 &= (1 + k_1 c_1 A_1^{-1} b_1) \cdots (1 + k_{n-1} c_{n-1} A_{n-1}^{-1} b_{n-1}) \\ &\quad \times [(1 + k_1 c_1 A_1^{-1} b_1) (1 + k_2 c_2 A_2^{-1} b_2) a_2 \\ &\quad - (1 + k_1 c_1 A_1^{-1} b_1) k_2 c_0 A_0^{-1} A_1^{-1} A_2^{-1} b_2 \\ &\quad + k_1 k_2 c_0 A_0^{-1} A_1^{-1} b_1 c_1 A_1^{-1} A_2^{-1} b_2] c_2 \\ &\quad \times A_3^{-1} \cdots A_{n-2}^{-1} A_{n-1}^{-1} c_2^+. \end{aligned}$$

One immediately verifies that

$$\frac{\partial f_2}{\partial k_j}(k^0) = 0$$

for $j > 2$. In general it may be verified that

$$\frac{\partial f_i}{\partial k_j}(k^0) = 0$$

for $j > i$.

As for the second diagonal element of the Jacobian matrix one obtains

$$\begin{aligned} \frac{\partial f_2}{\partial k_2}(k^0) &= -(1 + k_1^0 c_1 A_1^{-1} b_1) (1 + k_3^0 c_3 A_3^{-1} b_3) \\ &\quad \cdots (1 + k_{n-1}^0 c_{n-1} A_{n-1}^{-1} b_{n-1}) \\ &\quad \times c_2 A_2^{-1} \cdots A_{n-1}^{-1} c_2^+ (a_3 c_3 + a_4 c_4 A_3 \\ &\quad + \cdots + a_n c_n A_{n-1} A_{n-2} \cdots A_3) b_2. \end{aligned}$$

This expression is different from zero since (22) holds and the nominal k_i^0 exist (i.e., the denominators are not equal to zero).

Similar conclusions are obtained for the other diagonal elements of the Jacobian matrix. Therefore the Jacobian matrix, evaluated at k^0 , is nonsingular if

- (Assumption 6) the nominal gains k_i^0 , for $i = 1, \dots, n-1$, exist and satisfy (22),
- $v^+ A_0^{-1} b_0 \neq 0$, $c_0 A_0^{-1} b_0 \neq 0$ (Assumption 6) and $\alpha_0 \neq 0$.

Note that $v^+ A_0^{-1} b_0 \neq 0$ is equivalent to (Assumption 5)

$$\text{rank}[b_{vq} \quad A_{1q} b_{vq} \quad \cdots \quad A_{n-1,q}^{n-2} b_{vq} \quad A_0^{-1} b_0] = n \quad (26)$$

if the controllability condition (10) is satisfied at k^0 .

Fault Detection and Isolation for Unstable Linear Systems

M. Kinnaert, R. Hanus, and Ph. Arte

Abstract—In the design of a residual generator for an unstable plant, the unstable modes are made unobservable from the residual vector. We point out that this cannot be achieved in practice due to the discrepancy between the estimated model and the “true” plant model. Hence, we deduce that it is not possible to design a residual generator for an unstable plant, unless it is stabilized by an adequate controller. As a by-product, we provide expressions which can be used to quantify the effect of modeling uncertainties on the performance of a residual generator. The factorization approach to control theory is used for the developments.

I. INTRODUCTION

There are many approaches to perform the synthesis of a residual generator for automatic fault detection on linear time invariant systems: the geometric approach [1]–[2], the factorization approach [3]–[5], the parity space approach [6]–[8], and the approach based on eigenstructure assignment [9]–[10]. The stability of the plant never appears as a necessary condition for the design of a residual generator in these works. We show here that this is due to the assumption that the estimated plant model exactly coincides with the “true” plant model. By introducing a mismatch between both models, we prove that it is not possible to design a residual generator for unstable plants when they are not stabilized by an adequate controller. Beside its theoretical interest, this remark might be useful when one considers unstable processes running during a finite time period or processes containing an integrating action.

This note is organized as follows. In the second part, the so called extension of the fundamental problem of residual generation (EFPRG) [1] is stated. In Section III, its solution using the factorization approach is reviewed, and the effect of the modeling error is exhibited. In the fourth section, the EFPRG is solved for an unstable plant controlled by a stabilizing controller, and the influence of modeling uncertainties is analyzed.

II. THE EXTENSION OF THE FUNDAMENTAL PROBLEM OF RESIDUAL GENERATION

For the sake of simplicity and to clearly show the influence of the initial state of the system, we first state the problem in the time domain.

We consider the class of systems described by

$$\dot{x}(t) = Ax(t) + Bu(t) + Ff(t) \quad (1)$$

$$y(t) = Cx(t) + Du(t) + Gf(t) \quad (2)$$

where $x(t) \in R^n$ is the state vector, $u(t) \in R^r$ is the actuator command vector, $y(t) \in R^l$ is the measurement vector, and $f(t) \in R^q$ is a vector made of arbitrary functions of time referred to as the failure modes.

Our aim is to design a linear time invariant (LTI) system with inputs $u(t)$ and $y(t)$, and with q outputs, namely the q components of a vector $r(t)$, called the residual vector, so that the map from $f(t)$ to $r(t)$ fulfills specific requirements. More precisely, a nonzero i th component of $f(t)$, $f_i(t)$, must induce a nonzero i th component of $r(t)$, $r_i(t)$, and it cannot influence the other components of $r(t)$. The

most general form for such a LTI system is

$$\dot{x}_i(t) = A_i x_i(t) + B_i u(t) + \Gamma_i y(t) \quad (3)$$

$$r_i(t) = C_i x_i(t) + D_i u(t) + F_i y(t) \quad (4)$$

Combining (1)–(4), we obtain

$$\begin{bmatrix} \dot{x}_i(t) \\ r_i(t) \end{bmatrix} = \begin{bmatrix} A_i & 0 \\ F_i C_i & A_i \end{bmatrix} \begin{bmatrix} x_i(t) \\ r_i(t) \end{bmatrix} + \begin{bmatrix} B_i \\ B_i + E_i D_i \end{bmatrix} u(t) + \begin{bmatrix} \Gamma_i \\ F_i \Gamma_i \end{bmatrix} f(t) \quad (5)$$

$$\begin{bmatrix} \dot{x}_i(t) \\ r_i(t) \end{bmatrix} = \begin{bmatrix} \Gamma_i C_i & C_i \end{bmatrix} \begin{bmatrix} x_i(t) \\ r_i(t) \end{bmatrix} + (F_i D_i + D_i) u(t) + F_i \Gamma_i f(t) \quad (6)$$

The objectives can now be stated as follows:

- O1) In the absence of failure, $r_i(t)$ decays asymptotically to zero $i = 1, 2, \dots, q$.
- O2) In the presence of the i th failure mode ($f_i(t) \neq 0$), $r_i(t)$ decays asymptotically to zero $j = 1, 2, \dots, i-1, i+1, \dots, q$ and $r_i(t)$ depends on $f_i(t)$ in a sense made precise below in R2). This should be verified for $i = 1, 2, \dots, q$.

This yields the following requirements on the system described by (5) and (6):

- R1) All the observable modes of the pair $\left(\begin{bmatrix} F_i C_i & C_i \end{bmatrix}, \begin{bmatrix} A_i & 0 \\ \Gamma_i C_i & A_i \end{bmatrix} \right)$ are asymptotically stable and the map from $u(t)$ to $r_i(t)$ is equal to zero.
- R2) The map from $f_i(t)$ to $r_i(t)$ corresponds to a diagonal transfer matrix with nonzero diagonal elements.

Remark 1

—Although the failure signals $f_i(t)$, $i = 1, \dots, q$, are arbitrary, we do not consider the situation where the system initial condition and the signal $f_i(t) \neq 0$ are such that $r_i(t) = 0$ due to a transmission zero. The probability of the occurrence of this phenomenon is zero for all practical purpose.

The observability condition in R1) guarantees that the effect on $r_i(t)$ of a nonzero initial state of the process or the filter asymptotically vanishes.

—The EFPRG is stated in a more general framework in [1]. Indeed, a failure can be modeled by several nonzero components in $f(t)$. In most practical situations, however, a single nonzero entry suffices to model a failure. Hence, we only consider this situation here.

—The diagonal fault response (i.e., hypothesis R2)) is a particular case. Yet, any other kind of response can be derived from it by an additional transformation [8].

It is now straightforward to translate the problem in the frequency domain. Taking into account the transient due to a nonzero initial state x^0 , the Laplace transform of (1) and (2) yields

$$y(s) = G(s)u(s) + G_f(s)f(s) + G_0(s)x^0 \quad (7)$$

where $G(s) = C(sI - A)^{-1}B + D$, $G_f(s) = C(sI - A)^{-1}F + F$, and $G_0(s) = C(sI - A)^{-1}x^0$.

Now, as only the observable part of the filter is useful, we assume without loss of generality that (C, A) is observable. Hence, to fulfill R1), A must be a Hurwitz matrix. Thus, we can take the Laplace transform of (3)–(4) and neglect the transient due to the initial state of the filter, as it decays asymptotically to zero. This yields

$$r_i(s) = L_i(s)y(s) + K_i(s)u(s) \quad (8)$$

Manuscript received April 26, 1994.

The authors are with the Laboratoire d'Automatique, Université Libre de Bruxelles, CP165 ULB, 50 Ave F. D. Roosevelt, B-1050, Brussels, Belgium. IEEE Log Number 9408786.

where $K(s) = C_r(sI - A_r)^{-1}B_r + D_r$, $L(s) = C_r(sI - A_r)^{-1}E_r + F_r$, and $L(s), K(s) \in RH_\infty$. Here, and in the sequel, RH_∞ denotes the set of stable proper rational matrices.

Substituting $y(s)$ by (7) in (8) yields

$$r(s) = (L(s)G(s) + K(s))u(s) + L(s)G_f(s)f(s) + L(s)G_0(s)x^0. \quad (9)$$

From (9), we deduce that R1) and R2) are equivalent to the following.

R1') $L(s)G(s) + K(s) = 0$ $L(s), K(s)$ and $L(s)G_0(s)$ belong to RH_∞ .

R2') $L(s)G_f(s)$ is a diagonal transfer matrix with nonzero diagonal entries.

III. EFFECT OF UNSTABLE MODES IN THE PLANT

We first review the class of all the solutions to EFPRG. For the sake of simplicity, we assume that the number of measurements, p , is the same as the number of failures, q . The more general case where $p > q$ can be handled as in [5].

The following lemma is stated slightly differently in [5]. Indeed, here, to simplify the equations, we have used the fact that there exist matrices $N(s)$, $N_f(s)$, and $N_0(s)$ such that

$$G(s) = M(s)^{-1}N(s) \quad (10a)$$

$$G_f(s) = M(s)^{-1}N_f(s) \quad (10b)$$

$$G_0(s) = M(s)^{-1}N_0(s) \quad (10c)$$

are left coprime factorizations of $G(s)$, $G_f(s)$, and $G_0(s)$ over RH_∞ .

Lemma [5]: Assume that $G_f(s)$ is invertible, and let (10a)–(10b) be left coprime factorizations of $G(s)$ and $G_f(s)$ over RH_∞ . Then the class of all stable proper filters which solve the extension of the fundamental problem of residual generation (i.e., which fulfill R1) and R2)), for the system (7), is parameterized as follows

$$r(s) = P_{N_f}(s)(M(s)y(s) - N(s)u(s))$$

where

$$P_{N_f}(s) = Q(s)S_{N_f}(s)N_f(s)^{-1} \quad (12)$$

with $Q(s)$, an arbitrary $q \times q$ diagonal RH_∞ matrix with nonzero diagonal entries

$$S_{N_f}(s) = \text{diag} \frac{\prod_{j=1}^{n_i} (s + z_j)}{(s + \alpha_i)^{n_i + p_i}} = \text{diag } s_i(s) \quad (13)$$

where z_j , $j = 1, \dots, n_i$ are the unstable poles of the i th row of $N_f(s)^{-1}$, α_i is an arbitrary positive real number and p_i is determined so that

$$\lim_{s \rightarrow \infty} s_i(s)[N_f(s)]^{-1} \quad (14)$$

is a nonzero row vector. Here $[X]_i$ denotes the i th row of X .

To show what goes wrong with an unstable plant, we now introduce a discrepancy between the "true" plant model (7), and the estimated plant model, denoted by hats ("^"), which is used to design the residual generator.

In this framework, (9) can be written

$$r(s) = (\hat{L}(s)G(s) + \hat{K}(s))u(s) + \hat{L}(s)G_f(s)f(s) + \hat{L}(s)G_0(s)x^0 \quad (15)$$

where

$$\hat{L}(s) = P_{\hat{N}_f}(s)\hat{M}(s); \quad \hat{K}(s) = -P_{\hat{N}_f}(s)\hat{N}(s). \quad (16)$$

Here $P_{\hat{N}_f}(s)$ is obtained by substituting $N_f(s)$ by $\hat{N}_f(s)$ in (12)–(14).

Now, using (10c), one can rewrite the map from x^0 to r as

$$\hat{L}(s)G_0(s) = P_{\hat{N}_f}(s)\hat{M}(s)M(s)^{-1}N_0(s). \quad (17)$$

From (17), one concludes that, due to the modeling error, when the plant is unstable, the effect of the initial conditions will not vanish. On the contrary a nonzero x^0 will yield an "explosion" in the residual. From (15)–(17) it is clear that whatever $\hat{L}(s)$ may be, it is impossible to avoid instability when $\hat{M}(s) \neq M(s)$. Notice that it is also impossible to assure that the effect of the initial condition on the residual vanishes for a plant with a pole at the origin. The residual will be affected by a bias whose magnitude depends on the initial state, in this case.

We now investigate the situation where a controller stabilizes the unstable plant.

IV. THE EFPRG FOR AN UNSTABLE PROCESS STABILIZED IN CLOSED LOOP

Let us consider a stabilizing controller

$$u(s) = C(s)(w(s) - y(s)). \quad (18)$$

For the plant (7), and let $N_r(s)M_r(s)^{-1}$ be a right coprime factorization of $C(s)$ over RH_∞ . In (18), $w(s)$ is the Laplace transform of the reference vector.

We can now state the following theorem.

Theorem: Consider the stable closed-loop system (7), (18), and assume that $G_f(s)$ is invertible. Let $\hat{C}(s) = \hat{M}(s)^{-1}\hat{N}(s)$, $\hat{G}_f(s) = \hat{M}(s)^{-1}\hat{N}_f(s)$, and $\hat{G}_0(s) = \hat{M}(s)^{-1}\hat{N}_0(s)$ be left coprime factorizations of the transfer matrices of the estimated plant model. Then the class of filters parametrized by

$$r(s) = \hat{L}(s)y(s) + \hat{K}(s)u(s) \quad (19)$$

where $\hat{L}(s)$ and $\hat{K}(s)$ are given in (16) fulfills

$$\lim_{s \rightarrow \infty} sr(s) = \Gamma w_0 \quad (20)$$

in the absence of failure, for a step-like reference signal $w(s) = w_0/s$, $w_0 \in R^p$. Here Γ is a constant real matrix.

Moreover, in the presence of step-like failure $f(s) = f_0/s$, $f_0 \in R^q$, and reference $w(s) = w_0/s$

$$\lim_{s \rightarrow \infty} sr(s) = \Gamma w_0 + \Theta f_0 \quad (21)$$

where Θ is a constant real matrix. Besides, when \hat{G} and \hat{G}_f , respectively, tend to G and G_f , Γ tends to zero, and Θ tends to a diagonal matrix.

Proof: In the sequel, the Laplace variable s is omitted to shorten the expressions. To find an expression of $r(s)$ in terms of $w(s)$, $f(s)$, and x^0 , we first write down the equations of the closed-loop systems (7) and (18), where we substitute the different transfer functions by their factorization. This yields

$$y = M_c D_{cl}^{-1} N_f f + M_c D_{cl}^{-1} N N_r M_c^{-1} w + M_c D_{cl}^{-1} N_0 x^0 \quad (22)$$

where $D_{cl} = MM_c + NN_r$. As the controller assures the internal stability of the closed-loop system by hypothesis, D_{cl} is a unimodular matrix [11]. Substituting $y(s)$ and $u(s)$ by (22) and (18), respectively, in (19) of the residual generator, we obtain

$$r = (\hat{L}M_c - \hat{K}N_r)D_{cl}^{-1}N_f f + (\hat{L}M_c - \hat{K}N_r)D_{cl}^{-1}N_0 x^0 + (\hat{L}M_c D_{cl}^{-1}NN_r M_c^{-1} + \hat{K}N_r D_{cl}^{-1}M)w. \quad (23)$$

As $\hat{L}(s)$ and $\hat{K}(s)$ are asymptotically stable, so are the transfer matrices between $f(s)$, x^0 , $w(s)$, and $r(s)$. This is obvious, except for the map from $w(s)$ to $r(s)$. Notice, however, that

$$\hat{L}M_c D_{cl}^{-1}NN_r M_c^{-1} = \hat{L}\hat{N}\hat{D}_{cl}^{-1}\hat{N}_r \quad (24)$$

where we introduce a left coprime and a right coprime factorization, respectively, for the transfer matrices $G_c(s)$ and $G(s)$ as follows [11]

$$\begin{aligned} N_c M_c^{-1} &= \bar{M}_c^{-1} \bar{N}_c \quad \text{and} \quad \bar{N}_c N_c + \bar{M}_c M_c = I \\ M^{-1} N &= \bar{N} \bar{M}^{-1} \quad \text{and} \quad \bar{N} \bar{N} + \bar{M} \bar{M} = I \\ \bar{D}_{cl} &= \bar{M}_c \bar{M} + \bar{N}_c \bar{N} \end{aligned}$$

(24) clearly shows that the transfer matrix from w to r also belongs to RH_∞ . For a step-like reference and a failure of the same nature, we deduce

$$\begin{aligned} \lim_{s \rightarrow 0} sr(s) &= [(\hat{L} M_c - \hat{K} N_c) D_{cl}^{-1} N_f]_{s=0} f_0 \\ &+ [\hat{L} M_c D_{cl}^{-1} N N_c M_c^{-1} + \hat{K} N_c D_{cl}^{-1} M]_{s=0} \end{aligned} \quad (25)$$

where $[X]_{s=0}$ indicates that the transfer matrix $X(s)$ is evaluated for $s = 0$. This proves (20) and (21), by identifying Γ and Θ with the corresponding bracketed expression in (25).

Finally, we consider each term of (25) when $\hat{G} \rightarrow G$ and $\hat{G}_f \rightarrow G_f$. We obtain successively

$$\begin{aligned} \lim_{\substack{\hat{G} \rightarrow G \\ \hat{G}_f \rightarrow G_f}} (\hat{L} M_c D_{cl}^{-1} N N_c M_c^{-1} + \hat{K} N_c D_{cl}^{-1} M) \\ = \lim_{\substack{\hat{G} \rightarrow G \\ \hat{G}_f \rightarrow G_f}} Q S_{N_f} \hat{G}_f^{-1} (M_c D_{cl}^{-1} N N_c M_c^{-1} - \hat{G} N_c D_{cl}^{-1} M) \\ = \lim_{\hat{G} \rightarrow G} Q S_{N_f} \hat{G}_f^{-1} (G - \hat{G}) C (I + GC)^{-1} = 0. \end{aligned} \quad (26)$$

$$= \lim_{\hat{G} \rightarrow G} Q S_{N_f} \hat{G}_f^{-1} (G - \hat{G}) C (I + GC)^{-1} = 0. \quad (27)$$

Hence $\Gamma \rightarrow 0$ as $\hat{G} \rightarrow G$. Equation (26) is easily deduced from (12) and (16), while (27) is obtained by straightforward computations.

On the other hand, using (16), we obtain

$$\begin{aligned} \lim_{\substack{\hat{G} \rightarrow G \\ \hat{G}_f \rightarrow G_f}} (\hat{L} M_c - \hat{K} N_c) D_{cl}^{-1} N_f \\ = \lim_{\substack{\hat{G} \rightarrow G \\ \hat{G}_f \rightarrow G_f}} P_{N_f} \hat{M} (I + \hat{G} C) (I + GC)^{-1} G_f \end{aligned} \quad (28)$$

$$= \lim_{\hat{G} \rightarrow G} P_{N_f} \hat{M} G_f + P_{N_f} \hat{M} (\hat{G} - G) C (I + GC)^{-1} G_f \quad (29)$$

$$= \lim_{\hat{G} \rightarrow G} (Q S_{N_f} + Q S_{N_f} \hat{G}_f^{-1} (G_f - \hat{G}_f) + P_{N_f} \hat{M} (\hat{G} - G) C (I + GC)^{-1} G_f) \quad (30)$$

where (30) is deduced from (29) by using (12). The first term in (30) is obviously a diagonal matrix, which concludes the proof. \square

Note that from (19) and (16), (20) and (21) could intuitively be expected. Indeed, as the plant is stabilized, the residual generator needs to be BIBO stable for (20) and (21) to be fulfilled. Since it is designed using the plant model exclusively, model inaccuracies do not affect its stability.

From (27) and (30), we can expect that, when the discrepancy between the estimated and the "true" plant model is sufficiently small, the matrices Γ and Θ will respectively be sufficiently close to zero and to a diagonal matrix to guarantee a satisfactory operation of the residual generator.

V. CONCLUSION

We have analyzed the problem of residual generation for an unstable plant, and we have proved that it cannot be solved for such a plant (as soon as there is a slight modeling uncertainty), unless the

plant is stabilized by an adequate controller. This is due to the fact that the unstable modes of the plant cannot be made unobservable from the residual when the model is not exactly known. As a by-product, we have obtained expressions such as (27) and (30), which could be used to quantify the effect of modeling uncertainties on the performance of a residual generator.

For the sake of simplicity, the results are stated and proved for the extension of the fundamental problem of residual generation, and when the number of failures, q , is equal to the number of measurements, p . In the presence of modeling uncertainties, however, the asymptotic stability of the plant model is also required to be able to solve the fundamental problem of residual generation defined in [8]. As this is the basic problem for the design of a residual generator for any coding set, one deduces that the above stability requirement is also necessary when $q > p$. Yet, in this case one cannot isolate simultaneous failures [8].

Zeros of Discretized Continuous Systems Expressed in the Euler Operator—An Asymptotic Analysis

Addisu Tesfaye and Masayoshi Tomizuka

Abstract—The structure of the zeros of SISO continuous-time systems, which are discretized via a zero-order hold and expressed in the Euler operator, is studied. In particular, it will be shown that when state-space descriptions of linear SISO continuous-time systems with relative degree ≥ 2 are discretized, then the zero dynamics of the resulting discrete system is singularly perturbed and shows a separation of time scale. The part of the zero dynamics associated with the fast time scale is shown to correspond to the zeros introduced by the sampling process (sampling zeros). An asymptotic formula for this part of the zero dynamics is given, and implications of the result to control design based on pole zero cancellation is discussed.

I. INTRODUCTION

In the design of linear control systems, the existence of unstable zeros makes it difficult to construct some control procedures, such as inverse systems, model matching systems, and model reference adaptive controllers [6]. Furthermore, it restricts the control ability of robust controllers [18]. When we use conventional digital control (i.e., z operator) with zero-order hold (ZOH) input, zeros appear in the discrete-time model even though the continuous-time system is minimal phase [1]. These zeros are commonly referred to in the literature as sampling zeros because they arise from the sampling process. Whether these zeros are stable (minimum phase) or unstable (nonminimum phase) depends mainly on the sampling interval T . Generally at fast sampling rates, the sampling zeros appear outside or on the unit circle while at slower sampling speeds they are stable. This poses a paradox for control engineers since generally a sufficiently small sampling interval T is desired from the control point of view, while the sampling zeros tend to become unstable as T becomes smaller.

Many researchers have sought to address this problem by different techniques. Hagiwara and Araki [3] have proposed a multirate sampling scheme which requires n times sampling between a sample period where n is the order of the plant such that the resulting discrete-time system has no finite zeros. A similar double-delay scheme proposed by Mita *et al.* [10] where control input or output measurements are taken twice in one sampling interval also constructs a discrete-time model with no finite zeros. Such controllers inevitably require intersample control or measurement which makes the design of the control systems comparatively difficult or requires additional hardware. Kabamba [5] has proposed the idea of using generalized sampled data hold functions (GSHF) where the input matrix of the discrete-time model can be chosen freely and hence can avoid the unstable sampling zero problem. While this idea has potential advantages, it seems difficult to generate continuous-time hold functions by a digital computer, although they can be approximated by fast input samplers. Other researchers have sought instead to cope with the unstable sampling zeros by compensating for their effects. Notable among such works is the zero phase error tracking control (ZPETC) proposed by Tomizuka [16]. For constructing inverse systems such as in feedforward applications or model reference control, the essential idea behind ZPETC is direct cancellation of all stable zeros and

compensation for the effects of unstable zeros by phase cancellation over all frequencies while making the overall gain approximately equal to one over a desired frequency range.

Recently, one simple and more direct way of overcoming the unstable sampling zero problem has been developed by Middleton and Goodwin [2], [9]. They propose to use an operator called the delta operator ($\delta = \frac{q-1}{T}$ where q is the shift operator in the time domain). In the frequency domain an equivalent operator called the Euler operator can be similarly defined as $\epsilon = \frac{z-1}{T}$ where z is the conventional z operator for discrete-time models written in difference equation form. One major advantage of using these operators is that the dichotomy between results obtained using continuous and discrete-time control laws are resolved especially in regards to the limiting properties as $T \rightarrow 0$ [9]. Furthermore, the zeros arising from sampling are easily distinguished if these operators are utilized. In [2] these authors recommend that the sampling zeros which are unstable for the T selected be ignored if the sampling interval T is sufficiently small. Although ignoring the zeros introduces an error in the discrete-time model, experimental tests on electromechanical systems [2] and electrohydraulic systems [4] indicate that the resulting adaptive control law give excellent performances. Tesfaye and Tomizuka have also applied this procedure successfully in the model reference tracking control of a single axis NSK direct drive robot arm [14], [15].

In this paper we seek to address the structure of the zeros of discretized linear continuous systems modeled by $\delta(\epsilon)$ operators. In particular it will be shown that, under sampling of a continuous linear single-input/single-output (SISO) time system of relative degree ≥ 2 , the resulting δ model system can be regarded as a regular perturbation of the underlying continuous-time system if the sampling interval is considered as a parameter but that the zero dynamics is singularly perturbed i.e., exhibits two-time scales. The conclusion is that the finite sampling zeros become infinite as $T \rightarrow 0$ while the rest of the zeros tend as a set to the zeros of the underlying continuous-time system. An example depicting the behavior of the zeros for a hypothetical continuous-time system is included to substantiate our results.

II. SISO CONTINUOUS-TIME SYSTEM

We investigate linear SISO systems of the form

$$\begin{aligned}\dot{x} &= A_c x + b_c u \\ y &= c_c^T x \quad x \in \mathbb{R}^n, \quad u, y \in \mathbb{R}\end{aligned}\quad (1)$$

Assume (1) is minimal (both controllable and observable) and has relative degree $\gamma \geq 2$ i.e.,

$$\begin{aligned}c_c^T A_c^{i-1} b_c &= \cdots = c_c^T A_c^{\gamma-1} b_c = 0 \\ c_c^T A_c^{\gamma-1} b_c &\neq 0.\end{aligned}\quad (2)$$

Remark: The case where $\gamma \geq 2$ is considered because continuous-time systems give rise to discrete-time models having nonminimum phase zeros only when the relative degree is greater than one [1]. To characterize the zero dynamics of (1) we transform it into normal form by means of the following change of coordinates

$$[\zeta, \eta]^T = [c_c^T, (c_c A_c)^T, \dots, (c_c A_c^{\gamma-1})^T]^T x \quad (3)$$

where $\zeta \in \mathbb{R}^\gamma$, $\eta \in \mathbb{R}^{n-\gamma}$ and H must be selected so that L_c is nonsingular. For simplicity we will choose H such that $H b_c = 0$. The system description (1) can then be rewritten in terms of the new

IEEE Log Number 9408798.

coordinates as

$$\begin{aligned}\dot{\zeta}_{i,1} &= \zeta_{i,2}, \dot{\zeta}_{i,2} = \zeta_{i,3}, \dots, \dot{\zeta}_{i,\gamma-1} = \zeta_{i,\gamma} \\ \dot{\zeta}_{i,\gamma} &= R_{\zeta}\zeta_i + S_{\eta}\eta_i + cA_i^{\gamma-1}b_i u \\ \dot{\eta}_i &= P_{\zeta}\zeta_i + Q_{\eta}\eta_i\end{aligned}\quad (4)$$

where $R_{\zeta}^{(i)} \in \mathbb{R}^{\gamma}$, $S_{\eta}^{(i)} \in \mathbb{R}^{n-\gamma}$, $P_{\zeta}^{(i)} \in \mathbb{R}^{(n-\gamma) \times \gamma}$ and $Q_{\eta}^{(i)} \in \mathbb{R}^{(n-\gamma) \times (n-\gamma)}$. $R_{\zeta}\zeta_i + S_{\eta}\eta_i = cA_i^{\gamma}x$, $Q_{\eta}\eta_i + P_{\zeta}\zeta_i = HA_i x$. Equation (4) expresses (1) in normal form, and it is well known that Q_{η} is a companion matrix whose $n - \gamma$ eigenvalues are precisely the zeros of system (1).

III. SAMPLED DATA SYSTEM IN δ FORM

The sampled ZOH representation of system (1) can be written in δ ($\delta = \frac{T}{T}$ where q is the shift operator) form as

$$\begin{aligned}\delta x(k) &= A_{\delta}x(k) + b_{\delta}u(k) \\ y &= c x(k)\end{aligned}\quad (5)$$

where $A_{\delta} = A_c + TA_1$, $b_{\delta} = b_c + Tb_1$

$$\begin{aligned}A_1 &= \frac{1}{2!}A_c^2 + \frac{T}{3!}A_c^3 + \dots + \frac{T^{k-2}}{k!}A_c^{k-1} + \dots \\ b_1 &= \left(\frac{1}{2!}A_c + \frac{T}{3!}A_c^2 + \dots + \frac{T^{k-1}}{(k+1)!}A_c^k + \dots \right) b_c.\end{aligned}$$

Notice that if we regard the sampling time, T , as a perturbation parameter, A_{δ} , b_{δ} can be considered as regular perturbations of A_c and b_c , respectively. Further based on the assumption of minimality of (1) we conclude that (5) remains minimal for T small. Consider a transformation of (5) to normal coordinates

$$\begin{aligned}[\zeta^T \eta^T]^T &= \\ &\underbrace{\left[c^T, (c(A_c + TA_1))^T, \dots, (c(A_c + TA_1)^{\gamma-1})^T, H^T \right]^T}_{L} x.\end{aligned}\quad (6)$$

Again notice that matrix L of the above equation is a regular perturbation of matrix L_c of (3) and that $\det(L) \neq 0$ for T sufficiently small. Let

$$A_1 = A_c A_1^*, \quad b_1 = b_1^* b_c$$

where

$$\begin{aligned}A_1^* &= \frac{1}{2!}A_c + \frac{T}{3!}A_c^2 + \dots + \frac{T^{k-2}}{k!}A_c^{k-1} + \dots \\ b_1^* &= \frac{1}{2!}A_c + \frac{T}{3!}A_c^2 + \dots + \frac{T^{k-2}}{k!}A_c^{k-1} + \dots\end{aligned}$$

i.e.,

$$\begin{aligned}A_1^* &= b_1^* \\ A_c + TA_1 &= A_c (I + Tb_1^*) \\ b_c + Tb_1 &= (I + Tb_1^*) b_c.\end{aligned}$$

In the subsequent analysis we will repeatedly use the properties given by (2) of the underlying continuous system (1). Considering the transformation of b_{δ} we have for each row of Lb_{δ}

$$\begin{aligned}0) \quad c(b_c + Tb_1) &= T^{\gamma-1}\alpha_0 + T^2\{\cdot\}\end{aligned}$$

where

$$\alpha_0 = \frac{1}{\gamma!}cA_c^{\gamma-1}b_c.$$

1)

$$\begin{aligned}c(A_c + TA_1)(b_c + Tb_1) &= cA_c(I + Tb_1^*)^2 b_c \\ &= T^{\gamma-1}\alpha_{11} + T^{\gamma-2}\alpha_{12} + T^2\{\cdot\}\end{aligned}$$

where

$$\alpha_{11} = \frac{2}{\gamma!}cA_c^{\gamma}b_c, \quad \alpha_{12} = \frac{2}{(\gamma-1)!}cA_c^{\gamma-1}b_c.$$

2)

$$\begin{aligned}c(A_c + TA_1)^2(b_c + Tb_1) &= cA_c^2(I + Tb_1^*)^3 b_c \\ &= T^{\gamma-2}\alpha_{21} + T^{\gamma-1}\alpha_{22} + T^2\{\cdot\}\end{aligned}$$

where

$$\alpha_{21} = \frac{3}{(\gamma-1)!}cA_c^{\gamma}b_c, \quad \alpha_{22} = \frac{3}{(\gamma-2)!}cA_c^{\gamma-1}b_c.$$

⋮

• i)

$$\begin{aligned}c(A_c + TA_1)^i(b_c + Tb_1) &= cA_c^i(I + Tb_1^*)^{i+1} b_c \\ &= T^{\gamma-i}\alpha_{i1} + T^{\gamma-i+1}\alpha_{i2} + T^2\{\cdot\}\end{aligned}$$

where

$$\alpha_{i1} = \frac{(i+1)}{(\gamma-i+1)!}cA_c^{\gamma}b_c, \quad \alpha_{i2} = \frac{(i+1)}{(\gamma-i)!}cA_c^{\gamma-1}b_c.$$

• (i-1)

$$\begin{aligned}c(A_c + TA_1)^{\gamma-1}(b_c + Tb_1) &= cA_c^{\gamma-1}\left(b_c + \frac{\gamma T}{2}A_1 b_c\right) \\ &\quad + O(T^2)\end{aligned}$$

Also

$$H(b_c + Tb_1) = \frac{T}{2}HA_c + O(T^2)$$

The expression $T^2\{\cdot\}$ denotes some function which we drop because it will not affect the asymptotic solutions to be developed. Even after dropping the expression $T^2\{\cdot\}$ we note, from the above, that the first $\gamma - 2$ rows of Lb_{δ} have coefficients which are at least of order $O(T^1)$. At this stage, in view of facilitating an asymptotic analysis which: 1) captures the overall behavior without sacrificing the structure of Lb_{δ} , and 2) avoids a cumbersome analysis involving a multiplicity of time scales, we replace the first $\gamma - 2$ rows of Lb_{δ} by bounding functions of the form $T\alpha'_0, T\alpha'_1, \dots, T\alpha'_{\gamma-3}$ where the α'_i 's are independent of T . For example, a particular choice for the α'_i 's is $\alpha'_0 = \alpha_0, \alpha'_1 = \alpha_{11} + \alpha_{12}, \alpha'_{\gamma-3} = \alpha_{(\gamma-3)1} + \alpha_{(\gamma-3)2}$. The above simplification will not affect the final conclusions and is justified because we seek asymptotic solutions. Taking this into consideration, a simplified expression which captures the behavior of Lb_{δ} (with respect to T) can be expressed as

$$\begin{bmatrix} T\alpha'_0 \\ T\alpha'_1 \\ \vdots \\ T\alpha'_{\gamma-3} \\ T^{\frac{\gamma-1}{2}}cA_c^{\gamma-1}b_c \\ cA_c^{\gamma-1}(b_c + \frac{\gamma T}{2}A_1 b_c) \\ \frac{T}{2}HA_c \end{bmatrix} \quad (7)$$

Note that if $T = 0$, the above matrix equals $L_c b_c$, the transformed continuous-time input matrix (i.e., applying (2) and (3)). It is obvious from this last expression that if we transform system (5) into normal

form by means of the transformation given by (6) the feedback law

$$u = \frac{-1}{T\alpha'_0} \zeta_2 = \frac{-1}{T\alpha'_0} c(A_c + T A_1)x \quad (8)$$

makes

$$y(k) = \delta y(k) = 0$$

and that the zero dynamics subspace is

$$\begin{aligned} \nu &= \{x: y = cx = 0\} \\ &= \{(0, \bar{\zeta}, \eta) : \bar{\zeta}^T = [\bar{\zeta}_1 \ \bar{\zeta}_2 \ \cdots \ \bar{\zeta}_{\gamma-1}] \\ &\quad \in \mathbb{R}^{\gamma-1}, \eta \in \mathbb{R}^{n-\gamma}\}. \end{aligned}$$

It should be noted that ζ has been decomposed as $\zeta^T = [\zeta_1 \ \bar{\zeta}^T]$ i.e., in the last expression $\bar{\zeta}_1 = c(A_c + T A_1)x$, $\zeta_2 = c(A_c + T A_1)^2 x$, \dots , $\bar{\zeta}_{\gamma-1} = c(A_c + T A_1)^{\gamma-1} x$. The most important thing to observe from (7) is that all the entries of the matrix are multiplied by the sampling time T except for the one next to the last row block. On the subspace ν , the dynamics, under the feedback law (8), is given by

$$\begin{aligned} \delta \zeta(k) &= \begin{bmatrix} \frac{-\alpha'_1}{\alpha'_0} & 1 & 0 \\ \frac{\alpha'_2}{\alpha'_0} & 0 & 1 & 0 \\ \vdots & & & \\ \frac{\alpha'_{\gamma-1}}{\alpha'_0} & 0 & & 1 \\ -\frac{(c A_c^{\gamma-1} b_c)}{2\alpha'_0} & & & & 1 \\ \frac{(c A_c^{\gamma-1} b_c + \frac{\gamma-1}{2} \alpha'_1 b_c)}{T\alpha'_0} + r_2 & r_1 & \cdots & \cdots & r_{\gamma-1} \end{bmatrix} \bar{\zeta}(k) \\ &+ \begin{bmatrix} 0 \\ \vdots \\ \vdots \\ 0 \\ s \end{bmatrix} \eta(k) \quad (9) \end{aligned}$$

$$\delta \eta(k) = \left[\left(p_2 - \frac{H A_c}{2\alpha'_0} \right) p_1 \ \cdots \ p_{\gamma-1} \right] \bar{\zeta}(k) + Q_\eta \eta(k). \quad (10)$$

In the above $r_2, r_1, \dots, r_{\gamma-1}, s, p_2, p_1, \dots, p_{\gamma-1} \in \mathbb{R}$. From the above expression, for a sampling time $T \neq 0$, we observe that the ZOH equivalent representations of continuous-time systems expressed in the Euler (ϵ) operator will have relative degree one regardless of the relative degree of the underlying continuous-time system. This means that such representations always lead to $n-1$ zeros. These zeros are composed of: 1) $n-\gamma$ zeros which are due to the continuous-time system, and 2) $\gamma-1$ zeros which are a consequence of the sampling

process. The latter zeros are commonly referred to as sampling zeros. To establish the structure of the sampling zeros we note from (9) that the T dependent term corresponding to $\delta \bar{\zeta}_{\gamma-1}(k)$ (i.e., last row of $\delta \bar{\zeta}(k)$) is of the order of $1/T$ and thus is not a regular perturbation but rather a singular perturbation. This singular perturbation is due to the high-gain form of the feedback control (8) (division by T). High-gain systems arising from small regular perturbations have been investigated by many researchers in particular in [12] and [17] in continuous-time systems and by Rao and Naidu in discrete-time systems [11]. More recently Sastry and Hauser [13] have investigated the appearance of such singular perturbations arising from regular perturbations in both linear and nonlinear systems. The following conclusion is analogous to Theorem 2.1 of [13].

Theorem 1 Consider a continuous-time system of the form (1) and its ZOH equivalent representation given by (5) which is expressed by means of the δ operator. Then if system (1) has relative degree γ , system (5) has $n-1$ zeros which according to their asymptotic behavior as $T \rightarrow 0$ belong to two groups:

- 1) The $\gamma-1$ sampling zeros tend to ∞ asymptotically as

$$\left(\frac{-1}{T} \frac{c A_c^{\gamma-1} b_c}{\alpha'_0} \right)^{\frac{1}{\gamma-1}}.$$

- 2) The remaining $n-\gamma$ zeros tend to zeros of the continuous-time system given by (1).

Proof. The proof is straightforward if we can cast (9) and (10) into a standard singular perturbation form. This can be accomplished by rescaling $\bar{\zeta}$ in the following manner. Denote

$$\begin{aligned} z_1 &= \bar{\zeta}_1, \quad z_2 = T^{\frac{1}{\gamma-1}} \bar{\zeta}_2, \quad z_3 = T^{\frac{2}{\gamma-1}} \bar{\zeta}_3 \\ z_i &= T^{\frac{i-1}{\gamma-1}} \bar{\zeta}_i, \quad \dots, \quad z_{\gamma-1} = T^{\frac{\gamma-2}{\gamma-1}} \bar{\zeta}_{\gamma-1}. \end{aligned}$$

This expresses a transformation (rescaling) of (9) and (10) which can be written in matrix form as

$$\begin{bmatrix} \bar{\zeta} \\ \eta \end{bmatrix} = M \begin{bmatrix} z \\ \eta \end{bmatrix} \quad (11)$$

where

$$\begin{aligned} M &= \begin{bmatrix} M_1 & M_2 \\ M_3 & M_4 \end{bmatrix} \\ M_1 &= \begin{bmatrix} 1 & 0 \\ 0 & T^{\frac{1}{\gamma-1}} & & \\ & T^{\frac{2}{\gamma-1}} & 0 & \\ & 0 & \ddots & \\ & & & T^{\frac{\gamma-2}{\gamma-1}} \end{bmatrix} \\ M_2 &= 0_{(\gamma-1) \times (n-\gamma)}, \quad M_3 = 0_{(n-\gamma) \times (\gamma-1)} \\ M_4 &= I_{(n-\gamma) \times (n-\gamma)}. \end{aligned}$$

$$\begin{aligned} T^{\frac{1}{\gamma-1}} \delta z_1(k) &= -T^{\frac{1}{\gamma-1}} \frac{\alpha'_1}{\alpha'_0} z_1(k) + z_2(k) \\ T^{\frac{1}{\gamma-1}} \delta z_2(k) &= z_1(k) + O(T^{\frac{2}{\gamma-1}}) \\ &\vdots \\ T^{\frac{1}{\gamma-1}} \delta z_{\gamma-2}(k) &= z_{\gamma-1}(k) + O(T^{\frac{\gamma-2}{\gamma-1}}) \\ T^{\frac{1}{\gamma-1}} \delta z_{\gamma-1}(k) &= \frac{-c A_c^{\gamma-1} b_c}{\alpha'_0} z_1(k) + T^{\frac{1}{\gamma-1}} r_\gamma z_{\gamma-1}(k) + \\ &\quad -T \left(\frac{\gamma T}{2} \frac{c A_c^{\gamma-1} b_c}{\alpha'_0} + r_2 \right) z_1(k) + T^{\frac{\gamma-2}{\gamma-1}} r_3 z_2(k) + \cdots + T^{\frac{\gamma-1}{\gamma-1}} r_{\gamma-1} z_{\gamma-2}(k) + T s \eta(k) \\ &\quad \underbrace{\hspace{10em}}_{O(T^{\frac{\gamma-1}{\gamma-1}})} \end{aligned}$$

Fig. 1. Singularly perturbed (two-time scale) zero dynamics.

For simplicity let us express (9) and (10) as

$$\begin{aligned}\delta\tilde{\zeta}(k) &= A_1\tilde{\zeta}(k) + A_2\eta(k) \\ \delta\eta(k) &= A_3\tilde{\zeta}(k) + A_4\eta(k).\end{aligned}\quad (12)$$

Combining (11) and (12) we can write (9) and (10) in terms of the new state variables as

$$\begin{bmatrix} \delta z(k) \\ \vdots \\ \delta\eta(k) \end{bmatrix} = \begin{bmatrix} M_1 A_1 M_1^{-1} & M_1 A_2 \\ A_3 M_1^{-1} & A_4 \end{bmatrix} \begin{bmatrix} z(k) \\ \vdots \\ \eta(k) \end{bmatrix}\quad (13)$$

$$M_1 A M_1^{-1} = \begin{bmatrix} \frac{-\alpha'_1}{\alpha'_0} & T^{\frac{-1}{\gamma-1}} & 0 \\ -T^{\frac{-1}{\gamma-1}} \frac{\alpha'_2}{\alpha'_0} & 0 & T^{\frac{-1}{\gamma-1}} & 0 \\ -T^{\frac{-2}{\gamma-1}} \frac{\alpha'_3}{\alpha'_0} & 0 & 0 & \ddots \\ \vdots & & \vdots & T^{\frac{-1}{\gamma-1}} \\ -T^{\frac{-\gamma}{\gamma-1}} \{\bar{r}_2 + r_2\} & T^{\frac{-1}{\gamma-1}} r_3 & T^{\frac{-4}{\gamma-1}} r_4 & \cdots & r_\gamma \end{bmatrix} \tilde{\zeta}(k)$$

$$\bar{r}_2 = \frac{c A_i^{\gamma-1} (b_i + \frac{\gamma}{2} A_i b_i)}{T \alpha'_0}.$$

Equivalently we have the equation found at the bottom of the previous page. Note that $M_1 A_2 = T^{\frac{\gamma-1}{\gamma-1}} \bar{s}$ and (13) can be concisely written as

$$\begin{bmatrix} T^{\frac{-1}{\gamma-1}} \delta z(k) \\ \delta\eta(k) \end{bmatrix} = \begin{bmatrix} W_1 & 0 \\ \tilde{P} & Q \end{bmatrix} \begin{bmatrix} z(k) \\ \eta(k) \end{bmatrix} + \begin{bmatrix} T^{\frac{-1}{\gamma-1}} W_2 z(k) \\ 0 \end{bmatrix} + \begin{bmatrix} O(T^{\frac{-4}{\gamma-1}}) \\ 0 \end{bmatrix}\quad (14)$$

$$\tilde{P} = A_1 M_1^{-1}$$

where

$$W_1 = \begin{bmatrix} 0 & 1 & 0 & & 0 \\ 0 & 0 & 1 & & 0 \\ & & & \ddots & \\ & & & 0 & 1 \\ \frac{-c A_i^{\gamma-1} b_i}{\alpha'_0} & 0 & \cdots & 0 & 0 \end{bmatrix}$$

$$W_2 = \begin{bmatrix} \frac{-\alpha'_1}{\alpha'_0} & 0 & & & \\ 0 & 0 & & & \\ & & & \ddots & \\ & & 0 & & 0 \\ 0 & \cdots & 0 & & r_\gamma \end{bmatrix}.$$

From the above, (14) is observed to be in the standard two-time scale form of [7]. Its right-hand side is regularly perturbed by the term $T^{\frac{-1}{\gamma-1}} W_2$, while the matrix of the unperturbed part is block lower triangular. This unperturbed matrix is nonsingular as required for a standard two-time scale form. It follows that the eigenvalues of (9) are asymptotically

$$(T^{\frac{-1}{\gamma-1}} \lambda(W_1)) \cup \lambda(Q_\eta)$$

Fig. 2. Pole/zero variation with respect to sampling time

$$(T^{\frac{-1}{\gamma-1}} \lambda(W_1)) = \left(\frac{-1}{T} \frac{c A_i^{\gamma-1} b_i}{\alpha'_0} \right)^{\frac{-1}{\gamma-1}} \quad (15)$$

where (15) is the asymptotic expression of the $\gamma - 1$ sampling zeros which tend to ∞ as $T \rightarrow 0$. This completes the proof of part 1) of the theorem. To prove part 2) observe that from (14) the remaining $n - \gamma$ zeros tend as a set to the eigenvalues of (Q_η) which are the zeros of the underlying system. Following the standard two-time scale form of [7] we can depict the behavior of the zero dynamics of system (5) as composed of a fast and a slow subsystem as follows (the external inputs characterize the effect of initial conditions).

Remark: Theorem 1 states that $\gamma - 1$ sampling zeros become infinite as $T \rightarrow 0$. Moreover one can deduce that the sampling zeros move in specific directions as determined by (15). The consequence of Theorem 1 is that sampling zeros of discrete-time models expressed in the $\delta(\epsilon)$ operator are located far off in the right- or left-half planes for sufficiently small sampling times and hence are slightly nonminimum phase. This supports the recommendation made by Goodwin *et al.* [2] to discard the unstable sampling zeros if T is sufficiently small.

IV. ILLUSTRATIVE EXAMPLE

The following example is taken from [8]. Consider the following transfer function of a continuous-time system

$$G(s) = \frac{s^2 + s + 1}{s(s+1)(s^2+4)}.$$

The system has relative degree two with zeros located at $\{-0.5 \pm 0.866j\}$ while the poles are at $\{0, \pm 2j, -1\}$. Fig. 1 portrays the influence of the sampling time, T , on the location of the poles and zeros for the delta and shift operator (z) models. We notice for the delta model that the sampling zero departs to $-\infty$ as $T \rightarrow 0$ while the rest of the poles and zeros converge to the continuous-time poles and zeros, respectively. This behavior supports Theorem 1 above which predicts that the sampling zero goes to $-\frac{2}{T}$ since in this case $\alpha'_0 = \alpha_0 = \frac{1}{\gamma} cA^{-1}b$. For the shift operator model we notice that the zero introduced by sampling remains fixed around -1 while the rest of the poles and zeros converge to one on the real axis irrespective of the locations of the poles and zeros of the underlying continuous-time system. To give an indication of the behavior of the sampling zero in the delta model we calculate for $T = 0.1, 0.07, 0.04, 0.01$, and 0.001 secs. the location of the zero at $-20, -28.6, -50, -200$, and -2000 , respectively. The numerical data validates Theorem 1 since the sampling zero goes to $-\frac{2}{T}$.

V. CONCLUSION

The effect of the sampling time on the zero dynamics of continuous linear SISO systems expressed in the δ operator has been investigated. It is shown that as the sampling time tends to zero that the $\gamma - 1$ zeros introduced by sampling (sampling zeros) migrate to negative infinity while the remaining $n - \gamma$ zeros converge uniformly to that of the underlying continuous-time system. From this we can conclude that under fast sampling, i.e., as $T \rightarrow 0$, one can neglect the sampling zeros (which are easily distinguished). This conclusion is important for control systems constructed based on system inversion and/or model reference control systems especially when the dynamics of the plant are imperfectly known.

Further Theoretical Results on Direct Strain Feedback Control of Flexible Robot Arms

Zheng-Hua Luo and Baozhu Guo

Abstract—This paper is concerned with stability analyses for some nonstandard second-order partial differential equations arising from direct strain feedback control of flexible robot arms. Exponential stability issues are addressed for three types of differential equations, one of which is in general abstract evolution equation form and the other two are in partial differential equation form. The obtained results are of especially theoretical interest because they reveal the essence of direct strain feedback control and demonstrate its power in control of flexible arms.

I. INTRODUCTION

We consider the following initial-boundary problem

$$\begin{aligned} \ddot{w}(t, x) + u''''(t, x) + kx\dot{w}(t, 0) &= 0 \\ w(t, 0) &= w'(t, 0) = 0 \\ u''(t, t) &= u'''(t, t) = 0 \end{aligned} \quad (1)$$

$$w(0, x) = w_0(x), \quad \dot{w}(0, x) = w_1(x), \quad x \in (0, l).$$

Equation (1) represents a closed-loop dynamic equation of a single-link flexible arm with the so-called direct strain feedback (DSFB) control [9], [10]. The symbol $w(t, x)$ denotes the arm's bending vibration deflection at time t and position x ; \ddot{w} and u'''' represent time and spacial derivatives of w , respectively. The symbols l and $k > 0$ are, respectively, the length of the arm and strain feedback gain. $w_0(x)$ and $w_1(x)$ are respectively initial position and initial velocity of flexible arms. Originally, the dynamic model of a single-link flexible arm rotating in the horizontal plane by a control motor is given by the following partial differential equation

$$\ddot{w}(t, x) + u''''(t, x) = -x\ddot{\theta}(t)$$

together with the same initial and boundary conditions as in (1), where $\ddot{\theta}(t)$ represents motor rotating acceleration [16]. Note that here a nonlinear term $x\ddot{\theta}(t)^2 w(t, x)$ which should appear on the right-hand side of the above equation, is neglected to obtain a linear model, as in most literature [1] and [16]. The simple yet efficient DSFB control

is to control the motion of the motor in such a way that $\ddot{\theta}(t)$ is proportional to $\dot{w}''(t, 0)$. This objective is easily achieved by direct feedback of the bending moment $w''(t, 0)$ which can be measured by cementing strain gauge foils at the root end of the arm. The interested reader is referred to [9] and [10] for details.

We are also interested in an equation

$$\begin{cases} \ddot{w}(t, x) + w''''(t, x) + kx\dot{w}''(t, 0) = x(k_1\dot{e}(t) + k_2e(t)) \\ \dot{e}(t) + k_1\dot{e}(t) + k_2e(t) = k\dot{w}''(t, 0) \\ w(t, 0) = w'(t, 0) = w''(t, \ell) = w'''(t, \ell) = 0 \\ w(0, x) = w_0(x), \quad \dot{w}(0, x) = w_1(x) \end{cases} \quad (2)$$

which arises from simultaneous vibration/motion control of flexible arms. More precisely, if we not only control vibration of the arm, but also control the motor position $\theta(t)$, then we can command the motor to move so that $\dot{\theta}(t) = -k_1\dot{e}(t) - k_2e(t) + k\dot{w}''(t, 0)$, where $e(t) (= \theta(t) - \theta_d)$ denotes difference between current motor position $\theta(t)$ and a set-point position θ_d , and $k_1 > 0, k_2 > 0$ are servo feedback gain constants.

Let $H = L^2(0, \ell)$ be the usual square integrable function space, with inner product $\langle \cdot, \cdot \rangle$ and the induced norm $\| \cdot \|$. For later use, let us first introduce an operator A on H as

$$\begin{cases} D(A) = \{w \mid w \in H, w'''' \in H, \\ w(0) = w'(0) = w''(\ell) = w'''(\ell) = 0\} \\ Aw = w'''' \quad \forall w \in D(A) \end{cases}$$

which is known to be positive definite with a compact inverse. Also let us define an operator Π by

$$\Pi w = xw''(0), \quad x \in (0, \ell), \forall w \in D(\Pi).$$

It is obvious that operator Π is neither self-adjoint nor positive definite. It is shown, however, that Π is A -symmetric and A -positive semi-definite [9], [10]. So that Π can be decomposed as $\Pi = Q\dot{A}$ when restricted on $D(A)$, with Q being a bounded, positive semi-definite operator. By making use of these properties of the above mentioned operators, (1) can be written as an abstract equation on H as follows

$$\begin{cases} \ddot{w}(t) + kQ\dot{A}\dot{w}(t) + Aw(t) = 0 \\ w(0) = w_0, \quad \dot{w}(0) = w_1 \end{cases} \quad (3)$$

We say that (1)–(3) are nonstandard since they possess a special damping term $x\dot{w}''(t, 0)$, or equivalently $Q\dot{A}\dot{w}(t)$, which does not appear elsewhere in the existing literature, although some special cases where $Q = I, A^{-1/2}$, or A^{-1} have appeared in [3], [5], and [7].

Let $H_1 = D(A^{1/2}) \times H$ and $H_2 = D(A) \times D(A^{1/2})$. Then H_1 and H_2 are Hilbert spaces when equipped with the following inner products and the corresponding induced norms

$$\begin{aligned} \left\langle \begin{bmatrix} h_1 \\ h_2 \end{bmatrix}, \begin{bmatrix} \tilde{h}_1 \\ \tilde{h}_2 \end{bmatrix} \right\rangle_{H_1} &= \langle A^{1/2}h_1, A^{1/2}\tilde{h}_1 \rangle + \langle h_2, \tilde{h}_2 \rangle \\ \left\langle \begin{bmatrix} h_1 \\ h_2 \end{bmatrix}, \begin{bmatrix} \tilde{h}_1 \\ \tilde{h}_2 \end{bmatrix} \right\rangle_{H_2} &= \langle Ah_1, A\tilde{h}_1 \rangle + \langle A^{1/2}h_2, A^{1/2}\tilde{h}_2 \rangle. \end{aligned}$$

Now let $z(t) = \begin{bmatrix} A^{1/2}w(t) \\ A^{1/2}\dot{w}(t) \end{bmatrix}$. Then (3) can be rewritten as

$$\dot{z}(t) = \tilde{A}z(t)$$

$$z(0) = \begin{bmatrix} A^{1/2}w_0 \\ A^{1/2}w_1 \end{bmatrix}$$

on H_1 , where operator \tilde{A} is defined by

$$\begin{aligned} D(\tilde{A}) = \left\{ h = \begin{bmatrix} h_1 \\ h_2 \end{bmatrix} \mid h_2 \in D(A^{1/2}), A^{1/2}h_1 \right. \\ \left. + kQA^{1/2}h_2 \in D(A^{1/2}) \right\} \end{aligned}$$

$$\tilde{A}h = \begin{bmatrix} I & 0 \\ 0 & -A^{1/2} \end{bmatrix} \begin{bmatrix} 0 & I \\ A^{1/2} & kQA^{1/2} \end{bmatrix} \begin{bmatrix} h_1 \\ h_2 \end{bmatrix},$$

$$\forall h \in D(\tilde{A}).$$

Such defined $D(\tilde{A})$ is dense in H_1 , and \tilde{A} is a closed operator. Thus the adjoint operator \tilde{A}^* of \tilde{A} can be uniquely defined. Moreover, it can be shown that, for any $h \in D(\tilde{A})$ and $h^* \in D(\tilde{A}^*)$, there hold $\langle \tilde{A}h, h^* \rangle_{H_1} \leq 0$ and $\langle \tilde{A}^*h^*, h \rangle_{H_1} \leq 0$. Consequently, there exists a strongly continuous semigroup of contractions $S(t)$ generated by \tilde{A} [4], [14], and for initial conditions w_0 and w_1 satisfying $w_0, w_1 \in D(A)$ and $Aw_0 + kQA^{1/2}w_1 \in D(A^{1/2})$, there exists a unique solution to (3) which can be expressed as

$$\begin{bmatrix} w(t) \\ \dot{w}(t) \end{bmatrix} = T(t) \begin{bmatrix} w_0 \\ w_1 \end{bmatrix} \quad (4)$$

where

$$T(t) = \begin{bmatrix} A^{-1/2} & 0 \\ 0 & A^{-1/2} \end{bmatrix} S(t) \begin{bmatrix} A^{1/2} & 0 \\ 0 & A^{1/2} \end{bmatrix} \quad (5)$$

is a strongly continuous semigroup on H_2 (this is easily verified). Also, it can be shown that the solution is asymptotically stable, if the operator Q is assumed to be positive definite.

It is the purpose of this paper to present some newly obtained stability results for (1)–(3). Specifically, in Section II, we want to show exponential stability of the solution of (3), under the positivity assumption of Q . This assumption can always be satisfied in flexible arm control if we consider the effect of the Kelvin-Voigt damping in arm's dynamics. The motivation of this section is to see whether the exponential stability result can be extended to the (3) which represents a wide class of systems, not just the DSFB controlled systems. For the specific (1), what is theoretically more interesting is whether we can show exponential stability without introducing any natural damping (internal damping in the material). This question is completely answered in Section III where we show exponential stability of (1). The significance of the obtained results is that they reveal the essence of direct feedback control and demonstrate its power in control of flexible arms. Finally, we provide a sufficient condition on feedback gain k_2 to guarantee the stability of (2), since this is a hybrid system in the sense that its state space consists of an infinite dimensional part and a finite dimensional part, and it is very hard to find a Lyapunov function for the entire system.

II. EXPONENTIAL STABILITY OF (3)

In this section, we study the exponential stability of (3) under the assumption that the operator Q is positive definite. This assumption is always satisfied in flexible arm control, if we take into account the effect of the Kelvin-Voigt viscous natural damping in arm's dynamics. An important reason that we want to do analyses here is that (3) may be considered as an abstract equation of a wide class of systems, not just flexible arm systems as described in [10], and there does not exist exponential results for such general abstract equations, although some results have been obtained for some specific boundary controlled partial differential equations [2], [12]. The energy multiplier method proposed by Chen [2] will be adopted.

Let

$$E(t) = \frac{1}{2} \begin{bmatrix} w(t) \\ \dot{w}(t) \end{bmatrix}_{H_2}^2 = \frac{1}{2} \|Aw(t)\|^2 + \frac{1}{2} \|A^{1/2}\dot{w}(t)\|^2 \quad (6)$$

be an energy function for (3). Then its time derivative along solutions of (3) is given by

$$\dot{E}(t) = -k\langle Q\dot{A}\dot{w}(t), A\dot{w}(t) \rangle \leq 0 \quad (7)$$

which means that the energy will be dissipating. Choose a positive constant $0 < \varepsilon < 1$ and define

$$V(t) = 2(1 - \varepsilon)tE(t) + \langle \dot{w}(t), Aw(t) \rangle. \quad (8)$$

Since

$$\langle \dot{w}(t), Aw(t) \rangle \leq \frac{1}{2} (\|A^{-1/2}\|^2 \|A^{1/2} \dot{w}(t)\|^2 + \|Aw(t)\|^2)$$

always holds, there exists a constant C such that

$$(2(1-\varepsilon)t - C)E(t) \leq V(t) \leq (2(1-\varepsilon)t + C)E(t). \quad (9)$$

Obviously $V(t)$ is a positive function for $t > T_1 := C/2(1-\varepsilon)$.

Considering now the time derivative of $V(t)$ along solutions of (3), we obtain

$$\begin{aligned} \dot{V}(t) &= 2(1-\varepsilon)E(t) + 2(1-\varepsilon)t\dot{E}(t) \\ &\quad + \langle \ddot{w}(t), Aw(t) \rangle + \langle \dot{w}(t), A\dot{w}(t) \rangle \\ &= (1-\varepsilon)\|A^{1/2}\dot{w}(t)\|^2 + (1-\varepsilon)\|Aw(t)\|^2 \\ &\quad - 2k(1-\varepsilon)t\langle Q\dot{w}(t), A\dot{w}(t) \rangle \\ &\quad - k\langle Q\dot{w}(t), Aw(t) \rangle - \langle Aw(t), Aw(t) \rangle \\ &\quad + \langle \dot{w}(t), A\dot{w}(t) \rangle \\ &= (2-\varepsilon)\|A^{1/2}\dot{w}(t)\|^2 - \|Aw(t)\|^2 \\ &\quad - 2k(1-\varepsilon)t\langle Q\dot{w}(t), A\dot{w}(t) \rangle \\ &\quad - k\langle Q\dot{w}(t), Aw(t) \rangle. \end{aligned}$$

Denote now $\lambda_{\max}(Q) = \max_{w \in H} \langle Qw, w \rangle$ and $\lambda_{\min}(Q) = \min_{w \in H} \langle Qw, w \rangle$. Then for an arbitrary constant $a \neq 0$, it holds

$$\begin{aligned} -\langle Q\dot{w}(t), Aw(t) \rangle &\leq \lambda_{\max}(Q)\|\dot{w}(t)\|\|Aw(t)\| \\ &\leq \frac{1}{2}\lambda_{\max}(Q)\left(\|\dot{w}(t)\|^2 + \frac{1}{a^2}\|Aw(t)\|^2\right). \end{aligned}$$

Consequently

$$\begin{aligned} \dot{V}(t) &\leq (2-\varepsilon)E(t) + \frac{a^2k}{2}\lambda_{\max}(Q) \\ &\quad - 2k(1-\varepsilon)t\lambda_{\min}(Q)\|\dot{w}(t)\| \\ &\quad - \left(\varepsilon - \frac{k}{2a^2}\lambda_{\max}(Q)\right)\|Aw(t)\|^2. \end{aligned}$$

Since a is arbitrary, it can be chosen to be large enough so that $-\frac{k}{2a^2}\lambda_{\max}(Q) > 0$. Therefore, if we put

$$T_2 = \frac{(2-\varepsilon)\|A^{-1/2}\|^2}{2k(1-\varepsilon)\lambda_{\min}(Q)}$$

then

$$\dot{V}(t) \leq 0, \quad \forall t > T_2.$$

Since $E(t)$ is energy dissipating for $t > 0$ and $V(t)$ is also energy dissipating for $t > T_2$, it is easily verified that for $t > T := \max\{T_1, T_2\}$, $E(t)$ can be estimated as

$$E(t) \leq \frac{V(T)}{2(1-\varepsilon)t - C} \leq \frac{[2(1-\varepsilon)T + C]E(0)}{2(1-\varepsilon)t - C},$$

from which we obtain

$$\int_1^\infty E(t)^2 dt \leq \int_1^\infty \frac{[2(1-\varepsilon)T + C]^2 E(0)^2}{[2(1-\varepsilon)t - C]^2} dt < \infty.$$

Noting that $E(t) = \frac{1}{2} \left\| T(t) \begin{bmatrix} w_0 \\ w_1 \end{bmatrix} \right\|_{H_2}^2$ and $T(t)$ is a strongly continuous semigroup on H_2 , the above relation implies the exponential stability of solutions of (3), by the well-known equivalent property of L^p ($p \geq 1$)-stability and exponential stability for a strongly continuous semigroup system [14, Theorem 4.1]. Thus we have proved the following theorem.

Theorem 1: The solution of (3) is exponentially stable, provided that Q is a bounded, self-adjoint, and positive definite operator.

Remark 1: It is seen that $V(t)$ is a Lyapunov function for $t > T$.

Remark 2: It should be noted that if a solution is exponentially stable for $t > T$, then it is exponentially stable for $t > 0$. To see this, suppose there exists a $T > 0$, independent of the system initial conditions, such that

$$\begin{aligned} \frac{w(t)}{\dot{w}(t)} &\leq M e^{-\delta(t-T)}, \quad t > T, M \geq 1, \delta > 0. \end{aligned}$$

Then, obviously

$$\frac{w(t)}{\dot{w}(t)} \leq \bar{M} e^{-\delta t}, \quad t > 0$$

where $\bar{M} = M e^{\delta T}$.

Remark 3: It has been shown that under positivity assumption of Q , system (3) generates an analytic semigroup, and moreover all the eigenvalues of (3) lie either on the negative real axis or within a circle with center at $(-\frac{1}{\lambda_{\min}(Q)}, 0)$ and radius $\frac{1}{\lambda_{\min}(Q)}$, on a complex plane [6]. Hence the exponential stability is proved, from a different viewpoint.

III. EXPONENTIAL STABILITY OF (1)

In this section, we investigate the exponential stability of (1) which does not include any natural damping. We solve this problem, in this section, by showing that (1) can be equivalently transformed into a boundary control system well studied in the existing literature [2]. To this end, let us introduce a new variable $y(t, x) = u''(t, x)$. If the initial conditions associated with (1) are sufficiently smooth such that the solution admits continuous spacial derivatives up to sixth order, then taking spacial derivative of both sides of (1) twice yields

$$\ddot{y}(t, x) + y''''(t, x) = 0. \quad (10)$$

Also, from the boundary conditions of (1), it is seen that $\ddot{w}(t, 0) = \ddot{w}'(t, 0) = 0$. Therefore, we obtain the following boundary conditions on $y(t, x)$

$$\begin{aligned} \begin{cases} y(t, 0) = w''(t, 0) = 0 \\ y'(t, 0) = w'''(t, 0) = 0 \\ y''(t, 0) = w''''(t, 0) = -\ddot{w}(t, 0) = 0 \\ y'''(t, 0) = w'''''(t, 0) = -\ddot{w}'(t, 0) - k\dot{w}(t, 0) = -k\dot{y}(t, 0). \end{cases} \end{aligned} \quad (11)$$

At this stage, letting $r = t - x$ and noting that

$$\begin{aligned} \frac{\partial y}{\partial x} &= \frac{\partial y}{\partial r} \frac{\partial r}{\partial x} = -\frac{\partial y}{\partial r}, \quad \frac{\partial^2 y}{\partial x^2} = \frac{\partial^2 y}{\partial r^2} \\ \frac{\partial^3 y}{\partial x^3} &= -\frac{\partial^3 y}{\partial r^3}, \quad \frac{\partial^4 y}{\partial x^4} = \frac{\partial^4 y}{\partial r^4} \end{aligned}$$

we get the following direct velocity feedback boundary control system

$$\begin{aligned} \begin{cases} \ddot{y}(t, r) + y''''(t, r) = 0, \quad r \in (0, t) \\ y(t, 0) = 0, y'(t, 0) = 0 \\ y''(t, 0) = 0 \\ y'''(t, 0) = k\dot{y}(t, 0) \end{cases} \end{aligned} \quad (12)$$

which is well studied by Chen [2] and Morgül [12], and the solution is known to be exponentially stable. Since the solution of (1) can be expressed as $w(t, x) = \int_0^t \int_0^x y(r, s) dr ds$, $w(t, x)$ is also exponentially stable. The transformation from w to y indicates an important relation between direct strain feedback control and direct boundary velocity feedback control, which makes us possible to study sufficient conditions for stability of (2), as will be described below.

IV. A SUFFICIENT CONDITION FOR STABILITY OF (2)

This section is devoted to studying the stability of the hybrid (2). Since it consists of two subsystems highly coupled to each other, one possible method to prove stability of the entire system is to find an appropriate Lyapunov function. Unfortunately, it seems very hard to do this, and until now we have not found an appropriate one. So, we

Fig. 1 Block diagram of the transformed closed loop system of (2)

again transform (2) into its corresponding boundary control form and present a sufficient condition for the closed loop stability

Again let $y(t) = u''(t, l)$. By the same way as in the previous section, we can transform (2) into the following form

$$\begin{cases} y(t) + y'''(t) = 0 \\ y(t, 0) = y'(t, 0) = 0 \\ y''(t, l) = 0 \\ y'''(t, l) = -k_1 e(t) - k_2 e(t) + k y(t, l) \\ e(t) + k_1 e(t) + k_2 e(t) = k y(t, l) \end{cases} \quad (13)$$

Now, put

$$z(t) = y(t, l) \quad u_1(t) = -k_1 e(t) - k_2 e(t) \quad u_2(t) = k y(t, l)$$

We obtain a block diagram as shown in Fig. 1. It is interesting to observe that the strain feedback plays a role of an inner loop controller (see the dotted block in Fig. 1) while the motion control part acts as an outer loop controller. Let the transfer function from z to u_1 be denoted by $\bar{K}(s)$. Then

$$\bar{K}(s) = - \frac{k(k_1 s + k_2)}{s^3 + k_1 s + k_2} \quad (14)$$

which is stable and its H^∞ norm $\|\bar{K}(s)\|_\infty$ is easily calculated as

$$\|\bar{K}(s)\|_\infty = \frac{k k_1}{(2\sqrt{k_2^2 + 2k_1^2 k_2^2} + k_1^2 - 2k_2^2 - 2k_1 k_2)^{1/2}} \quad (15)$$

Now, look at the dotted block in Fig. 1 whose transfer function will be denoted by $G(s)$ (note that we do not need the expression of $G(s)$). From the discussion in Section III we know that $G(s)$ is exponentially stable. Hence its H^∞ norm exists.

For direct boundary velocity feedback system

$$\begin{cases} y(t) + y'''(t) = 0 \\ y(t, 0) = y'(t, 0) = 0 \\ y''(t, l) = 0 \\ y'''(t, l) = k y(t, l) + u_1(t) \\ z(t) = y(t, l) \end{cases} \quad (16)$$

there are no existing results on how to calculate the H^∞ norm for the transfer function $G(s)$ from u_1 to z . Here we give an estimation of the upper bound of $\|G\|_\infty$. Taking the inner product of both sides of the first equation in (16) with $y(t, l)$ yields

$$\frac{d}{dt} E(t) + k[y(t, l)]^2 = -u_1(t)y(t, l) \quad (17)$$

where

$$E(t) = \frac{1}{2} \int_0^l ([y(t, l)]^2 + [y''(t, l)]^2) dl$$

represents the total energy stored in (16). Integrating (17) with respect

to t , from 0 to ∞ we obtain

$$k\|z(t)\|_2^2 + \langle u_1(t), z(t) \rangle_2 + E(\infty) - E(0) = 0 \quad (18)$$

where $\langle u_1(t), z(t) \rangle_2 = \int_0^\infty u_1(t) z(t) dt$, $\|z(t)\|_2$ is the induced norm, and

$$F(0) = \frac{1}{2} \int_0^l ([y(0, l)]^2 + [y''(0, l)]^2) dl$$

is the total initial energy. Note that in general $F(\infty)$ is a function of u_1 ; however, $E(\infty) \geq 0$ and for any $\|u_1(t)\|_2 \leq 1$ the upper bound of $F(\infty)$ can be estimated as

$$\begin{aligned} F(\infty) &= E(0) - k\|z(t)\|_2^2 - \langle u_1(t), z(t) \rangle_2 \\ &\leq E(0) - k\|z(t)\|_2^2 + \|z(t)\|_2 \\ &\leq F(0) + \frac{1}{4k} \end{aligned}$$

since the function $f(\|z(t)\|_2) = -k\|z(t)\|_2^2 + \|z(t)\|_2$ attains its maximum value $\frac{1}{4k}$ at $\|z(t)\|_2 = \frac{1}{2k}$. Thus $E(\infty)$ is bounded. So that when u_1 ranges in the unit ball the largest value $\|z(t)\|_2$ satisfying (18) is always smaller than the largest value $\|z(t)\|_2$ satisfying the following inequality

$$k\|z(t)\|_2^2 + \langle u_1(t), z(t) \rangle_2 - F(0) \leq 0 \quad (19)$$

In other words, $\|G(s)\|_\infty$ is small than the largest value $\|z(t)\|_2$ satisfying (19) which will be calculated below.

Let $u_* = \frac{(t)}{\|u_1\|_2}$. It is easy to show that for any u_1 satisfying $\|u_1\|_2 \leq 1$ there holds $\langle u_1, z \rangle_2 \geq \langle u_*, z \rangle_2$ since $\langle u_1, z \rangle_2 \geq -\|u_1\|_2 \|z\|_2 \geq -\|z\|_2 = \langle u_*, z \rangle_2$. So that for any u_1 in the unit ball the largest value that $\|z(t)\|_2$ can achieve is given by the positive root of the following quadratic algebraic equation in $\|z\|_2$

$$k\|z(t)\|_2^2 + \langle u_*(t), z(t) \rangle_2 - F(0) - \|z(t)\|_2 = 0 \quad (20)$$

which is evaluated as

$$\frac{1 + \sqrt{1 + 4kF(0)}}{2k}$$

From this we see that

$$\begin{aligned} \|G(s)\|_\infty &= \sup_{\|u_1\|_2 \leq 1} \|z(t)\|_2 \\ &\leq \frac{1 + \sqrt{1 + 4kF(0)}}{2k} \end{aligned} \quad (21)$$

Since in evaluating transfer function of a linear system the initial conditions are always set to zero we obtain

$$\|G(s)\|_\infty < \frac{1}{k} \quad (22)$$

by setting $E(0) = 0$ in (20). From (15) and (21) we see that

$$\begin{aligned} \|\bar{K}(s)\|_\infty \|G(s)\|_\infty &\leq \frac{k_1^2}{(2\sqrt{k_2^2 + 2k_1^2 k_2^2} + k_1^2 - 2k_2^2 - 2k_1 k_2)^{1/2}} \end{aligned} \quad (23)$$

If the value of the right-hand side of above inequality is less than one then the closed loop stability is implied by the well known small gain theorem. Unfortunately, this is not always the case. To guarantee closed-loop stability however, it is unnecessary to have $\|\bar{K}(s)\|_\infty \|G(s)\|_\infty < 1$ which is quite conservative. Instead, it is sufficient to have

$$|\bar{K}(j\omega)| |G(j\omega)| < 1 \quad (24)$$

for every $\omega \in (-\infty, \infty)$. In general, the low frequency gain of $G(j\omega)$ is very small (near zero) since the output of system (16) is taken to be velocity of $y(t, l)$. On the other hand, the low frequency gain of $\bar{K}(j\omega)$ is approximately one. Thus, if we choose $\sqrt{k_2}$ in such a way that the resonance frequency of $\bar{K}(j\omega)$ is much smaller than that of $G(j\omega)$, then (23) holds for a large range of strain feedback gain k .

It is interesting to note the upper bound $\|K(s)\|_\infty \|G(s)\|_\infty$ of $|K(j\omega)| |G(j\omega)|$ is independent of k , which is particularly useful for feedback design.

Remark 4: For the closed-loop system shown in Fig. 1, if $\|G\|_\infty \|K\|_\infty < 1$, then the closed-loop system is internally exponentially stable [8, Lemma 2.3], since G and K are internally exponentially stable [15]. Under the present condition $|G(j\omega)| |K(j\omega)| < 1$, whether input-output stability implies internal stability remains a problem.

V. CONCLUSION

Some newly obtained stability results have been presented in this paper. Specifically,

- 1) For a general abstract differential equation on a Hilbert space, exponential stability was shown under an additional condition (this condition is equivalent to the existence of a Voigt damping term in dynamic model in the case of control of flexible arms);
- 2) For a DSFB controlled closed-loop equation in partial differential equation form, the exponential stability is verified, which clearly indicates the power of direct strain feedback control of flexible arms and reveals an important relationship between the DSFB control and the energy dissipating direct boundary velocity feedback control;
- 3) For a simultaneous vibration/motion controlled hybrid equation, a sufficient condition for the entire system to be stable is given, which can be used as a guideline in choosing feedback gains in (2).

ACKNOWLEDGMENT

The first author thanks Prof. Y. Inouye for some useful discussions. The authors would also like to thank the anonymous referees for helpful comments.

H^∞ Optimal and Suboptimal Controllers for Infinite Dimensional SISO Plants

Onur Toker and Hitay Özbay

Abstract—This paper presents a simple formula for \mathcal{H}^∞ optimal and suboptimal controllers for unstable SISO distributed plants, with rational weighting functions. The controller is expressed in terms of i) inner and outer parts of the plant, ii) a finite dimensional spectral factor obtained from the weighting functions, and iii) a rational function satisfying certain interpolation conditions. Under certain genericity assumptions, this rational function is of dimension less than or equal to $n_1 + l - 1$ ($n_1 + l$ in the suboptimal case), where l is the number of unstable poles of the plant and n_1 is the order of the sensitivity weighting function. There are $2(n_1 + l)$ ($2(n_1 + l + 1)$ in the suboptimal case) linear equations, which determine this rational function. These linear equations can be written directly from the structure of the controller.

I. INTRODUCTION

In this paper the mixed sensitivity minimization (two-block) problem is considered for a class of infinite dimensional SISO, LTI plants with finitely many unstable poles, with rational weighting functions. The purpose of this paper is to present a formula for \mathcal{H}^∞ optimal and suboptimal controllers. In the one block problem (sensitivity minimization) the \mathcal{H}^∞ optimal performance and controller can be computed by finding the largest singular value, and corresponding singular vector, of an infinite rank Hankel (or "skew Toeplitz") operator. Earlier studies on the one-block problem, for stable infinite dimensional plants, have shown that the computation of singular values and vectors of this infinite rank operator reduces to finding a solution to a set of finitely many linear equations, [12], [5]. In the two block problem, the operator we are dealing with is a "Hankel plus Toeplitz" type, with possibly infinite rank Hankel part. This problem can be reduced to a set of finitely many linear equations; see [7] for the finite dimensional case and [13] for infinite dimensional stable plants case. More recently, these results have been extended to the case where the infinite dimensional plant has finitely many unstable modes; see [8] and [2] for detailed reviews and further references. This paper extends these results to the suboptimal case and gives a simple formula for the optimal controller as well as all suboptimal controllers. Previously it was known (see, e.g., [10], [8] and references therein) how to compute the optimal controller "numerically," by using Youla parameterization and computing the singular values and vectors of the associated infinite rank operator. We follow a similar technique to solve a more general problem. Moreover, we obtain a simple closed form expression for the \mathcal{H}^∞ controllers in terms of inner outer factors of the plant, a spectral factor of the weights, and a rational function to be determined. The set of linear equations, which determines the optimal performance and this rational function, can be written directly from the controller structure.

The rest of this paper is organized as follows. Two block \mathcal{H}^∞ optimal and suboptimal control problems are defined in Section II. Main results are presented in Section III. The proofs can be found in Section IV, and concluding remarks are made in Section V.

II. \mathcal{H}^∞ OPTIMAL AND SUBOPTIMAL MIXED SENSITIVITY

In this paper the plant and the controller are represented by their transfer functions $P(s)$ and $C(s)$, respectively. A system, whose transfer function is $G(s)$, will be said to be stable if $G \in \mathcal{H}^\infty$. Throughout the paper we consider "real" functions only, i.e., $\bar{R}(s) = R(\bar{s})$.

This paper deals with the mixed sensitivity reduction/minimization problem for a given plant $P(s)$ and two rational weighting functions $W_1(s)$ and $W_2(s)$.

Assumptions on the Problem Data: We assume that the plant admits a coprime factorization of the form $P(s) = m_n(s)N_0(s)/m_d(s)$ where $m_d(s) = \prod_{k=1}^l \frac{s - \alpha_k}{s + \alpha_k}$, $\alpha_1, \dots, \alpha_l \in \mathbb{C}_+$, are distinct, and $m_n \in \mathcal{H}^\infty$ is inner (i.e., stable all-pass function, possibly infinite dimensional) and $N_0 \in \mathcal{H}^\infty$ is outer (i.e., stable minimum phase, possibly infinite dimensional). Moreover, the weights are assumed to be rational with $W_1(s)$ being nonconstant and $W_1, (W_2 N_0), (W_2 N_0)^{-1} \in \mathcal{H}^\infty$; see [8] for a detailed discussion on these assumptions, and relations to other types of two block \mathcal{H}^∞ control problems.

The optimal \mathcal{H}^∞ performance is defined by

$$\gamma_0 := \inf_{C \text{ stabilizes } P} \left\| \begin{bmatrix} W_1 S \\ W_2 T \end{bmatrix} \right\|_\infty$$

where $S = (1 + PC)^{-1}$ and $T = PC(1 + PC)^{-1}$ are the sensitivity and complementary sensitivity functions. The condition " C stabilizes P " means that closed-loop transfer functions S , CS , and PS belong to \mathcal{H}^∞ . The optimal \mathcal{H}^∞ controller, denoted by C_{opt} , is the one which stabilizes the plant P , and yields

$$\left\| \begin{bmatrix} W_1(1 + PC_{\text{opt}})^{-1} \\ W_2 PC_{\text{opt}}(1 + PC_{\text{opt}})^{-1} \end{bmatrix} \right\|_\infty = \gamma_0.$$

The suboptimal \mathcal{H}^∞ control problem is to parameterize the set

$$\mathcal{C}_\rho = \left\{ C: C \text{ stabilizes } P, \left\| \begin{bmatrix} W_1 S \\ W_2 T \end{bmatrix} \right\|_\infty \leq \rho \right\} \quad (1)$$

for a given suboptimal performance level $\rho > \gamma_0$.

III. OPTIMAL AND SUBOPTIMAL \mathcal{H}^∞ CONTROLLERS

The main results of the paper are stated in this section. Their proofs are given in Section IV.

Let $\eta_1, \dots, \eta_{n_1} \in \mathbb{C}_+$, $n_1 \geq 1$, be the poles of $W_1(-s)$; if η_i has multiplicity ℓ_i then it is assumed to be repeated ℓ_i times in this list. The zeros of

$$F_\rho(s) := \left(\frac{W_1(-s)W_1(s)}{\rho^2} - 1 \right) \quad (2)$$

are denoted by $\beta_1, \dots, \beta_{2n_1}$, and they are assumed to be distinct for the given ρ . Then, β_i 's can be enumerated in such a way that $\beta_1, \dots, \beta_{n_1}$ are in \mathbb{C}_+ , and $\beta_{n_1+i} = -\beta_i$. Now define

$$G_\rho(s) := G_{\text{opt}}(s) \prod_{k=1}^{n_1} \frac{s - \eta_k}{s + \eta_k} \quad (3)$$

where $G_\rho \in \mathcal{H}^\infty$ is minimum phase and determined from the spectral factorization

$$G_\rho(s)G_\rho(-s) = \frac{W_1(-s)W_1(s)}{\rho^2} - 1 = \frac{W_2(-s)W_2(s)}{\rho^2} - 1 \quad (4)$$

Genericity Assumptions For the given $\rho > \gamma_0$ we assume that β_i 's are distinct and none of them coincide with any of the α_i 's. Furthermore, β_i 's are such that $m_n(\beta_i) \neq 0$, for all $i = 1, \dots, 2n_1$. We also assume that $\gamma_0 > \gamma_{\min}$, where γ_{\min} is the smallest ρ such that the right-hand side of (4) is greater or equal to zero for all $s = j\omega$.

Now, to obtain a parameterization of \mathcal{C}_ρ , pick an arbitrary real number $a > 0$. Then, we have the following formula.

Theorem 1: Consider the suboptimal \mathcal{H}^∞ control problem defined in Section II, and suppose that the above genericity assumptions hold. Then, $C_{\text{subopt}} \in \mathcal{C}_\rho$ if and only if

$$C_{\text{subopt}}(s) = E_\rho(s)m_d(s) \frac{N_0(s)^{-1}F_\rho(s)L_l(s)}{1 + m_n(s)F_\rho(s)L_l(s)} \quad (5)$$

where

$$L_l(s) = \frac{L_2(s) + L_1(-s)U(s)}{L_1(s) + L_2(-s)U(s)}, \quad \text{for some } U \in \mathcal{B}$$

and $L_1(s), L_2(s)$ are polynomials of degree $\leq n_1 + l$ satisfying interpolation conditions

$$0 = L_1(\beta_k) + m_n(\beta_k)F_\rho(\beta_k)L_2(\beta_k) \quad k = 1, \dots, n_1 \quad (6)$$

$$0 = L_1(\alpha_k) + m_n(\alpha_k)F_\rho(\alpha_k)L_2(\alpha_k) \quad k = 1, \dots, l \quad (7)$$

$$0 = L_2(-\beta_k) + m_n(\beta_k)F_\rho(\beta_k)L_1(-\beta_k) \quad k = 1, \dots, n_1 \quad (8)$$

$$0 = L_2(-\alpha_k) + m_n(\alpha_k)F_\rho(\alpha_k)L_1(-\alpha_k) \quad k = 1, \dots, l \quad (9)$$

$$0 = L_2(-a) + (E_\rho(a) + 1)F_\rho(a)m_n(a)L_1(-a) \quad (10)$$

$$1 = L_1(-a). \quad (11)$$

In the above system of equations, $\alpha > 0$ is arbitrary. For different values of α one can obtain different parameterizations of the suboptimal controllers.

Remark 1 The genericity assumption $\gamma_0 > \gamma_{\min}$ is actually not needed for Theorem 1, but it will be necessary for Theorem 2 which deals with the optimum case. Furthermore, in the optimum case the genericity assumptions are assumed to hold for $\rho = \gamma_0$.

Remark 2 If $W_1(s) = n(s)/d(s)$ with $n(s), d(s) \in \mathbb{R}[s]$ ($n(s), d(s) = 1$), $W_1^{-1} \in \mathcal{H}^\infty$ then $\Lambda_1(s) = n(s)n(-s)$ and $D_1(s) = d(s)d(-s)$ are relatively prime. If $\Lambda(s) - \rho^2 D_1(s)$ has a multiple root then at that point $\Lambda' - \rho^2 D_1' = 0$ and hence $D_1 \Lambda' - \Lambda D_1' = 0$. But $D_1 \Lambda' - \Lambda D_1'$ is not identically equal to zero, and hence has only finitely many zeros, so there are at most finitely many ρ values for which the genericity assumption on β is not satisfied. The fact that $D_1 \Lambda' - \Lambda D_1'$ is not identically equal to zero can be shown as follows. Let $\Lambda = Y$ be polynomials such that $\Lambda \Lambda' + Y_1 D_1 = 1$ and assume that $D_1 \Lambda' - \Lambda D_1' = 0$. Then we get $\Lambda_1 D_1 \Lambda' - \Lambda_1 \Lambda D_1' = 0$, $D_1' \Lambda \Lambda' + D_1 Y_1 D_1' = D_1'$ and hence D_1 divides D_1' which is absurd. This contradiction proves that $D_1 \Lambda' - \Lambda D_1'$ is not identically equal to zero, and hence shows that there are at most finitely many ρ value for which the genericity assumption on β is not satisfied.

Theorem 2 Suppose that C_{\min} is unique and γ_0 is the largest singular value of the associated Hankel plus Toeplitz operator defined in the next section. Moreover, suppose that the above genericity assumptions hold for γ_0 . Then

$$C(s) = F(s)m_1(s) \frac{\Lambda_1(s) - I_1(s)I_1(s)}{1 + m_1(s)F_0(s)I_1(s)} \quad (12)$$

where $I = I_1/L_1$ and $I_1(s), I_1(s)$ are nonzero polynomials with degrees less than or equal to $(n_1 + l - 1)$ satisfying (6)–(9) with $\rho = \gamma_0$.

To find C we first find an upper bound, e.g., by taking any stabilizing controller and evaluating its performance. Then we replace ρ with a new parameter in (6)–(9). Note that (6)–(9) can be written as $M\Psi = 0$ where Ψ is a $2(n_1 + l)$ column vector formed by the coefficients of $I_1(s)$ and $I_1(s)$ and M is a square matrix which depends on the parameter ρ . Therefore γ_0 can be found by plotting the smallest singular values of M as ρ varies between an upper and lower bound. The largest value of ρ for which the plot shows a zero is γ_0 (see the below example). In this sense, the algorithm of finding γ_0 is similar to standard iteration ([3], [6], [7]). But here the size of the matrix whose singularity is to be determined is $2(n_1 + l) \times 2(n_1 + l)$ even though the underlying system is infinite dimensional.

Example Let $P(s) = e^{-1}/(s-1)$, $W_1(s) = 2(s+1)/(10s+1)$ and $W_2(s) = 0.2/(s+1)$. In this example $m_1(s) = e^{-1}/(s-1)$, $m_2(s) = (s-\alpha_1)/(s+\alpha_1)$ and $\Lambda_1(s) = 1/(s+L_1)$ where $\alpha_1 = 1$. Note that we need to find $\gamma_0 = F$ and $I(s) = L_1(s)/I_1(s)$ in the controller expression given by (12). Since $n_1 = 1$ and $l = 1$ polynomials $I_1(s)$ and $I_1(s)$ are both first order. Therefore there are four unknown coefficients $\Psi = [I_{10} \ L_{20} \ L_{11} \ L_{11}]^T$ where $L_1(s) = I_{11}s + I_{10}$ and $L_2(s) = L_{21}s + L_{20}$. When $h = 0.2$ it can be shown that $0.2 < \gamma_0 < 1.5$ (see [4] and [9]).

In this case the largest value of γ which makes M_γ singular is $\gamma_0 = 0.6819$. It is obtained from Fig. 1 where the smallest singular value of M_γ is plotted. Once γ_0 is obtained from this plot, a nonzero Ψ_0 , which satisfies $M_{\gamma_0}\Psi_0 = 0$ can be obtained easily. The entries of Ψ_0 give $I(s) = L_2(s)/I_1(s)$ which determine the optimal controller via (12). For the above example $I(s)$ and F_{γ_0} can be computed as

$$I(s) = \frac{s+0.2129}{s-0.2129}, \quad F_{\gamma_0}(s) = \frac{3.566(s-0.1)}{(s+1.265)(s+0.788)}$$

Fig. 1 $\sigma_{\min}(M_\gamma)$ versus γ

For the suboptimal performance level $\rho = 0.7$ we get $F_\rho(s) = \frac{1}{(s+1)} \frac{2(s-1)}{(s+0.2129)}$ and if we choose $\alpha = 2$ then

$$F_\rho(s) = L_{\rho, \alpha}(s) \frac{1 + I(s)/D(s)}{1 + D(s)I(s)}$$

parameterizes all suboptimal controllers via (5) where

$$L_{\rho, \alpha}(s) = 0.96 \frac{(s+1.999)(s+0.2146)}{(s+1.94)(s-0.208)} \\ D(s) = 0.96 \frac{(s-1.999)(s-0.2146)}{(s+1.94)(s-0.208)}$$

We see that for this example $\sigma_{\min}(M_\gamma)$ behaves numerically well, i.e., it is easy to detect γ_0 from Fig. 1. Also note that in the optimal case $I(s)$ is all pass (but possibly unstable) and when ρ is close to γ_0 , $D(s)$ is close to being inner and $L_{\rho, \alpha}(s)$ and $I_\rho(s)$ are close to $I(s)$ of the optimal case.

IV. PROOFS OF THE MAIN RESULTS

Consider the \mathcal{H}^∞ control problems defined in Section II and define $G_r = \Lambda/m \in \mathcal{H}^\infty$ and $G_l = m/l \in \mathbb{RH}^\infty$ then $P = G_r/G_l$ is a coprime factorization. Let $\Lambda, Y \in \mathcal{H}^\infty$ be such that $\Lambda G_r + Y G_l = 1$. All stabilizing controllers are in the form (see [11])

$$C = \frac{\Lambda + Q G_l}{Y - Q G_r} \quad (13)$$

where Q is a free parameter in \mathcal{H}^∞ . Following the notation of [9], define G to be such that $W_1 W_1^* + W_2 W_2^* = G_r G_r^*$ and $G^{-1} \in \mathcal{H}^\infty$. Let $b_1 = b_1 G_r^* W_1 W_1^* \in \mathbb{RH}^\infty$. Then let $W_0 \in \mathbb{RH}^\infty$ be such that $\Lambda = (G_r - \Lambda W_0)/G_l$ and set $Q_1 = G_l W_0 Q + \Lambda$. $G_r = W_1 W_1^* G^{-1} = b_1 m_1 m_1^* = b_1 m_m$. It was shown that [9] the optimal control problem reduces to the computation of

$$\gamma_0 = \inf_{Q_1 \in \mathcal{H}^\infty} \left\| \frac{W_0 - m_1 W_0 - m Q_1}{G_r} \right\|_\infty \quad (14)$$

and determination of Q_{1, γ_0} and the suboptimal control problem reduces to

$$\{Q_1 \in \mathcal{H}^\infty \mid \left\| \frac{W_0 - m_1 W_0 - m Q_1}{G_r} \right\|_\infty \leq \gamma\} \quad (15)$$

The optimal performance γ_0 is the norm of the so-called "Hankel plus Toeplitz" operator $[\Gamma_{\rho(m_1 W_0 - W_0)} \Psi]_{\rho, 2}$ where Ψ_ρ denotes the Toeplitz operator with symbol G_r [8]. Note that $W_0, W_0 - m_1 W_0, G_r$ are stable and rational, and m_1 is inner and possibly infinite dimensional. Now let f be an \mathcal{H}^∞ function such that $f f^* = \gamma^2 - G_r G_r^*$ and $f^{-1} \in \mathcal{H}^\infty$. Note that by genericity assumptions $\gamma_0 > \gamma_{\min}$, and it is easy to show that $\gamma_{\min} = \|G_r\|_\infty$. Define $u_\gamma = W_0/f_\gamma$

$\hat{u}_\gamma = \hat{W}_0/f_\gamma$, and $Q_2 = f_\gamma^{-1}Q_1$. Then γ_0 is the maximum $\gamma > \gamma_{\min}$ value such that one is a singular value of the Hankel operator $\Gamma = \Gamma_{m^*(u_\gamma - m_1 \hat{u}_\gamma)}$, (see, e.g., [8] and references therein), furthermore

$$m^*(u_{\gamma_0} - m_1 \hat{u}_{\gamma_0}) - Q_{2, \text{opt}} = \frac{y_0^*}{x_0} \quad (16)$$

where x_0, y_0 are nonzero \mathcal{H}^2 functions satisfying

$$\Gamma x_0 = y_0^*, \quad \Gamma^* y_0^* = x_0^*. \quad (17)$$

Claim: When $\gamma > \gamma_0$ we have

$$m^*(u_\gamma - m_1 \hat{u}_\gamma) - Q_{2, \text{subopt}} = \frac{y_0^* + z_0 x_0^* U^*}{x_0 + z_0 y_0 U^*}, \quad \begin{matrix} s-a \\ s+a \end{matrix}, \quad U \in \mathcal{B} \quad (18)$$

where x_0, y_0 are \mathcal{H}^2 functions satisfying

$$y_0^* = \Gamma x_0, \quad x_0 = \frac{1}{s+a} + \Gamma^* y_0^*. \quad (19)$$

Proof. Let $V_\gamma(s) = m^*(s)(u_\gamma(s) - m_1(s)\hat{u}_\gamma(s))$ and $v_\gamma(z) = V_\gamma(a \frac{1+z}{1-z})$, for an arbitrary $a > 0$. Note that $\mathcal{S}_\gamma = \{f_\gamma Q_2 \in \mathcal{H}^\infty : \|V_\gamma - Q_2\|_\infty \leq 1\}$. So, to find all such Q_2 's one can find all $q_2 \in \mathcal{H}^\infty(\mathbb{D})$ such that $\|v_\gamma - q_2\|_\infty \leq 1$ and set $Q_2(s) = q_2(\frac{s-a}{s+a})$. The set of all such q_2 's is given by [1]

$$v_\gamma - q_2 = \frac{\mathcal{E}p^* + q^*}{p + \mathcal{E}q}, \quad \mathcal{E} \in \mathcal{B}(\mathbb{D})$$

where $p, q \in \mathcal{H}^2(\mathbb{D})$ such that $(I - \mathbf{F}\Gamma_v \Gamma_v^* \mathbf{F})p = 1$, and $q = \mathbf{S}\Gamma_v^* \mathbf{F}p$ (we use $v = v_\gamma$ whenever the notation is clear from the context).

Set $x(z) = p(z)$, $y(z) = z^{-1}q(z)$, then we have

$$y = \Gamma_v^* \mathbf{F}x, \quad \text{and} \quad x = 1 + \mathbf{F}\Gamma_v y.$$

By defining $x_0(s) = \frac{1}{s+a}x(\frac{s-a}{s+a})$, $y_0(s) = -\frac{1}{s+a}y(\frac{s-a}{s+a})$, we obtain an equivalent set of equations in terms of $x_0, y_0 \in \mathcal{H}^2$

$$y_0^* = \Gamma x_0, \quad x_0 = \frac{1}{s+a} + \Gamma^* y_0^*. \quad (20)$$

Finally, by setting $U(s) = -\mathcal{E}(\frac{s-a}{s+a})$, we obtain (18). \square

In summary, we consider the following system of equations, to find C_{opt} and C_p

$$x_0, y_0 \in \mathcal{H}^2, \quad y_0^* = \Gamma x_0, \quad x_0 = \frac{1}{s+a} + \Gamma^* y_0^*. \quad (21)$$

The suboptimal control problem is equivalent to (21) for $\delta = 1$, i.e., one has to find the unique nonzero x_0, y_0 satisfying (21), and then (18) can be used to obtain all $Q_{2, \text{subopt}}$. The optimal control problem amounts to solving (21) for $\delta = 0$, i.e., one has to find nonzero x_0, y_0 satisfying (21) and then $Q_{2, \text{opt}}$ can be obtained from (18) by setting $U = 0$.

A. On the Solution of x_0 and y_0

Let $u_\gamma = b_\gamma/k_\gamma$, $m_d = A^*/A$ where $b_\gamma, k_\gamma, A \in \mathbb{R}[s]$, $(b_\gamma, k_\gamma) = 1$. Define $n = \deg(k_\gamma)$ and $l = \deg(A)$. It is clear that (21) is equivalent to (22)–(24)

$$x_0, y_0, \phi_1, \phi_2 \in \mathcal{H}^2, \quad (22)$$

$$y_0^* = m^*(u_\gamma - m_1 \hat{u}_\gamma)x_0 + \phi_1, \quad (23)$$

$$x_0 = \frac{\delta}{s+a} + m(u_\gamma^* - m_1^* \hat{u}_\gamma^*)y_0^* + \phi_2^*, \quad (24)$$

Note that (23) implies that $m y_0^* \in \mathcal{H}_+^2$ and (24) implies that $m^*(x_0 - \frac{\delta}{s+a}) \in \mathcal{H}_+^2$, i.e., $m^*x_0 - \frac{\delta m(a)}{s+a} \in \mathcal{H}_+^2$. Since

$$\begin{aligned} \phi_1 + (u_\gamma - m_1 \hat{u}_\gamma) \frac{\delta m(a)}{s+a} \\ = -\mathbf{P}_{\mathcal{H}^2}(u_\gamma - m_1 \hat{u}_\gamma) \left(m^*x_0 - \frac{\delta m(a)}{s+a} \right) \\ = -\mathbf{P}_{\mathcal{H}^2} u_\gamma \left(m^*x_0 - \frac{\delta m(a)}{s+a} \right) \\ + \mathbf{P}_{\mathcal{H}^2} m_d^* \hat{u}_\gamma x_0 - \mathbf{P}_{\mathcal{H}^2} m_1 u_\gamma \frac{\delta m(a)}{s+a} \end{aligned}$$

we have

$$\begin{aligned} \mathbf{P}_{\mathcal{H}^2} u_\gamma \left(m^*x_0 - \frac{\delta m(a)}{s+a} \right) &= \frac{p_{1,1}}{k_\gamma} \\ \mathbf{P}_{\mathcal{H}^2} m_d^* \hat{u}_\gamma x_0 &= m_d^* \hat{u}_\gamma x_0 - \frac{p_{1,2}}{A^*} \end{aligned}$$

where $p_{1,1}, p_{1,2} \in \mathbb{R}[s]$ with $\deg(p_{1,1}) \leq n-1$, $\deg(p_{1,2}) \leq l-1$. Hence we obtain

$$\phi_1 = \frac{p_{1,1}}{k_\gamma A^*} + m_d^* \hat{u}_\gamma x_0 - u_\gamma \frac{\delta m(a)}{s+a}$$

where $p_1 \in \mathbb{R}[s]$ and $\deg(p_1) \leq n+l-1$. Similarly, since

$$\begin{aligned} \phi_2 &= -\mathbf{P}_{\mathcal{H}_+^2} m(u_\gamma^* - m_1^* \hat{u}_\gamma^*)y_0^* \\ &= -\mathbf{P}_{\mathcal{H}_+^2} m u_\gamma^* y_0^* - \mathbf{P}_{\mathcal{H}_+^2} m_d \hat{u}_\gamma^* y_0^* \end{aligned}$$

we have

$$\begin{aligned} \mathbf{P}_{\mathcal{H}_+^2} m u_\gamma^* y_0^* &= \frac{p_{2,1}}{k^*} \\ \mathbf{P}_{\mathcal{H}_+^2} m_d \hat{u}_\gamma^* y_0^* &= m_d u_\gamma^* y_0^* - \frac{p_{2,2}}{A} \end{aligned}$$

for some $p_{2,1}, p_{2,2} \in \mathbb{R}[s]$ with $\deg(p_{2,1}) \leq n-1$, $\deg(p_{2,2}) \leq l-1$. Thus

$$\phi_2 = \frac{p_{2,2}}{k^* A} + m_d u_\gamma^* y_0^*$$

for some $p_2 \in \mathbb{R}[s]$ and $\deg(p_2) \leq n+l-1$. Now define $P_1(s) = (s+a)p_1(s) - \delta b_\gamma(s)A^*(s)m(a)$ and $P_2(s) = (s+a)p_2(s) + \delta k_\gamma^*(s)A(s)$. Then, we have

$$x_0 = -\frac{\kappa_\gamma x_2 + m_1 v_\gamma x_1}{(s+a)\pi A}, \quad (25)$$

$$y_0^* = -\frac{k_\gamma^* P_1 + m_1^* b_\gamma P_2}{(s+a)\pi A^*}, \quad (26)$$

$$\phi_1 = \frac{P_1 \pi - k_\gamma u_\gamma (k_\gamma^* P_1 + m_1^* b_\gamma P_2)}{(s+a)\pi A^* k_\gamma}, \quad (27)$$

$$\phi_2^* = \frac{P_2 \pi - k_\gamma^* \hat{u}_\gamma^* (k_\gamma^* P_1 + m_1^* b_\gamma P_2)}{(s+a)\pi A L^*}, \quad (28)$$

where P_1 and P_2 satisfy

$$\deg(P_1) \leq n+l, \quad \deg(P_2) \leq n+l \quad (29)$$

$$k_\gamma P_2 + m_1 b_\gamma^* P_1|_\pi = 0 \quad (30)$$

$$P_2 \pi - k_\gamma^* \hat{u}_\gamma^* (k_\gamma^* P_1 + m_1^* b_\gamma P_2)|_{A^*} = 0 \quad (31)$$

$$P_2 \pi - k_\gamma^* u_\gamma^* (k_\gamma^* P_1 + m_1^* b_\gamma P_2)|_A = 0 \quad (32)$$

$$k_\gamma^* P_1 + m_1^* b_\gamma P_2|_{s=-a} = 0 \quad (33)$$

$$P_2(-a) = -\delta b_\gamma A^* m|_{s=-a}. \quad (34)$$

Conversely, if (29)–(34) hold, we can define x_0, y_0, ϕ_1, ϕ_2 by (25)–(28). In this case (22)–(24) hold and hence (21) holds.

If $\delta = 0$, (33) and (34) imply that $P_1(-a) = P_2(-a) = 0$. In this case (30)–(32) hold for P_i replaced by P'_i , $i = 1, 2$ and (29) replaced by $\deg(P'_i) \leq n+l-1$. Furthermore, (33)–(34) are redundant and

(25)–(28) hold if P_i replaced by P_i^* , $i = 1, 2$ and the $(s + a)$ factor is cleared from the denominators. Since (16) depends only on y_0^*/x_0 , it is enough to solve (21) for $\delta = 0$ and to set $U = 0$ in (18) to solve the optimal problem.

B. On the Structure of the Controller

Let $W_1 = B_1/K_1$, $W_2 = B_2/K_2$ with $(B_1, K_1) = (B_2, K_2) = 1$. Define A_{C_i} to be a stable polynomial such that

$$A_{C_i} A_{C_i}^* = B_1 B_1^* K_2 K_2^* + B_2 B_2^* K_1 K_1^*. \quad (35)$$

Then, it is easy to see that $G = \frac{A_G}{K_1 K_2}$. Similarly define B_γ to be a stable polynomial such that

$$B_\gamma B_\gamma^* = \gamma^2 A_{C_i} A_{C_i}^* - B_1 B_2 B_1^* B_2^*. \quad (36)$$

Then, we can define $f_\gamma = \frac{B_\gamma}{A_{C_i}}$. So G_γ defined in Section II is equal to $G_\gamma = \frac{\gamma^2 K_1 K_2}{B_\gamma}$. On the other hand, since b_1 is the Blaschke product of minimal order such that $W_0 = b_1 G^{-*} W_1 W_1^* = b_1 \frac{K_2^* B_1 B_1^*}{A_{C_i}^* K_1} \in \mathcal{H}^\infty$, we obtain $b_1 = \frac{A_{C_i}^*}{A_G}$. Furthermore, note that $W_0 = \frac{B_1 B_1^* K_2^*}{K_1 A_G}$, $u_\gamma = \frac{B_1 B_1^* K_2^*}{K_1 B_\gamma}$, $b_\gamma = B_1 B_1^* K_2^*$, $k_\gamma = K_1 B_\gamma$. Since $\pi(s) = b_\gamma b_\gamma^* - k_\gamma k_\gamma^* = (B_1 B_1^* - \gamma^2 K_1 K_1^*) A_{C_i} A_{C_i}^*$, and $m_1 = m_n \frac{A_G}{A_{C_i}}$, (30) implies that

$$P_1 = A_{C_i} L_2, \quad P_2 = A_{C_i}^* L_1. \quad (37)$$

In this case (30) reduces to

$$L_1 + m_n F_\gamma L_2|_{E_\gamma} = 0 \quad (38)$$

because $u_\gamma = \frac{W_1 W_1^*}{\gamma^2} F_\gamma$ and hence $(u_\gamma - F_\gamma)|_{E_\gamma} = 0$.

Similarly, (31)–(32) reduce to

$$L_1 + m_n F_\gamma L_2|_{A^*} = 0, \quad (39)$$

$$L_2 + m_n^* F_\gamma^* L_1|_A = 0 \quad (40)$$

because $X(\alpha_k) = G_n(\alpha_k)^{-1}$ and hence $\hat{u}_\gamma(\alpha_k) = \frac{A_G A_{C_i}}{B_\gamma K_1 K_2 m_n} |_{\alpha_k}$. Finally, (33)–(34) reduce to

$$L_2(-a) + (E_\gamma(a) + 1)F_\gamma(a)m_n(a)L_1(-a) = 0 \quad (41)$$

$$L_1(-a) = 1. \quad (42)$$

In fact (34) reduces to $L_1(-a) = -\delta \frac{b_\gamma A_{C_i}^* m}{A_G} |_{s=-a}$, but replacing this equation by (42) does not effect the ratios y_0^*/x_0 and $\frac{y_0^* + z_0 x_0^* U}{x_0 + z_0 y_0 U}$, hence it does not effect the controller formulas.

Note that, by [10]

$$C = m_d G^{-1} N_0^{-1} \frac{\Theta}{1 - m_n G^{-1} \Theta} \text{ where } \Theta = W_0 + m_d Q_2. \quad (43)$$

On the other hand, by (18)

$$\begin{aligned} \Theta &= f_\gamma \left[m_1^* u_\gamma - m_d \frac{y_0^* + \frac{s-a}{s+a} x_0^* U}{x_0 + \frac{s-a}{s+a} y_0 U} \right] \\ &= m_n^* G^{-*} W_1^* W_1 - f_\gamma m_d \frac{y_0^* + \frac{s-a}{s+a} x_0^* U}{x_0 + \frac{s-a}{s+a} y_0 U}. \end{aligned} \quad (44)$$

By substituting (25), (26), (37), (44) into (43), and simplifying the resulting expression, we obtain

$$C_{\text{subopt}}(s) = E_\gamma(s) m_d(s) \frac{N_0^{-1}(s) F_\gamma(s) L_1(s)}{1 + m_n(s) F_\gamma(s) L_1(s)} \quad (45)$$

where $\gamma = \rho$, and

$$L_U(s) = \frac{L_2(s) + L_1(-s)U(s)}{L_1(s) + L_2(-s)U(s)}, \quad U \in \mathcal{B} \quad (46)$$

and L_1, L_2 are the unique nonzero polynomials of degree at most $n + l$ satisfying (38)–(42). The controller structure is the same for the optimal case, except the free parameter U drops

$$C_{\text{opt}}(s) = E_\gamma(s) m_d(s) \frac{N_0^{-1}(s) F_\gamma(s) L(s)}{1 + m_n(s) F_\gamma(s) L(s)} \quad (47)$$

where $L(s) = L_2(s)/L_1(s)$ and L_1, L_2 are nonzero polynomials of degree at most $n + l - 1$ satisfying (38)–(40).

V. CONCLUDING REMARKS

In this paper, a simple expression is obtained for the optimal and suboptimal \mathcal{H}^∞ controllers for a class of unstable distributed plants, with rational weighting functions. We have shown that \mathcal{H}^∞ controllers are in the form (45), (47), where m_d, m_n, N_0 are inner and outer parts of the plant $P = m_n N_0 / m_d$; E_γ is given in terms of the sensitivity weighting function W_1 ; F_γ is computed from a spectral factorization which depends on γ, W_1 and W_2 ; and polynomials L_1 and L_2 are computed from a finite set of linear equations. These linear equations can be written directly as interpolation conditions on L_1 and L_2 , that are expressed in terms of m_n and F_γ evaluated at the zeros of E_γ , and at the poles and zeros of m_d . The number of equations is $2(n_1 + l + 1)$ (in the optimal case it is $2(n_1 + l)$), which is equal to the number of unknown coefficients of L_1 and L_2 .

Least Squares Type Algorithms for Identification in the Presence of Modeling Uncertainty

Er-Wei Bai and Krishan M. Nagpal

Abstract—The celebrated least squares and LMS (least-mean-squares) are system identification approaches that are easily implementable, need minimal *a priori* assumptions, and have very nice identification properties when the uncertainty in measurements is only due to noises and not due to unmodeled behavior of the system. When there is uncertainty present due to unmodeled part of the system as well, however, the performance of these algorithms can be poor. Here we propose a “modified” weighted least squares algorithm that is geared toward identification in the presence of both unmodeled dynamics and measurement disturbances. The algorithm uses very little *a priori* information and is easily implementable in a recursive fashion. Through an example we demonstrate the improved performance of the proposed approach. Motivated by a certain worst-case property of the LMS algorithm, an H_∞ estimation algorithm is also proposed for the same objective of identification in the presence of modeling uncertainty.

I. INTRODUCTION

The least squares and the LMS (least-mean-squares) algorithms are perhaps the most widely used identification algorithms [4], [7], [9], [11]. Their advantages lie in their simple recursive implementation and minimal use of *a priori* information. These algorithms perform very well in applications where the modeled behavior of the system closely approximates the behavior of the system to be identified. The performance of both least squares and LMS algorithms may become poor, however, if the assumed model structure is not rich enough to capture the dynamics of the system. Here we propose two algorithms that are motivated by the worst-case properties of the least squares and the normalized LMS approaches. While retaining most of the nice properties of the standard least squares (such as recursive implementation), these methods are also suitable for system identification in the presence of modeling inaccuracies.

Recently there has been a strong emphasis in the control community on “identification for control design.” The objective of system identification there is to obtain a good nominal plant together with some error bounds that are suitable for robust control design methodologies [2], [5], [6], [8], [10], [12], [13]. The approaches that have been proposed so far are, from a practical point of view, quite complicated and often result in nominal models of a very large order. There are other approaches to combine identification with control design [14], [16]. In the present approach we do not try to obtain nominal models with “hard” error bounds but instead sacrifice such rigid and precise objectives for optimality in a certain worst-case sense and ease of implementation. They do not rely much on the *a priori* information and especially the “modified” least squares algorithm is implementable in a recursive manner. For clarity of explanations, we will consider single input/single output systems. The approach is immediately generalizable to multi-input/multi-output systems.

The paper is organized as follows: in the next section we review some worst case properties of the standard least squares and the normalized LMS algorithms. Section III contains the precise problem formulation, Section IV the main results, and the Section V the proofs.

II. REVIEW OF THE LEAST SQUARES AND LMS ALGORITHMS

Suppose we observe an output sequence y_i of a system with an ARMA structure

$$y_i = \phi_i' \theta + \xi_i, \quad i = 0, 1, \dots, N. \quad (2.1)$$

Here y_i is the output at the i th time instant, ξ_i is the measurement noise at the i th instant, $\phi_i \in R^n$ is a known regressor vector composed of past inputs and outputs, and $\theta \in R^n$ is the unknown vector to be identified that describes the system behavior. We will also use the following notation

$$Y := [y_0, y_1, \dots, y_N]', \quad \Phi := [\phi_0, \phi_1, \dots, \phi_N]' \\ \xi := [\xi_0, \xi_1, \dots, \xi_N]'. \quad (2.2)$$

Let \mathcal{A} be an identification algorithm. For the identifier \mathcal{A} , $\hat{\theta}(i)$ will be used to denote the estimate of θ obtained using measurements up to the stage i , i.e., $\hat{\theta}(i) = \mathcal{A}(y_0, y_1, \dots, y_i)$.

The next lemma describes some well-known properties of the least squares algorithm that are pertinent for our later analysis [1], [9].

Lemma 2.1 (Least Squares Properties): For given data Y and Φ , the least squares estimate of θ given by $\hat{\theta}(N) := (\Phi' \Phi)^{-1} \Phi' Y$ is optimal for the following two cost functions

$$\begin{aligned} \text{a)} \quad & \hat{\theta}(N) = \arg \inf_{\theta} \{ \|\xi\|^2 : Y = \Phi \theta + \xi \} \\ \text{b)} \quad & \hat{\theta}(N) = \arg \inf_{\theta} \sup_{\xi} \frac{\|\Phi \theta - Y\|^2}{\|\xi\|^2} \end{aligned}$$

The first part of the above lemma states that the least squares estimate of θ is that value of θ which explains the data with minimum amount (in l_2 norm sense) of noise. In the literature, this approach is sometimes referred to as total least squares [3]. Since in this case the uncertainty is only due to noises, the least squares estimate would be the answer to the question “what is the θ that explains the data with minimum amount of uncertainty?” In the next section we will ask this very question but also include the contribution from unmodeled behavior of the system in describing amount (norm) of uncertainty. To interpret the second part of the above lemma, consider the problem of estimating $\phi_i' \theta$ for $i \in [0, N]$ using the measurements y_0 to y_N . The cost function to be minimized is the worst case amplification in the l_2 norm from noises $\{\xi_i\}$ to the estimation errors $\phi_i'(\theta - \hat{\theta})$. This is a discrete-time H_∞ smoothing (noncausal estimation) problem since $\hat{\theta}$ is obtained using the entire measurement sequence. The second part of the above lemma states that if $\hat{\theta}(N)$ is the least squares estimate of θ , then $\phi_i' \hat{\theta}(N)$ is the best worst case (in H_∞ sense) smoother estimate of $\phi_i' \theta$. Thus the least squares estimate can be viewed as an optimal H_∞ smoother estimate.

Similar results can be said about the normalized LMS algorithm. For a given identifier \mathcal{A} , we will define the filtered error at stage i as $e_{i+1} = \phi_{i+1}'(\theta - \hat{\theta}(i))$.

Lemma 2.2 (Normalized LMS Property): For any given $\mu > 0$, consider the following normalized LMS algorithm

$$\hat{\theta}(i+1) := \hat{\theta}(i) + \frac{\mu \phi_{i+1}'}{1 + \mu \phi_{i+1}' \phi_{i+1}} (y_{i+1} - \phi_{i+1}' \hat{\theta}(i)), \quad \hat{\theta}(0) = \theta_0.$$

Then the above estimator achieves the following optimal worst-case cost

$$\inf_{\theta \in \mathcal{A}(Y)} \sup_{\xi} \frac{\|e\|^2}{\|\xi\|^2 + \frac{1}{\mu} \|\theta - \theta_0\|^2}.$$

Fig. 1.

In the above, θ_0 represents the *a priori* estimate of θ . Thus the normalized LMS algorithm minimizes the worst-case l_2 gain from the “uncertainty” (in terms of *a priori* knowledge of θ and the disturbances) to the filtered error. The normalized LMS algorithm, however, is not the only algorithm that minimizes the above cost function [7]. The cost criterion in the above lemma and part b) of Lemma 2.1 are similar in the sense that in both cases one wants identifier for θ to give a good estimate for $\phi'_i \theta$. In part b) of Lemma 2.1, however, the estimate of θ used in predicting $\phi'_i \theta$ is based on the entire sequence of measurements available while in Lemma 2.2 the estimate of θ used in predicting $\phi'_i \theta$ is the one based on only the measurements up to time instant i .

III. THE PROBLEM FORMULATION

In this section we will formulate two approaches for identification in presence of both the measurement noises as well as unmodeled dynamics. It is worth reemphasizing that the objectives of the present approach are i) to make as few “hard” assumptions as possible (such as a bound on the noise, or an H_∞ bound on the unmodeled behavior), and ii) to come up with an algorithm that is easily implementable.

We will assume an additive uncertainty model (see Fig. 1) for describing the input-output behavior of the system

$$y = \hat{G}u + \Delta u + \xi. \quad (3.3)$$

Here \hat{G} is the nominal model that we wish to identify, ξ is the measurement noise, and Δ is an unknown stable linear time invariant system that captures the unmodeled dynamics of the system. Assuming an ARMA structure for the modeled part \hat{G} for the structure, one can write the above equation as

$$y_i = \phi'_i \theta + (\Delta u)_i + \xi_i, \quad i = 0, 1, \dots, N \quad (3.4)$$

where ϕ_i , the regressor vector is composed of known inputs and outputs and θ is the unknown parameter we wish to identify. Here we are also assuming that only a finite number of observations (N) are available for identification. Let the (unknown) impulse response of the uncertainty Δ be $\delta_0, \delta_1, \dots$. We can then rewrite (3.4) more compactly as

$$Y = \Phi \theta + U \delta + \xi \quad (3.5)$$

where Y , Φ , and ξ are defined in (2.2), and

$$\delta := \begin{bmatrix} \delta_0 \\ \delta_1 \end{bmatrix}, \quad U = \begin{bmatrix} u_0 & 0 \\ u_1 & u_0 \end{bmatrix} \quad (3.6)$$

Motivated by part a) of Lemma 2.1, we now propose our first approach for identification of θ .

Problem 1—Modified Weighted Least Squares Problem (MWLSP): Given are two positive definite weighting matrices $W_\delta = W_\delta$ and $W_\xi = W_\xi$. Find θ so as to

$$\begin{aligned} &\text{minimize} \quad \delta^T W_\delta \delta + \xi^T W_\xi \xi \\ &\text{subject to} \quad Y = \Phi \theta + U \delta + \xi. \end{aligned}$$

Before discussing the role of W_δ and W_ξ in the above problem, we will briefly discuss the underlying motivation behind the above

problem formulation. The motivation behind the above problem is qualitatively very similar to the property a) of the standard least squares stated in the Lemma 2.1. Let

$$J(W_\delta, W_\xi) := \|\delta\|_{W_\delta}^2 + \|\xi\|_{W_\xi}^2.$$

The quantity $J(W_\delta, W_\xi)$ can be interpreted as the size (or norm) of uncertainty (due to both unmodeled behavior and the measurement noises). Thus in the modified weighted least squares problem (MWLSP) we want to “find θ that explains the data with minimum amount of uncertainty.” In the standard least squares one asks this very question but there all the uncertainty is attributed to noises only.

The weighting matrices W_δ and W_ξ are chosen by designers to measure the individual contributions of the unmodeled behavior and the disturbances. This can be used to incorporate some prior knowledge. We discuss some cases here.

Case 1) Consider the following choice of weights

$$W_\delta = \lambda I, \quad \text{and} \quad W_\xi = (1 - \lambda)I, \quad 0 < \lambda < 1$$

where I is the $(N+1)$ -dimensional identity matrix. The quantity λ is chosen to reflect the relative contribution of unmodeled behavior and the disturbances. If $\lambda \rightarrow 0$ then one expects that most of the uncertainty is due to δ or the unmodeled behavior while $\lambda \rightarrow 1$ corresponds to the belief that most of the uncertainty is due to noises and not due to the unmodeled behavior. Indeed, as can be easily observed, the above method reduces to the standard least squares when $W_\delta = \lambda I \rightarrow I$ and $W_\xi = (1 - \lambda)I \rightarrow 0$.

Case 2) The weightings W_δ can also be used to shape the accuracy requirements of identification with respect frequency. For example, consider a situation where it is desired to have a more accurate description of the system behavior at low frequencies. In this case, we would want the unmodeled dynamics (system Δ in Fig. 1), which is “consistent” with the identified model in explaining the data, to be small at low frequencies. Let $\{h_i\}$ be the impulse response of a low pass filter. Consider now the following choice for W_δ

$$W_\delta = \begin{bmatrix} h_0 & 0 & & 0 & 0 \\ h_1 & h_0 & & 1 & h_0 \\ & & \ddots & & \\ h_N & & & h_0 & h_{N-1} & h_0 \end{bmatrix}$$

With the above choice of W_δ , the norm of the unmodeled uncertainty ($\|\delta\|_{W_\delta}^2 = \delta^T W_\delta \delta$) is given more weighting in the low frequency region.

Case 3) The unknown system is assumed to be stable. Then we would probably also desire the nominal model obtained from identification to be stable, and thus so would be the unmodeled dynamics Δ . Consequently, the impulse response $\{\delta_k\}$ of Δ converges to zero as $k \rightarrow \infty$. This *a priori* knowledge that $\delta_k \rightarrow 0$ as $k \rightarrow \infty$ can be incorporated in the identification process by suitable selection of W_δ and W_ξ . We next describe one such choice for W_δ and W_ξ . The weightings W_δ and W_ξ should reflect the fact that the “tail” contribution of $\{\delta_k\}$ for large k is much smaller than that of the disturbance sequence $\{\xi_k\}$. This can be easily incorporated into the weighting matrices by choosing them, for example, as follows

$$W_\delta = \text{diag}(\alpha, \alpha^2, \dots, \alpha^N) \quad \text{and} \quad W_\xi = cI$$

where c is some positive real number, I the identity matrix of appropriate size and $\alpha > 1$. With these choices of weightings, a unit ball of uncertainty defined as $B = \{(\delta, \xi): \|\delta\|_{W_\delta}^2 + \|\xi\|_{W_\xi}^2 \leq 1\}$ would have δ_k comparatively smaller than ξ_k for large k .

We shall observe in the next section that the optimal θ for the Problem 1 is also optimal in a worst-case sense, a property very similar to property b) of Lemma 2.1. To be more precise, the optimal θ for the MWLSP also satisfies

$$\text{optimal } \theta \text{ for MWLSP} = \arg \inf_{\theta \in \mathcal{A}(Y)} \sup_{\xi, \delta} \frac{\|\Phi\theta - \Phi\hat{\theta}\|^2}{\|\delta\|_{W_\delta}^2 + \|\xi\|_{W_\xi}^2}. \quad (3.7)$$

Property (3.7) has an obvious worst-case interpretation. Its usefulness can be seen from another angle as well. From a good model one would expect to be able to predict the uncorrupted system output accurately. From (3.4) it follows that for a good identification scheme, $\phi_i' \hat{\theta}$ would be close to $y_i - \xi_i$ for all i . Thus one meaningful criterion for system identification would be to find an identification algorithm that minimizes the worst-case gain from "uncertainty" to the error in predicting the actual system output or to find $\hat{\theta} = \mathcal{A}(Y)$ that achieves

$$J = \inf_{\hat{\theta} \in \mathcal{A}(Y)} \sup_{\xi, \delta} \frac{\|(\Phi\hat{\theta} + U\delta) - \Phi\hat{\theta}\|}{\{\|\delta\|_{W_\delta}^2 + \|\xi\|_{W_\xi}^2\}^{\frac{1}{2}}}. \quad (3.8)$$

It turns out that the solution to the above problem is not easily implementable. As we show next, however, the MWLSP algorithm minimizes an upper bound for J . To see this note that

$$\sup_{\xi, \delta} \frac{\|\Phi\hat{\theta} - (\Phi\theta + U\delta)\|}{\{\|\delta\|_{W_\delta}^2 + \|\xi\|_{W_\xi}^2\}^{\frac{1}{2}}} \leq \sup_{\xi, \delta} \frac{\|\Phi\hat{\theta} - \Phi\theta\|}{\{\|\delta\|_{W_\delta}^2 + \|\xi\|_{W_\xi}^2\}^{\frac{1}{2}}} + \sigma_{\max}(M_\delta^{-1}U'U^{-1}M_\delta^{-1})$$

where M_δ is the square root of W_δ , i.e., $M_\delta' M_\delta = W_\delta$ and σ_{\max} denotes the largest singular value. The second term in the above inequality is independent of the algorithm, while the first one is precisely the quantity that is minimized by MWLSP [see (3.7)]. Thus the MWLSP has an additional property of minimizing an upper bound for J , the worst case gain from "uncertainty" to the error in estimating the uncorrupted system output (output when there is no measurement noise).

Next we present the second problem we will consider. The motivation for the next problem comes from Lemma 2.2, a framework that follows from an immediate generalization of the worst-case property of the normalized LMS algorithm. Recall that for any given identifier \mathcal{A} , the filtered error at stage i is defined as $e_{i,i} = \phi_i'(\theta - \hat{\theta}(i))$.

Problem 2— H_∞ Filtering Identification Problem (HFIP): Given are two positive definite matrices W_δ and W_ξ and real numbers $\mu > 0$. Find the identification algorithm \mathcal{A} so that $\hat{\theta} = \mathcal{A}(Y)$ achieves

$$\inf_{\theta \in \mathcal{A}(Y)} \sup_{\xi, \delta, \theta} \frac{\|\delta\|_{W_\delta}^2 + \|\xi\|_{W_\xi}^2 + \frac{1}{\mu} \|\theta - \theta_0\|^2}{\|\delta\|_{W_\delta}^2 + \|\xi\|_{W_\xi}^2}$$

where the supremum over ξ, δ and θ is taken over all ξ, δ, θ that satisfy $Y = \Phi\theta + U\delta + \xi$.

Again the motivation is similar to before—we want to minimize the worst case amplification from "uncertainty" to the prediction error of the modeled part of the system. The previous discussions about the roles of W_δ and W_ξ also apply for this case.

IV. MAIN RESULTS

In this section, we present the solution to MWLSP and HFIP problems.

Fig. 2.

Theorem 4.1 (Solution of the MWLSP Problem). Consider the identification problem for a system whose input–output behavior is described by (3.5). For given input–output data Y , Φ and the weighting matrices W_δ and W_ξ , if Φ is full column rank, then

1)

$$\hat{\theta}_{mwls} = (\Phi'Q\Phi)^{-1}\Phi'QY \quad (4.9)$$

with

$$Q = (W_\xi^{-1} + U'W_\delta^{-1}U)^{-1} \quad (4.10)$$

solves the MWLSP problem. Moreover, the solution is unique and also admits a recursively implementable algorithm as shown in Lemma 4.2.

2) $\hat{\theta}_{mwls}$ also achieves the following worst-case cost

$$\inf_{\theta \in \mathcal{A}(Y)} \sup_{\xi, \delta} \frac{\|\Phi\theta - \Phi\hat{\theta}\|^2}{\|\delta\|_{W_\delta}^2 + \|\xi\|_{W_\xi}^2}.$$

The solution $\hat{\theta}_{mwls}$ to the MWLSP is basically a weighted least squares estimate of θ with the weight Q . Unlike the standard weighted least squares problems, however, here the weighting matrix Q also depends on the input. Being a weighted least squares algorithm, it possesses all the nice properties of the least squares, such as recursive implementation as is discussed in the Lemma 4.2.

Before presenting the next results, we present an example to demonstrate the performance of the MWLSP algorithm. The system to be identified is the following second-order system

$$y_i = -1.3y_{i-1} - 0.4y_{i-2} + 1.5u_{i-1} + 0.6u_{i-2} + \xi_i.$$

For simulation, ξ_i was assumed to be an independent uniformly distributed random variable in $[0, 0.6]$, input $u_i = \sin(i) + 2\cos(2.3 * i)$ and $N = 50$. The nominal model is assumed to be of the first order. Simulations were done for two choices of weights: in one case the weights were chosen as $W_\delta = 0.9I$, $W_\xi = 0.1I$ (from the discussion of the Case 1) in the previous section, this choice corresponds to an *a priori* assumption that measurement noises are more important/dominant than unmodeled dynamics) and in another case chosen as $W_\delta = 0.1I$, $W_\xi = 0.9I$ (similarly corresponds to an *a priori* belief that unmodeled dynamics are more important than noises). Fig. 2 shows the Nyquist plots of the true but unknown system (solid), the least squares estimate (dashdot) and the MWLSP estimates proposed in the paper with $W_\delta = 0.9I$, $W_\xi = 0.1I$ (**) and $W_\delta = 0.1I$, $W_\xi = 0.9I$ (+), respectively. As one might have expected, for both these choices of weights, the proposed algorithm outperforms the least squares algorithm.

The calculation of $\hat{\theta}_{mwls}$ in Theorem 4.1 can be made recursive. Before summarizing the recursive procedure, we describe some

notation used in the recursion. As defined previously, W_δ and W_ξ are $(N+1) \times (N+1)$ positive definite matrices where N denotes the number of data points. Let $W_\delta(k)$ and $W_\xi(k)$ denote the upper left $k \times k$ submatrix of W_δ and W_ξ respectively, i.e.,

$$W_\xi = \begin{bmatrix} W_\xi(k) & * \\ * & W_\delta = W_\delta(k) & * \end{bmatrix}$$

where $*$ indicates the remaining portions of the respective matrices. Because of the symmetry of the weighting matrices $W_\delta(k)$ and $W_\xi(k)$, their inverses can be written as

$$W_\xi^{-1}(k) := \begin{bmatrix} A(k-1) & a_k \\ a_k' & a_{k,k} \end{bmatrix}$$

$$W_\delta^{-1}(k) := M_\delta^{-1}(k) V_\delta^{-1}(k)$$

with $M_\delta^{-1}(k) := \begin{bmatrix} B(k-1) & 0 \\ b_k' & b_{k,k} \end{bmatrix}$ being the Cholesky factor of $W_\delta^{-1}(k)$, where $a_{k,k}$ and $b_{k,k}$ are scalars, and a_k and b_k are column vectors. The data is given by

$$Y(k) := \begin{bmatrix} y_0 \\ y_1 \\ \vdots \\ y_k \end{bmatrix}, \quad \Phi(k) := \begin{bmatrix} \phi_0' \\ \phi_1' \\ \vdots \\ \phi_k' \end{bmatrix}$$

$$\begin{bmatrix} u_0 & 0 & \cdots & 0 \\ u_1 & u_0 & 0 & \cdots \\ \vdots & \vdots & \vdots & \vdots \\ u_k & u_{k-1} & \cdots & u_0 \end{bmatrix} \begin{bmatrix} C'(k-1) & 0 \\ c_k' & c_{k,k} \end{bmatrix}$$

with $c_{k,k}$ being a scalar and c_k a column vector. Define

$$Z(k) := U(k) V_\delta^{-1}(k) = \begin{bmatrix} C'(k-1)B(k-1) & 0 \\ c_k' B(k-1) + u_0 b_k' & u_0 b_{k,k} \end{bmatrix}$$

$$= \begin{bmatrix} Z(k-1) & 0 \\ z_k' & z_{k,k} \end{bmatrix}$$

$$Q(k) := (W_\xi^{-1}(k) + U(k) W_\delta^{-1}(k) U'(k))^{-1}$$

$$= (A(k) + Z(k) Z'(k))^{-1} = L'(k) L(k)$$

with

$$L^{-1}(k) := \begin{bmatrix} L^{-1}(k-1) & 0 \\ l_k' & l_{k,k} \end{bmatrix}$$

or

$$L(k) = \begin{bmatrix} L(k-1) \\ \frac{1}{l_{k,k}} l_k' L(k-1) \end{bmatrix}$$

The next lemma summarizes the recursive formula for obtaining θ_{mwt} for the MWLSP stated in the Theorem 4.1.

Lemma 4.2 (Recursive Algorithm for MWLSP): A recursive algorithm for obtaining

$$\hat{\theta}_{\text{mwt}}(k) = (\Phi'(k) Q(k) \Phi(k))^{-1} \Phi'(k) Q(k) Y(k)$$

is given as follows.

Given initial data y_0, ϕ_0' , calculate

$$L(0) = (A(0) + Z(0)Z'(0)B(0)B'(0))^{1/2}, Y(0) = L(0)y_0,$$

$$\bar{\Phi}(0) = L(0)\phi_0'.$$

Step 1) At k th step, for any given new data u_k, y_k , and ϕ_k' , calculate

$$Z(k) = U(k)B(k), \quad l_k = L(k-1)(a_k + Z(k-1)z_k)$$

$$l_{k,k} = \sqrt{a_{k,k} + z_{k,k}^2 + z_k' z_k - l_k' l_k}$$

$$\bar{y}_k = \frac{1}{l_{k,k}}(y_k - l_k' \bar{Y}(k-1)),$$

$$\bar{\phi}_k' = \frac{1}{l_{k,k}}(\phi_k' - l_k' \bar{\Phi}(k-1)).$$

Step 2)

$$\hat{\theta}_{\text{mwt}}(k) = \theta_{\text{mwt}}(k-1)$$

$$+ \frac{P(k-1)\bar{\phi}_k}{1 + \bar{\phi}_k' P(k-1)\bar{\phi}_k} (\bar{y}_k - \bar{\phi}_k' \hat{\theta}_{\text{mwt}}(k-1))$$

$$P(k) = P(k-1) \frac{P(k-1)\bar{\phi}_k \bar{\phi}_k' P(k-1)}{1 + \bar{\phi}_k' P(k-1)\bar{\phi}_k}$$

Step 3) Set

$$Y(k) = \begin{bmatrix} \bar{Y}(k-1) \\ \bar{y}_k \end{bmatrix}, \quad \bar{\Phi}(k) = \begin{bmatrix} \bar{\Phi}(k-1) \\ \bar{\phi}_k' \end{bmatrix}$$

$$L(k-1)$$

$$L(k) = \frac{1}{l_{k,k}} l_k' L(k-1)$$

Step 4) Set $k+1 = k$ and go to Step 1.

Note that $l_{k,k}$ is away from zero since $W_\xi(k) > 0$ for all k .

We next present the solution to the H_∞ filtering identification problem. The following result can be obtained by immediate application of the standard results for the discrete-time H_∞ filtering problem (see, for example, [7], [15]). Recall that for any given identifier \mathcal{A} , the filtered error at stage i is defined as $e_{f,i} = \phi_i'(\theta - \theta(i))$.

Theorem 4.3 (Solution to the HFIP): Given are a positive definite matrix W_δ and a real number $\mu > 0$. There exists an identification algorithm \mathcal{A} so that $\hat{\theta} = \mathcal{A}(Y)$ achieves

$$J := \sup_{\theta} \left(\|\hat{\theta} - \theta\|_{W_\delta}^2 + \|\hat{\theta} - \theta\|^2 + \frac{1}{\mu} \|\theta - \hat{\theta}\| \right)$$

$$+ h_i' h_i - \frac{1}{\mu} l_i' l_i > 0, \quad i = 1, \dots, N \quad (4.11)$$

where

$$P(0) = \begin{bmatrix} \mu I & 0 \\ 0 & W_\delta^{-1} \end{bmatrix}, \quad h_i = [\phi_i' u_i \ u_{i-1} \ \cdots \ u_0 \ 0]$$

$$l_i = [\phi_i' \ 0 \ \cdots \ 0]$$

and $P(i)$ satisfy the following recursion

$$P^{-1}(i+1) = P^{-1}(i) + h_i' h_i - \frac{1}{\mu} l_i' l_i. \quad (4.12)$$

Moreover, if (4.11) is satisfied, the following identifier achieves $J < \gamma^2$

$$\begin{bmatrix} \hat{\theta}(i+1) \\ \hat{\delta}(i+1) \end{bmatrix} = \begin{bmatrix} \hat{\theta}(i) \\ \hat{\delta}(i) \end{bmatrix} + \frac{P(i+1)h_{i+1}}{1 + h_{i+1}' P(i+1)h_{i+1}} \left\{ y_{i+1} - h_{i+1}' \begin{bmatrix} \hat{\theta}(i) \\ \hat{\delta}(i) \end{bmatrix} \right\}$$

with $[\theta(0), \delta(0)] = [\theta_0, 0]$.

From an implementation point of view, the above algorithm is not as nice as the MWLSP algorithm for two reasons—i) the order of the estimator is equal to the size of the unknown vector θ plus the number of data points (while in recursive implementation of MWLSP, the order of estimator is just equal to the size of the unknown vector θ) and ii) to check whether (4.11) holds, one has to iterate with respect to γ . The recursive computation of $P(i)$ in (4.12) can be simplified, however, using the Matrix Inversion Lemma so that in obtaining $P^{-1}(i+1)$ from $P^{-1}(i)$, one only needs to invert a 2×2 matrix.

V. PROOFS

In this section, we will give a brief outline of the proofs for the Theorem 4.1 and the Lemma 4.2.

In the proofs, we will use an observation that we present in the next lemma. Define a set

$$\mathcal{C} = \{\mathcal{A}: \mathcal{A}(Y) = \theta \text{ if } \delta = 0 \text{ and } \xi = 0\}. \quad (5.13)$$

The set \mathcal{C} is referred to as the set of correct algorithms which represents all the identification algorithms that give the exact estimate θ if both δ and ξ are absent. The following lemma is quite straightforward.

Lemma 5.1: Let \mathcal{A} be any identification algorithm $\mathcal{A}(Y) = \theta$. Then, $\sup_{\xi, \delta} \frac{\|\Phi\hat{\theta} - \Phi\theta\|^2}{\|\delta\|_{W_\delta}^2 + \|\xi\|_{W_\xi}^2}$ is bounded only if $\mathcal{A} \in \mathcal{C}$.

Proof of Theorem 4.1:

Part 1): From (3.5), ξ can be written in terms of θ and δ as

$$\xi = Y - \Phi\theta - U\delta.$$

Thus

$$\begin{aligned} J_1 &:= \|\delta\|_{W_\delta}^2 + \|\xi\|_{W_\xi}^2 \\ &= \delta' W_\delta \delta + (Y - \Phi\theta - U\delta)' W_\xi (Y - \Phi\theta - U\delta). \end{aligned}$$

Taking derivative of J_1 with respect to θ and δ , respectively, and setting them to zero yield

$$\begin{aligned} 0 &= 2W_\delta \delta - 2U' W_\xi (Y - \Phi\theta - U\delta), \\ 0 &= -2\Phi' W_\xi (Y - \Phi\theta - U\delta). \end{aligned}$$

Solving these two equations for θ , we have

$$\hat{\theta}_{\text{mwls}} = (\Phi' Q \Phi)^{-1} \Phi' Q Y$$

with

$$\begin{aligned} Q &= W_\xi - W_\xi U (W_\delta + U' W_\xi U)^{-1} U' W_\xi \\ &= W_\xi (I + U' W_\delta^{-1} U' W_\xi)^{-1} \\ &= (W_\xi^{-1} + U' W_\delta^{-1} U)^{-1}. \end{aligned} \quad (5.14)$$

The uniqueness follows from convexity. This completes the proof.

Part 2) Let

$$\Phi = U_1 \begin{bmatrix} D_1 & | & 0 \end{bmatrix} U_1' \quad (5.15)$$

be the singular value decomposition of Φ , where U_1 and V_1 are unitary matrices and D_1 is a diagonal positive definite matrix. Let \bar{Q} be defined as

$$Q = U_1 \bar{Q} U_1' = U_1 \begin{bmatrix} \bar{Q}_{11} & \bar{Q}_{12} \\ \bar{Q}_{12}' & \bar{Q}_{22} \end{bmatrix} U_1'. \quad (5.16)$$

Also, M_δ and M_ξ are defined as $M_\delta' M_\delta = W_\delta$ and $M_\xi' M_\xi = W_\xi$. Now, the proof is divided into two parts. In the first part, we will show that if $\hat{\theta} = \mathcal{A}(Y)$ and $\mathcal{A} \in \mathcal{C}$, then

$$\sup_{\xi, \delta} \|\Phi\hat{\theta} - \Phi\theta\| \begin{bmatrix} M_\delta \delta \\ M_\xi \xi \end{bmatrix} \geq \frac{1}{\sigma_{\min}(\bar{Q}_{11})}. \quad (5.17)$$

In the second part, we will show that for the MWLSP estimate $\hat{\theta}_{\text{mwls}}$,

$$\sup_{\xi, \delta} \|\Phi\hat{\theta}_{\text{mwls}} - \Phi\theta\| \begin{bmatrix} M_\delta \delta \\ M_\xi \xi \end{bmatrix} \leq \frac{1}{\sigma_{\min}(\bar{Q}_{11})}. \quad (5.18)$$

We now show (5.17). Let θ be the unknown vector to be identified and let θ^* be any vector of the same dimension. Let δ and ξ be as follows

$$\begin{bmatrix} \delta \\ \xi \end{bmatrix} = \begin{bmatrix} W_\delta^{-1} & 0 \\ 0 & W_\xi^{-1} \end{bmatrix} \begin{bmatrix} U_1' \\ I \end{bmatrix} Q \Phi (\theta^* - \theta).$$

For the above δ and ξ , from (3.5) and (5.14), $Y = \Phi\theta + U\delta + \xi = \Phi\theta^*$. The resulting data Y and Φ are as if θ^* were the true value

of the unknown parameter and there were no uncertainties/noises present. From Lemma 5.1, thus for any $\mathcal{A} \in \mathcal{C}$ (the class of "correct algorithms"), the estimate $\hat{\theta} = \mathcal{A}(Y) = \theta^*$. Since from Lemma 5.1, our search is restricted to the class of "correct algorithms," we obtain using (5.14)–(5.16) that

$$\begin{aligned} \|\Phi\mathcal{A}(Y) - \Phi\theta\| & \begin{bmatrix} M_\delta \delta \\ M_\xi \xi \end{bmatrix} \\ &= \begin{bmatrix} (\theta^* - \theta)' U_1' D_1 D_1 U_1' (\theta^* - \theta) \\ (\theta^* - \theta)' U_1' \bar{Q}_{11} D_1 U_1' (\theta^* - \theta) \end{bmatrix} = \begin{bmatrix} \zeta' \zeta \\ \zeta' \bar{Q}_{11} \zeta \end{bmatrix} \end{aligned}$$

where $\zeta = D_1 U_1' (\theta^* - \theta)$. Since $D_1 U_1'$ is nonsingular and θ^* is arbitrary, ζ is arbitrary. Thus

$$\sup_{\xi, \delta} \|\Phi\hat{\theta} - \Phi\theta\| \begin{bmatrix} M_\delta \delta \\ M_\xi \xi \end{bmatrix} > \frac{1}{\sigma_{\min}(\bar{Q}_{11})}$$

or that (5.17) holds. We now show (5.18). Note that

$$\theta_{\text{mwls}} = (\Phi' Q \Phi)^{-1} \Phi' Q Y = \theta + (\Phi' Q \Phi)^{-1} \Phi' Q (U\delta + \xi),$$

$$\text{and } \Phi(\Phi' Q \Phi)^{-1} \Phi' = U_1 \begin{bmatrix} \bar{Q}_{11}^{-1} & 0 \\ 0 & 0 \end{bmatrix} U_1'.$$

Hence

$$\|\Phi\theta_{\text{mwls}} - \Phi\theta\|^2 = \left\| S \begin{bmatrix} M_\delta \delta \\ M_\xi \xi \end{bmatrix} \right\|^2$$

where $S = U_1 \begin{bmatrix} \bar{Q}_{11}^{-1} & 0 \\ 0 & 0 \end{bmatrix} U_1' Q (U' M_\delta^{-1} U' M_\xi^{-1})$. Thus $S S' = U_1 \begin{bmatrix} \bar{Q}_{11}^{-1} & 0 \\ 0 & 0 \end{bmatrix} U_1'$ and from above it follows that

$$\sup_{\xi, \delta} \frac{\|\Phi\hat{\theta}_{\text{mwls}} - \Phi\theta\|^2}{\|\delta\|_{W_\delta}^2 + \|\xi\|_{W_\xi}^2} \leq \sigma_{\max}(\bar{Q}_{11}^{-1}) = \frac{1}{\sigma_{\min}(\bar{Q}_{11})}.$$

This completes the proof. \square

Proof of Lemma 4.2. Note that

$$\theta_{\text{mwls}}(k) = (\Phi'(k) Q(k) \Phi(k))^{-1} \Phi'(k) Q(k) Y(k)$$

where $Q(k)$ is symmetric and positive definite. Let $Q(k) = L'(k) L(k)$, we have

$$\begin{aligned} \theta_{\text{mwls}}(k) &= \arg \min_{\theta} \|L(k)(Y(k) - \Phi(k)\theta)\| \\ &= \arg \min_{\theta} \|\bar{Y}(k) - \Phi(k)\theta\| \end{aligned}$$

where $\bar{Y}(k) = L(k)Y(k)$ and $\Phi(k) = L(k)\Phi(k)$. From above, we see that $\hat{\theta}_{\text{mwls}}(k)$ can be obtained recursively (using the standard recursive least squares algorithm) if $\bar{Y}(k)$ and $\Phi(k)$ can be calculated so. It can be easily verified that the algorithm shown in Lemma 4.2 recursively estimates $Y(k)$ and $\Phi(k)$ and then generates the estimate by implementing the recursive least squares approach on the new data. \square

Square-Root Bryson-Frazier Smoothing Algorithms

PooGyeon Park and Thomas Kailath

Abstract—Some new square-root algorithms for Bryson-Frazier smoothing formulas are suggested: square-root algorithms and a fast square-root (or so-called Chandrasekhar type) algorithm. The new square-root algorithms use square-root arrays composed of smoothed estimates and their error covariances. These algorithms provide many advantages over the conventional algorithms with respect to systolic array and parallel implementations as well as numerical stability and conditioning. For the case of constant-parameter systems, a fast square-root algorithm is suggested, which requires less computation than others.

I. INTRODUCTION

Square-root (or factorized, as they are sometimes called) algorithms for state-space estimation have been found to have several advantages over the conventional equation-based algorithms in numerical stability, conditioning, and amenability to parallel and systolic implementation. While such algorithms for prediction and filtering have by now been studied quite extensively (see, e.g., [1]-[8]), the picture is not quite as complete for smoothed estimates. Square-root smoothing algorithms in the literature have various advantages and disadvantages (see, e.g., [4], [9]-[15]); all of them require certain inversion on back-

substitution steps, and none of them are particularly well suited for parallel implementation.

In another direction, there has been considerable effort in speeding up Kalman filtering [7], [16]. While the conventional equation-based or square-root algorithms require $O(n^2)$ flops per iteration, fast square-root (or Chandrasekhar type) algorithms for time-invariant systems [17]-[20] require only $O(n(p+q))$ flops, where p and q are the number of outputs and the displacement rank of Riccati solutions $P_{i|i-1}$, (i.e., $\text{rank}\{P_{i+1|i} - P_{i|i-1}\}$), respectively. For smoothing, however, there seems to be no fast square-root algorithms in the literature.

In our paper, we shall present some new square-root smoothing algorithms which are more suitable for parallel implementation than any algorithm in the literature and also a fast square-root smoothing algorithm for constant-parameter systems. As a target, we shall consider the basic Bryson-Frazier smoothing formulas [21].

Section II reviews Kalman filtering and some recast versions [22], and Section III describes the Bryson-Frazier smoothing formulas, presents several square-root versions, and briefly compares them on the basis of constraints, memory size, and computational speed.

For convenience we first introduce some notational conventions.

Square-Root Factors: Given a positive definite matrix A , $A > 0$, a square-root factor will be defined as any matrix, say $A^{1/2}$, such that $A = (A^{1/2})(A^{1/2})^*$, where the "*" denotes matrix transpose. Such square-root factors are clearly not unique. In most applications, the triangular form is preferred. For convenience we shall also write $(A^{1/2})^* = A^{*/2}$, $(A^{1/2})^{-1} = A^{-1/2}$, $(A^{-1/2})^* = A^{-*/2}$.

Square-Root Forms: Given a matrix A , assume that we apply a unitary operator Θ to the A so as to get some special form of a matrix B such as $A\Theta = B$, where $AA^* = BB^*$, then we shall call the A a pre-array and the B a post-array.

Matrix Inversion Lemma $(A + BC^*D)^{-1} = A^{-1} - A^{-1}B(C^{-1} + DA^{-1}B)^{-1}DA^{-1}$.

State-Space Model: $x_{i+1} = F_i x_i + G_i u_i$, $y_i = H_i x_i + v_i$, $i \geq 0$, where $F_i \in \mathbb{C}^{n \times n}$, $H_i \in \mathbb{C}^{p \times n}$, $G_i \in \mathbb{C}^{n \times m}$, and $\{x_0, u_i, v_i\}$ are independent zero-mean white Gaussian random variables with the covariances $\{\Pi_0, Q_i, R_i\}$. The matrices $\{F_i, G_i, H_i, Q_i, R_i, \Pi_0\}$ are assumed to be known. For simplicity, we shall define $\hat{x}_{i|i} \triangleq$ the linear least-squares estimate of x_i given $\{y_0, \dots, y_i\}$, $P_{i|i} \triangleq E[x_i - \hat{x}_{i|i}][x_i - \hat{x}_{i|i}]^*$, the error covariance of the estimate $\hat{x}_{i|i}$. For compactness we shall write, unless necessary for emphasis or comparison, $P_{i|i-1} \triangleq P_i$.

II. SQUARE-ROOT KALMAN FILTERING

Given the standard state-space model described above, we have the following recursions: for measurement updates

$$\hat{x}_{i|i} = \hat{x}_i + K_i \epsilon_i, \quad P_{i|i} = P_i - K_i R_i^{-1} K_i^*$$

and for time updates

$$x_{i+1} = F_i \hat{x}_{i|i}, \quad P_{i+1} = F_i P_{i|i} F_i^*$$

where $K_i \triangleq P_i H_i^* R_i^{-1}$, $R_{i-1} \triangleq R_i + H_i P_i H_i^*$, $\epsilon_i \triangleq y_i - H_i \hat{x}_i$, and the P_i are propagated via the Riccati difference equation: $P_{i+1} = F_i P_i F_i^* + G_i Q_i G_i^* - F_i K_{i-1} R_{i-1}^{-1} K_{i-1}^* F_i^*$, $P_0 = \Pi_0$.

When Π_0 is very large, it is often preferred to propagate P_i^{-1} , which can be performed when $\Pi_0 > 0$, $R_i > 0$, and the F_i are invertible. The resulting so-called "Information Filter" formulas are as follows: for measurement updates

$$P_{i|i}^{-1} \hat{x}_{i|i} = P_i^{-1} \hat{x}_i + H_i^* R_i^{-1} y_i, \quad P_{i|i}^{-1} = P_i^{-1} + H_i^* R_i^{-1} H_i$$

for time updates

$$P_{i+1}^{-1} \hat{x}_{i+1} = (I + F_i^{-*} P_{i|}^{-1} F_i^{-1} G_i Q_i G_i^*)^{-1} (F_i^{-*} P_{i|}^{-1} \hat{x}_{i|}),$$

$$P_{i+1}^{-1} = F_i^{-*} P_{i|}^{-1} F_i^{-1} \{I - G_i Q_i G_i^* F_i^{-*} P_{i|}^{-1} F_i^{-1}\}$$

where $\bar{Q}_i \triangleq Q_i - G_i Q_i P_{i+1}^{-1} G_i Q_i$. For convenience, we shall define $K_{p,i} \triangleq F_i P_i H_i^* R_i^{-1}$, $\bar{K}_{p,i} \triangleq K_{p,i} R_i^{1/2}$, $\bar{K}_{f,i} \triangleq K_{f,i} R_i^{1/2}$, and $\bar{K}_{b,i} \triangleq F_i^{-*} P_{i|}^{-1} F_i^{-1} G_i Q_i^{1/2}$.

Square-root algorithms for Kalman filtering can be nicely organized by combining what we call the covariance and information-form updates [22]. Let us first consider the basic so-called square-root covariance filter (SRCF) algorithm for measurement updates. Form the pre-array \mathcal{A} and block triangularize it by applying any unitary rotation Θ so that $\mathcal{A}\Theta$ has the form

$$\mathcal{A} = \begin{bmatrix} R_i^{1/2} & H_i P_i^{1/2} \\ 0 & P_i^{1/2} \\ -y_i^* R_i^{-*/2} & \hat{x}_i^* P_i^{-*/2} \end{bmatrix} \quad \mathcal{A}\Theta = \begin{bmatrix} X & 0 \\ Y & Z \end{bmatrix}$$

We may regard this as saying that the rotation Θ sets up a conformal (i.e., a norm- and angle-preserving) mapping between the (block) rows of \mathcal{A} and the rows of the post-array. An inner-product of the first row and a cross-product between the first and second rows yield the relations $R_i + H_i P_i H_i^* = X X^*$ and $H_i P_i = X Y^*$, from which we can identify $X = R_i^{1/2}$ and $Y = \bar{K}_{f,i}$. From the second block rows we obtain $P_i = \bar{K}_{f,i} \bar{K}_{f,i}^* + Z Z^*$, so that we can identify $Z = P_i^{1/2}$. Forming a cross-product between the first row and the third row, we obtain the relation that $y_i - H_i \hat{x}_i = X \alpha$, and verify that $\alpha = R_i^{-1/2} e_i$. Similarly, forming a cross-product between the second row and the third row gives us $\hat{x}_i = Y \alpha + Z \beta$. Therefore, we can select Z as $P_i^{-1/2} \hat{x}_{i|}$.

By inverting and transposing the first two blocks of the \mathcal{A} , we can form another basic so-called square-root information filter (SRIF) algorithm for measurement updates and combine the SRCF and the SRIF into a nice array form shown in the measurement-update equation of the following algorithm.

As far as time updates are concerned, we can form the following pre-array

$$\mathcal{A} = \begin{bmatrix} F_i P_{i|}^{1/2} & G_i Q_i^{1/2} \\ 0 & Q_i^{1/2} \\ \hat{x}_{i+1}^* P_{i+1}^{-*/2} & 0 \end{bmatrix}$$

and, after identifying the post-array by performing inner- or cross-products of the pre-array and comparing them, we can obtain the result shown in the time-update equation below.

Algorithm II.1—Square-Root Covariance and Information Filtering (Two-Array Form): Assume that $R_i > 0$, $\Pi_0 > 0$, and the F_i are invertible. Given $P_0^{-*/2} = \Pi_0^{-*/2}$, $P_0^{1/2} = \Pi_0^{1/2}$, and $P_0^{-*/2} \hat{x}_0 = 0$, we can write the following.

Measurement Updates:

$$\begin{bmatrix} R_i^{1/2} & H_i P_i^{1/2} \\ 0 & P_i^{1/2} \\ -H_i^* R_i^{-*/2} & P_i^{-*/2} \\ -y_i^* R_i^{-*/2} & \hat{x}_i^* P_i^{-*/2} \end{bmatrix} \Theta = \begin{bmatrix} R_{e,i}^{1/2} & 0 \\ \bar{K}_{f,i} & P_{i|}^{1/2} \\ R_{e,i}^{-*/2} & -R_i^{-1} H_i P_{i|}^{1/2} \\ 0 & P_{i|}^{-*/2} \\ -e_i^* R_{e,i}^{-*/2} & \hat{x}_{i|}^* P_{i|}^{-*/2} \end{bmatrix}$$

where Θ is any unitary rotation that zeros out the (1, 2) or (4, 1) entry of the pre-array.

Time Updates:

$$\begin{bmatrix} F_i P_{i|}^{1/2} & G_i Q_i^{1/2} \\ 0 & Q_i^{1/2} \\ -F_i^{-*} P_{i|}^{-*/2} & 0 \\ -G_i^* F_i^{-*} P_{i|}^{-*/2} & Q_i^{-*/2} \\ \hat{x}_{i+1}^* P_{i+1}^{-*/2} & 0 \end{bmatrix} \Theta = \begin{bmatrix} P_{i+1}^{1/2} & 0 \\ Q_i G_i P_{i+1}^{-*/2} & \bar{Q}_i^{1/2} \\ P_{i+1}^{-*/2} & -\bar{K}_{b,i} \\ 0 & \bar{Q}_i^{-*/2} \\ \hat{x}_{i+1}^* P_{i+1}^{-*/2} & -\hat{x}_{i+1}^* \bar{K}_{b,i} \end{bmatrix}$$

where Θ is any unitary rotation that zeros out the (1, 2) or (4, 1) entry of the pre-array.

Estimate Construction: The filtered estimates \hat{x}_{i+1} can be constructed from the post-array of the time-update equation in Algorithm II.1 as $\hat{x}_{i+1} = (P_{i+1}^{1/2})^{-1} (P_{i+1}^{-1/2} \hat{x}_{i+1})$ or from the post-array of the measurement-update equation in Algorithm II.1 as $\hat{x}_{i+1} = (F_i) \{(\hat{x}_i) + (\bar{K}_{f,i}) (R_{e,i}^{-1/2} e_i)\}$.

The following corollary shows the square-root covariance and information filtering (SRCIF) algorithm in a single-array form, which is useful when the input and output noises are correlated; see [22]. We shall use this single-array form in Section III to implement the Bryson-Frazier smoothing formula in square-root form.

Corollary II.1—Square-Root Covariance and Information Filtering (Single-Array Form): Assume that $R_i > 0$, $\Pi_0 > 0$, and the F_i are invertible. Given $P_0^{-*/2} = \Pi_0^{-*/2}$, $P_0^{1/2} = \Pi_0^{1/2}$, and $P_0^{-*/2} \hat{x}_0 = 0$

$$\begin{bmatrix} R_i^{1/2} & H_i P_i^{1/2} & 0 \\ 0 & F_i P_i^{1/2} & G_i Q_i^{1/2} \\ -F_i^{-*} H_i^* R_i^{-*/2} & F_i^{-*} P_i^{-*/2} & 0 \\ G_i^* F_i^{-*} H_i^* R_i^{-*/2} & -G_i^* F_i^{-*} P_i^{-*/2} & Q_i^{-*/2} \\ -y_i^* R_i^{-*/2} & \hat{x}_i^* P_i^{-*/2} & 0 \end{bmatrix} = \begin{bmatrix} R_{e,i}^{1/2} & 0 & 0 \\ \bar{K}_{p,i} & P_{i+1}^{1/2} & 0 \\ 0 & P_{i+1}^{-*/2} & -\bar{K}_{b,i} \\ 0 & 0 & \bar{Q}_i^{-*/2} \\ -e_i^* R_{e,i}^{-*/2} & \hat{x}_{i+1}^* P_{i+1}^{-*/2} & -\hat{x}_{i+1}^* \bar{K}_{b,i} \end{bmatrix}$$

where Θ is any unitary rotation that either lower-triangularizes the first two (block) rows or upper-triangularizes the third and fourth (block) rows of the pre-array. The filtered estimates \hat{x}_{i+1} can be constructed via $\hat{x}_{i+1} = (P_{i+1}^{1/2})^{-1} (P_{i+1}^{-1/2} \hat{x}_{i+1})$ or $\hat{x}_{i+1} = F_i(\hat{x}_i) + \bar{K}_{p,i} (R_{e,i}^{-1/2} e_i)$.

III. BRYSON-FRAZIER FORMULAS AND THEIR SQUARE-ROOT ALGORITHMS

The fixed-interval smoothing problem is to find $\{\hat{x}_{i|N}\}_{i=0:N}$ given output data $\{y_j\}_{j=0:N}$. In 1963, Bryson and Frazier [21] suggested two smoothing formulas that use the $\{\hat{x}_i\}$ or the $\{\hat{x}_{i|}\}$ of Kalman filtering, and certain quantities defined by the recursions

$$\lambda_{i|N} = F_{p,i}^* \lambda_{i+1|N} + H_i^* R_{e,i}^{-1} \lambda_{N+1|N} = 0, \quad (1)$$

$$\Lambda_{i|N} = F_{p,i}^* \Lambda_{i+1|N} F_{p,i} + H_i^* R_{e,i}^{-1} H_i \Lambda_{N+1|N} = 0 \quad (2)$$

where $F_{p,i} \triangleq F_i - K_{p,i} H_i$. (See the Appendix for the brief derivation.)

Algorithm III.1—BF Smoothing Formulas:

Case 1) (based on \hat{x}_i) $\hat{x}_{i|N} = \hat{x}_i + P_i \lambda_{i|N}$,

$$P_{i|N} = P_i - P_i \Lambda_{i|N} P_i.$$

Case 2) (based on $\hat{x}_{i|}$) $\hat{x}_{i|N} = \hat{x}_{i|} + P_{i|} F_i^* \lambda_{i+1|N}$,

$$P_{i|N} = P_{i|} - P_{i|} F_i^* \Lambda_{i+1|N} F_i P_{i|}.$$

Square-Root BF Smoothing Algorithms

The coefficients $F_{p,i}^*$ and $H_i^* R_{i,i}^{-1/2}$ of (1) can be computed simultaneously when the P_i are computed via the conventional equation-based algorithm. Similarly, we can get some terms related to the coefficients when we use a square-root algorithm for propagating the P_i . Consider the following array, formed from the array of Corollary II.1 extended with one more row

$$\begin{bmatrix} R_i^{1/2} & H_i P_i^{1/2} & 0 \\ 0 & F_i P_i^{1/2} & G_i Q_i^{1/2} \\ 0 & I & 0 \\ -y_i^* R_{i,i}^{-*/2} & \hat{x}_i^* P_i^{-*/2} & 0 \end{bmatrix} \Theta = \begin{bmatrix} R_{i,i}^{1/2} & 0 & 0 \\ \bar{K}_{p,i} & P_{i+1}^{1/2} & 0 \\ X_i & Y_i & (*) \\ -c_i^* R_{i,i}^{-*/2} & \hat{x}_{i+1}^* P_{i+1}^{-*/2} & (*) \end{bmatrix}$$

Cross-products between the first and the third rows and between the second and the third ones yield the equation $X_i = P_i^{-1/2} (P_i H_i^* R_{i,i}^{-*/2})$, $Y_i = P_i^{*/2} (F_i - \bar{K}_{p,i} H_i)^* P_{i+1}^{-*/2} = P_i^{*/2} F_{p,i}^* P_{i+1}^{-*/2}$. Rewriting (1) using the $\{X_i\}$ and $\{Y_i\}$ gives the formulas

$$(P_i^{*/2} \lambda_{i|N}) = (Y_i) (P_{i+1}^{*/2} \lambda_{i+1|N}) + (X_i) (R_{i,i}^{-1/2} e_i)$$

which recursively propagates $\{P_i^{*/2} \lambda_{i|N}\}$ instead of $\{\lambda_{i|N}\}$. With the $\{P_i^{-1/2} \hat{x}_i\}$ recursively found from the above array, we can use the Bryson-Frazier formulas to obtain

$$\hat{x}_{i|N} = (P_i^{1/2}) \{ (P_i^{-1/2} \hat{x}_i) + (P_i^{*/2} \lambda_{i|N}) \}. \quad (3)$$

It is impossible, however, to find the quantities $\{\lambda_{i|N}\}$ in (2) by directly using the $\{X_i\}$ and $\{Y_i\}$. Therefore, we shall separate the $\{P_i^{*/2} \lambda_{i|N}\}$ into $\{P_i^{*/2} \Lambda_{i|N}^{1/2}\}$ and $\{\Lambda_{i|N}^{-1/2} \lambda_{i|N}\}$ and form another array using the $\{X_i\}$, $\{Y_i\}$ and $\{P_i^{*/2} \Lambda_{i|N}^{1/2}\}$

$$\begin{bmatrix} X_i & (Y_i) (P_{i+1}^{*/2} \Lambda_{i+1|N}^{1/2}) \\ c_i^* R_{i,i}^{-*/2} & (\lambda_{i+1|N}^* \Lambda_{i+1|N}^{-*/2}) \end{bmatrix} \bar{\Theta} = \begin{bmatrix} W \\ \mu \end{bmatrix}$$

where $\bar{\Theta}$ is any unitary operator that zeros out the (1, 2) entry of the pre-array. Inner- or cross-products of the array entries yield

$$W W^* = X_i X_i^* + (Y_i) (P_{i+1}^{*/2} \Lambda_{i+1|N}^{1/2}) (\Lambda_{i+1|N}^{*/2} P_{i+1}^{1/2}) (Y_i)^*, \\ \mu = W^{-1} \{ (X_i) (R_{i,i}^{-1/2} e_i) + (Y_i) (\Lambda_{i+1|N}^{-1/2} \lambda_{i+1|N}) \}.$$

Hence, the new array recursively provides $\{W = P_i^{*/2} \Lambda_{i|N}^{1/2}\}$ and $\{\mu = \Lambda_{i|N}^{-1/2} \lambda_{i|N}\}$, so that the $\{P_{i|N}\}$ can then be found as

$$P_{i|N} = (P_i^{1/2}) \{ I - (P_i^{*/2} \Lambda_{i|N}^{1/2}) (\Lambda_{i|N}^{*/2} P_i^{1/2}) \} (P_i^{*/2}). \quad (4)$$

These results are summarized in the following proposition.

Proposition III.1—Square-Root BF Smoothing (Case 1): Assume that $R_i > 0$. Perform Step 1 first, and then Step 2 and Step 3, together.

Step 1: For $(P_0^{-1/2} \hat{x}_0) = 0$ and $(P_0^{1/2}) = \Pi_0^{1/2}$, propagate $\{P_i^{-1/2} \hat{x}_i\}$ and $\{P_i^{1/2}\}$ using a forward recursion

$$\begin{bmatrix} R_i^{1/2} & H_i P_i^{1/2} & 0 \\ 0 & F_i P_i^{1/2} & G_i Q_i^{1/2} \\ 0 & I & 0 \\ -y_i^* R_{i,i}^{-*/2} & \hat{x}_i^* P_i^{-*/2} & 0 \end{bmatrix} \Theta = \begin{bmatrix} R_{i,i}^{1/2} & 0 & 0 \\ \bar{K}_{p,i} & P_{i+1}^{1/2} & 0 \\ X_i & Y_i & (*) \\ -c_i^* R_{i,i}^{-*/2} & \hat{x}_{i+1}^* P_{i+1}^{-*/2} & (*) \end{bmatrix}$$

where Θ is any unitary operator that lower-triangularizes the first and second rows of the pre-array and $(*)$ indicates the redundant entries. During this forward recursion, generate and save the following variables: for Step 2, $\{P_i^{*/2} H_i^* R_{i,i}^{-*/2}\}$, $\{P_i^{*/2} F_{p,i}^* P_{i+1}^{-*/2}\}$, $\{R_{i,i}^{-1/2} e_i\}$, and for Step 3, $\{P_i^{1/2}\}$, $\{P_i^{-1/2} \hat{x}_i\}$.

Step 2: For $(\Lambda_{N+1|N}^{-1/2} \lambda_{N+1|N}) = 0$ and $(P_{N+1|N}^{*/2} \Lambda_{N+1|N}^{1/2}) = 0$, propagate $\{\Lambda_{i|N}^{-1/2} \lambda_{i|N}\}$ and $\{P_i^{*/2} \Lambda_{i|N}^{1/2}\}$ using a backward recursion

$$\begin{bmatrix} (P_i^{*/2} H_i^* R_{i,i}^{-*/2}) & (P_i^{*/2} F_{p,i}^* P_{i+1}^{-*/2}) (P_{i+1}^{*/2} \Lambda_{i+1|N}^{1/2}) \\ (c_i^* R_{i,i}^{-*/2}) & (\lambda_{i+1|N}^* \Lambda_{i+1|N}^{-*/2}) \end{bmatrix} \bar{\Theta} = \begin{bmatrix} (P_i^{*/2} \Lambda_{i|N}^{1/2}) & 0 \\ (\lambda_{i|N}^* \Lambda_{i|N}^{-*/2}) & (*) \end{bmatrix}$$

where $\bar{\Theta}$ is any unitary operator that zeros out the (1, 2) entry of the pre-array.

Step 3: Calculate smoothed estimates and their error covariances in parallel with Step 2 via (3) and (4).

If we are interested only in smoothed estimates but not in their error covariances, then we can speed up the algorithm and reduce the amount of storage.

Proposition III.2—Square-Root BF Smoothing (Estimates Only):

Step 1: For $(P_0^{-1/2} \hat{x}_0) = 0$ and $(P_0^{1/2}) = \Pi_0^{1/2}$, propagate $\{P_i^{-1/2} \hat{x}_i\}$ and $\{P_i^{1/2}\}$ using the same array as in Step 1 in Proposition III.1. Save the following: $\{P_i^{1/2}\}$, $\{P_i^{-1/2} \hat{x}_i\}$, $\{P_i^{*/2} F_{p,i}^* P_{i+1}^{-*/2}\}$, $\{c_i = (P_i^{*/2} H_i^* R_{i,i}^{-*/2}) (R_{i,i}^{-1/2} e_i)\}$.

Step 2: For $(P_{N+1|N}^{*/2} \lambda_{N+1|N}) = 0$, propagate $\{P_i^{*/2} \lambda_{i|N}\}$ using the following backward equation

$$(P_i^{*/2} \lambda_{i|N}) = (P_i^{*/2} F_{p,i}^* P_{i+1}^{-*/2}) (P_{i+1}^{*/2} \lambda_{i+1|N}) + c_i.$$

Step 3: Calculate smoothed estimates as

$$\hat{x}_{i|N} = (P_i^{1/2}) \{ (P_i^{-1/2} \hat{x}_i) + (P_i^{*/2} \lambda_{i|N}) \}.$$

Remark 1: The main advantages of the square-root BF algorithm are that there is neither matrix inversion nor back substitution, and all gains for forward and backward recursions can be computed via a forward pass only. Therefore, whereas the forward pass procedure requires a large computation, the backward pass procedure requires relatively small computation. As disadvantages, the error covariance $P_{i|N}$ might not be positive semi-definite due to round-off errors and, during the procedures, we should save $\{P_i^{*/2} H_i^* R_{i,i}^{-*/2}\}$, $\{P_i^{*/2} F_{p,i}^* P_{i+1}^{-*/2}\}$, $\{R_{i,i}^{-1/2} e_i\}$, $\{P_i^{1/2}\}$, $\{P_i^{-1/2} \hat{x}_i\}$, which requires memory of the order of $(N+1)np$, $(N+1)n^2$, $(N+1)p$, $(N+1)n(n+1)/2$, $(N+1)n$, respectively. The major costs come from $\{P_i^{*/2} F_{p,i}^* P_{i+1}^{-*/2}\}$ and $\{P_i^{1/2}\}$.

If we are interested in $\hat{x}_{i|N}$ but not in $P_{i|N}$ and the F_i are nonsingular, we can find another square-root form that compensates for the latter drawback. Let us think about a method for propagating $\{\hat{x}_i\}$ and $\{P_i \lambda_{i|N}\}$. The first quantities can be composed from the array in Step 1 of Proposition III.1 via $(P_i^{1/2}) (P_i^{-1/2} \hat{x}_i)$. For the second quantities, let us consider the following variation of (1): $(P_i \lambda_{i|N}) = F_{s,i} (P_{i+1} \lambda_{i+1|N}) + (\bar{K}_{f,i}) (R_{i,i}^{-1/2} e_i)$, where $F_{s,i}$ denotes

$$P_i F_{p,i}^* P_{i+1}^{-1} = F_i^{-1} (I - G_i Q_i G_i^* P_{i+1}^{-1}) = F_i^{-1} (I - G_i \bar{Q}_i^{1/2} \bar{K}_{b,i}^*),$$

Since the two equations in Algorithm II.1 give $\{\bar{K}_{f,i}\}$, $\{R_{i,i}^{-1/2} e_i\}$, $\{\bar{K}_{b,i}\}$, and $\{\bar{Q}_i^{1/2}\}$, we can find $\{P_i \lambda_{i|N}\}$ via

$$(P_i \lambda_{i|N}) = (F_i^{-1}) \{ I - G_i (\bar{Q}_i^{1/2}) (\bar{K}_{b,i}^*) \} (P_{i+1} \lambda_{i+1|N}) + (\bar{K}_{f,i}) (R_{i,i}^{-1/2} e_i). \quad (5)$$

Proposition III.3—Square-Root BF Smoothing (Case 2): Assume that $R_i > 0$ and the F_i are nonsingular.

Step 1: For $(P_0^{-1/2} \hat{x}_0) = 0$ and $(P_0^{1/2}) = \Pi_0^{1/2}$, propagate $\{(P_i^{-1/2} \hat{x}_i)\}$ and $\{(P_i^{1/2})\}$ using measurement- and time-update equations.

Measurement Updates:

$$\begin{bmatrix} 0 & P_i^{1/2} \\ -H_i^* R_i^{-*/2} & P_i^{-*/2} \\ -y_i^* R_i^{-*/2} & \hat{x}_i^* P_i^{-*/2} \end{bmatrix} \Theta = \begin{bmatrix} \bar{K}_{f,i} & P_{f,i}^{1/2} \\ 0 & P_{f,i}^{-*/2} \\ -\bar{c}_i^* R_{f,i}^{-*/2} & \hat{x}_{f,i}^* P_{f,i}^{-*/2} \end{bmatrix}$$

where Θ is any unitary operator that zeros out the (2, 1) entry of the pre-array. Save $\{(\bar{K}_{f,i})(R_{f,i}^{-1/2} \bar{c}_i)\}$.

Time Updates:

$$\begin{bmatrix} F_i P_{f,i}^{1/2} & G_i Q_{f,i}^{1/2} \\ 0 & Q_{f,i}^{1/2} \\ F_i^{-*/2} P_{f,i}^{-*/2} & 0 \\ \hat{x}_{f,i}^* P_{f,i}^{-*/2} & 0 \end{bmatrix} \Theta = \begin{bmatrix} P_{i+1}^{1/2} & 0 \\ Q_{i+1}^* P_{i+1}^{-1/2} & \bar{Q}_{i+1}^{1/2} \\ P_{i+1}^{-*/2} & -\bar{K}_{b,i} \\ \hat{x}_{i+1}^* P_{i+1}^{-*/2} & -\hat{x}_{i+1}^* \bar{K}_{b,i} \end{bmatrix}$$

where Θ is any unitary operator that zeros out the (1, 2) entry of the pre-array. Save the following: $\{(P_i^{1/2})(P_i^{-1/2} \hat{x}_i)\}$, $\{(\bar{Q}_{i+1}^{1/2})(\bar{K}_{b,i}^*)\}$.

Step 2: For $(P_{N+1|N} \lambda_{N+1|N}) = 0$, propagate $(P_i \lambda_{i|N})$ via (5).

Step 3: Calculate smoothed estimates via $\hat{x}_{i|N} = \{(P_i^{-1/2} \hat{x}_i)\} + (P_i \lambda_{i|N})$. ■

Remark 2: An interesting feature of this algorithm is that the SRIF block in the measurement-update equation in Algorithm II.1 is chosen for measurement updates, whereas the SRCF block in the time-update equation in Algorithm II.1 is chosen for time updates.

Remark 3: When the F_i are time-variant, there is no difference of memory size between the two propositions if we save the P_i by writing over the F_i . Otherwise, the memory size is quite different. The latter case requires memory of the order of $(N+1)n$, $(N+1)n$, $(N+1)n$ corresponding to $\{(P_i^{1/2})(P_i^{-1/2} \hat{x}_i)\}$, $\{(\bar{K}_{f,i})(R_{f,i}^{-1/2} \bar{c}_i)\}$ and $\{(\bar{Q}_{i+1}^{1/2})(\bar{K}_{b,i}^*)\}$, respectively.

Fast Square-Root BF Smoothing Algorithms

Now, we shall derive a fast square-root (or so-called Chandrasekhar-type) form for the BF formulas. If the system matrices are constant, we can apply a fast square-root algorithm for forwards Kalman filtering, which will produce the normalized Kalman gain \bar{K}_p , and the square-root innovation covariance $R_{f,i}^{1/2}$. Recall that we generated some quantities from a forward pass using the array in Proposition III.3: $\{(\bar{K}_{f,i})(R_{f,i}^{-1/2} \bar{c}_i)\}$ and $\{(\bar{Q}_{i+1}^{1/2})(\bar{K}_{b,i}^*)\}$, which are needed to form $F_{*,i} \triangleq F^{-1}(I - G\bar{Q}_{i+1}^{1/2}\bar{K}_{b,i}^*)$ for the backward pass. Unfortunately, the term $F_{*,i}$ cannot be found using the fast square-root covariance algorithm for forwards Kalman filtering, because this term contains P_{i+1}^{-1} which is impossible to obtain through the displacement of the P_i . Therefore, we must employ one more fast square-root algorithm related to the displacement of the P_{i+1}^{-1} .

Fast Square-Root Covariance Filtering. We first recall that the fast square-root form uses matrices $\{L_i\}$ or $\{N_i\}$ defined as $L_i J_i L_i^* \triangleq P_{i+1} - P_i$ or $N_i J_i N_i^* \triangleq P_{i+1|+1} - P_{i|+}$. Consider the following array

$$\begin{bmatrix} R_{f,i}^{1/2} & H L_i \\ \bar{K}_{f,i} & F L_i \end{bmatrix} \Theta = \begin{bmatrix} X & 0 \\ Y & Z \end{bmatrix}, J = \begin{bmatrix} I & 0 \\ 0 & J_L \end{bmatrix}$$

where Θ is any J -unitary operator that zeros out the (1, 2) entry of the pre-array. J -inner or J -cross products of the array entries yield $XX^* = R_{f,i+1}$, $YX^* = \bar{K}_{f,i+1} R_{f,i+1}^{1/2}$, $ZJ_L Z^* = P_{i+2} - P_{i+1} =$

$L_{i+1} J_L L_{i+1}^*$. Therefore, we can identify $X = R_{f,i+1}^{1/2}$, $Y = \bar{K}_{f,i+1}$, $Z = L_{i+1}$.

If we want to find the $\bar{K}_{f,i}$ from this array, we should use N_i rather than L_i , which obey the interesting formula $L_{i+1} \Theta = F N_i$, where Θ is some J_L -unitary operator. For a proof, note that, since $P_{i+1} = F P_{i|+} F^* + G Q G^*$ and thus $L_{i+1} J_L L_{i+1}^* = P_{i+2} - P_{i+1} = F(P_{i+1|+1} - P_{i|+})F^* = F N_i J_i N_i^* F^*$, therefore, the above array form can be rewritten by

$$\mathcal{F} \begin{bmatrix} R_{f,i}^{1/2} & H F N_{i-1} \\ \bar{K}_{f,i} & F N_{i-1} \end{bmatrix} \Theta = \mathcal{F} \begin{bmatrix} R_{f,i+1}^{1/2} & 0 \\ \bar{K}_{f,i+1} & N_i \end{bmatrix}$$

where $\mathcal{F} = I - F$ and Θ is any J -unitary operator that zeros out the (1, 2) entry of the pre-array. Hence, unless the matrix F is singular, we can generate the $\{(\bar{K}_{f,i})(R_{f,i}^{1/2})^{-1}\}$ from the fast square-root covariance algorithm. Now, to construct the $F_{*,i}$, we are going to provide a fast square-root information algorithm.

Fast Square-Root Information Filtering. The objective of the algorithm is to find $\Gamma_{*,i} = F^{-1}(I - G\bar{Q}_{i+1}^{1/2}\bar{K}_{b,i}^*)$, and indeed, $\{(\bar{Q}_{i+1}^{1/2})(\bar{K}_{b,i}^*)\}$. Consider the following array

$$\begin{bmatrix} \bar{Q}_{i+1}^{*/2} & G^* F^{-*} M_i \\ \bar{K}_{b,i} & F^{-*} M_i \end{bmatrix} \Theta = \begin{bmatrix} X & 0 \\ Y & Z \end{bmatrix}, J = \begin{bmatrix} I & 0 \\ 0 & J_M \end{bmatrix}$$

where Θ is any J -unitary operator that zeros out the (1, 2) entry of the pre-array, and $M_i J_M M_i^* \triangleq P_{i+1}^{-1} - P_i^{-1}$. Forming J -inner or J -cross products of the array entries yields

$$XX^* = Q + G^* F^{-*} (P_{i+1}^{-1} + H^* R^{-1} H) F^{-1} G = Q_{i+1}^{-1},$$

$$YX^* = F^{-*} (P_{i+1}^{-1} + H^* R^{-1} H) F^{-1} G = K_{b,i+1} Q_{i+1}^{1/2},$$

$$ZJ_M Z^* = P_{i+2}^{-1} - P_{i+1}^{-1} = M_{i+1} J_M M_{i+1}^*.$$

Therefore, we can identify $X = Q_{i+1}^{*/2}$, $Y = K_{b,i+1}$, $Z = M_{i+1}$. Here we note that the minimal rank of the J_L is as same as that of the J_M . To show this, consider initial conditions M_0 and N_0 . Then note that since $P_1 - P_0 \triangleq L_0 J_L L_0^* = F^{-1} N_{-1} J_L N_{-1}^* F^{-1}$, $P_1^{-1} - P_0^{-1} = -P_0^{-1} L_0 (J_L + L_0^* P_0^{-1} L_0)^{-1} L_0^* P_0^{-1} (\triangleq M_0 J_M M_0^*)$. Based on these results, we can present a fast square-root smoothing algorithm.

Proposition III.4

Step 1 (Fast Square-Root Covariance Filtering)

$$\begin{bmatrix} R_{f,i}^{1/2} & H F N_{i-1} \\ \bar{K}_{f,i} & F N_{i-1} \\ R_{f,i}^{-*/2} & 0 \end{bmatrix} \Theta = \begin{bmatrix} R_{f,i+1}^{1/2} & 0 \\ \bar{K}_{f,i+1} & N_i \\ R_{f,i+1}^{-*/2} & (*) \end{bmatrix}$$

where $J = I - J_L$ and Θ is any J -unitary operator which zeros out the (1, 2) entry of the pre-array and

$$L_0 J_L L_0^* = P_1 - P_0, L_0 = F N_{-1},$$

$$R_{f,0}^{1/2} = (R + H P_0 H^*)^{1/2}, \bar{K}_{f,0} = P_0 H^* R_{f,0}^{-*/2}.$$

For $\hat{x}_0 = 0$, compute $\{\mu_i\}$ and $\{x_i\}$ via $\mu_i = \bar{K}_{f,i} R_{f,i}^{*/2} (y_i - H \hat{x}_i)$ and $\hat{x}_{i+1} = F(\hat{x}_i + \mu_i)$, respectively, and save them.

Step 2 (Fast Square-Root Information Filtering)

$$\begin{bmatrix} \bar{Q}_{i+1}^{*/2} & G^* F^{-*} M_i \\ \bar{K}_{b,i} & F^{-*} M_i \\ \bar{Q}_{i+1}^{1/2} & 0 \end{bmatrix} \Theta = \begin{bmatrix} \bar{Q}_{i+1}^{*/2} & 0 \\ \bar{K}_{b,i+1} & M_{i+1} \\ \bar{Q}_{i+1}^{1/2} & (*) \end{bmatrix}$$

where $J = I - J_M$ and Θ is any J -unitary operator that zeros out the (1, 2) entry of the pre-array and

$$M_0 J_M M_0^* = -P_0^{-1} L_0 (J_L + L_0^* P_0^{-1} L_0)^{-1} L_0^* P_0^{-1},$$

$$\bar{Q}_0^{*/2} = (Q - Q G P_1^{-1} G^* Q)^{-*/2}, \bar{K}_{b,0} = P_1^{-1} G Q \bar{Q}_0^{*/2}.$$

During the procedure, save $\{(\bar{Q}_{i+1}^{1/2})(\bar{K}_{b,i}^*)\}$. For $(P_{N+1} \lambda_{N+1|N}) = 0$, propagate

$$(P_i \lambda_{i|N}) = F^{-1} \{I - G\{(\bar{Q}_{i+1}^{1/2})(\bar{K}_{b,i}^*)\}\} (P_{i+1} \lambda_{i+1|N}) + \mu_i.$$

TABLE I
CONSTRAINTS

SR algorithms	Error Cov.	F_i	System
Prop. III.1	yes		
Prop. III.2	no		
Prop. III.3	no	invertible	
Prop. III.4	no	invertible	constant

TABLE II
COMPARISONS

SR algorithms	Storage	Speed	Stability
Prop. III.1	$O(\frac{3}{2}(N+1)n^2)$	slowest	Good
Prop. III.2	$O(\frac{3}{2}(N+1)n^2)$	slow	Good
Prop. III.3	$O((N+1)np)$	slow	Good
Prop. III.4	$O((N+1)np)$	fastest	(?)

Step 3 (Smoothed Estimates): Compute the smoothed estimates as $\hat{x}_{i|N} = \hat{x}_i + (P_i \lambda_{i|N})$.

Remark 4: This algorithm requires memory of order of $(N+1)n$, $(N+1)n$, $(N+1)np$ for the $\{\hat{x}_i\}$, $\{\mu_i\}$, and $\{(\hat{Q}_i^{1/2})(\hat{K}_{b,i}^*)\}$.

Remark 5 (Comparisons): If error covariances need to be computed, only Proposition III.1 is available. If the matrices F_i are not nonsingular, Propositions III.1 and III.2 are possible, where using the latter is faster than using the former. If the F_i are nonsingular and error covariances do not need to be computed, Propositions III.1, III.2, and III.3 can be used, where Proposition III.3 gives better performance than the other propositions because of less storage and computation. If, in addition, the system matrices are constant, all the propositions can be used. In this case, we recommend Proposition III.3 and Proposition III.4, depending on a trade-off between speed and stability—see Tables I and II.

IV. CONCLUDING REMARKS

The new square-root algorithms use arrays including filtered or smoothed estimates and their covariances and avoid inversion or back substitution, which are major advantages over previously known algorithms with respect to systolic array and parallel implementations as well as numerical stability and conditioning. Moreover, the square-root array form supplies flexibility in implementing the rotation in various ways.

For constant-parameter systems with invertible F , a fast square-root (or Chandrasekhar-type) smoothing algorithm is suggested, which has advantages of small storage and fast computation over the others. But the numerical properties of this algorithm need further investigation because it uses J -unitary rotations rather than unitary rotations.

APPENDIX

BRIEF DERIVATION OF BF FORMULAS

The fixed-interval smoothing problem is to find $\{\hat{x}_{i|N}\}_{i=0:N}$ given output data $\{y_j\}_{j=0:N}$. In this case, since the smoothed estimate can be rewritten with the innovations e_j so that $\hat{x}_{i|N} = \sum_{j=0}^N E(x_i e_j^*) E^{-1}(e_j e_j^*) e_j$, where " $E(x)$ " denotes the expectation of x , we have the following two expressions of $\hat{x}_{i|N}$

$$\sum_{j=0}^{i-1} E(x_i e_j^*) E^{-1}(e_j e_j^*) e_j + \sum_{j=i}^N E(x_i e_j^*) E^{-1}(e_j e_j^*) e_j$$

or

$$\sum_{j=0}^i E(x_i e_j^*) E^{-1}(e_j e_j^*) e_j + \sum_{j=i+1}^N E(x_i e_j^*) E^{-1}(e_j e_j^*) e_j$$

where $\sum_{j=0}^{i-1} E(x_i e_j^*) E^{-1}(e_j e_j^*) e_j$ can be denoted as \hat{x}_i and $\sum_{j=i}^N E(x_i e_j^*) E^{-1}(e_j e_j^*) e_j$, as $\hat{x}_{i|N}$. After performing complicated calculation, we can verify that, for $i \leq j$

$$E(x_i e_j^*) = P_i \Phi_p^*(j, i) H_j^* = P_{i|j} F_i^* \Phi_p^*(j, i+1) H_j^*$$

where $\Phi_p(j, i) = F_{p,j-1} F_{p,j-2} \cdots F_{p,i}$, $F_{p,i} = F_i - K_{p,i} H_i^*$, $K_{p,i} = F_i K_{f,i}$. Therefore, defining $\lambda_{i|N}$ as $\sum_{j=i}^N \Phi_p^*(j, i) H_j^* R_{e,j}^{-1} e_j$ gives the two recursive equations for the smoothed estimates in Algorithm III.1.

Since e_i is orthogonal to e_j for $i \neq j$, the two recursive equations for the smoothed estimates in Algorithm III.1 provide the relation

$$\begin{aligned} E(\hat{x}_{i|N} \hat{x}_i^*) &= E(\hat{x}_{i|N} \hat{x}_i^*) + P_{i|j} F_i^* E(\lambda_{i+1|N} \lambda_{i+1|N}^*) F_i P_{i|j} \\ &= E(\hat{x}_i \hat{x}_i^*) + P_i E(\lambda_{i|N} \lambda_{i|N}^*) P_i. \end{aligned}$$

Using the fact that $P_{i|N} = E(x_i x_i^*) - E(\hat{x}_{i|N} \hat{x}_{i|N}^*)$, $P_{i|j} = E(x_i x_i^*) - E(\hat{x}_{i|j} \hat{x}_{i|j}^*)$, and $P_i = E(x_i x_i^*) - E(\hat{x}_i \hat{x}_i^*)$, we can obtain the two recursive equations for the covariance matrices in Algorithm III.1.

Robust H_∞ Control of Uncertain Nonlinear System via State Feedback

Tielong Shen and Katsutoshi Tamura

Abstract—This technical note presents a solution of robust H_∞ control problem for an affine nonlinear system with gain bounded uncertainty. It is shown that the L_2 -induced norm of a closed-loop system with the uncertainty is less than one if an extended nonlinear system with no uncertainty is dissipative with respect to a supply rate. In consequence of this result, a state feedback law such that the closed-loop system has H_∞ robust performance is derived based on the Hamilton–Jacobi inequality. It is also shown that the existing results for linear systems are special cases of the presented results.

I. INTRODUCTION

A popular method to solve the standard H_∞ control problem is the state-space approach developed in [1] which is based on the relation between the H_∞ norm of linear system and the Riccati equation or inequality. Recently, attention was focused to robust H_∞ performance problem and the state-space approach has been extended to solve this problem for linear systems with parameter perturbation [6]–[9]. In this literature, it was shown that a controller ensuring robust stability of the closed system with an H_∞ norm restriction can be obtained by solutions of the Riccati inequalities. The background of these results is that the robust stability of the system with parameter perturbation can be guaranteed by a positive definite solution of the Riccati equation (see [10]–[12]). The state feedback problem ([6], [8]) and the measurement feedback ([7], [9]) have been solved using the state-space approach.

On the other hand, the state-space approach was extended to nonlinear H_∞ control problems [2] and [3] where the terminology of nonlinear H_∞ control means that the L_2 induced norm from input to output is less than one. This extension was possible based on the relation between the L_2 induced norm of nonlinear system and the Hamilton–Jacobi equation or inequality. The relation is a generalization of the one between H_∞ norm and Riccati equation in linear systems. The classical notion of dissipativeness in [4] and [5] plays an important role to obtain this result. A nonlinear state feedback [2] and measurement feedback [3] approaches were developed, respectively, along this research line.

In this note, the line of the research is kept to develop robust H_∞ suboptimal control of uncertain nonlinear systems. We will extend the approach given in [6] to solve the robust H_∞ performance problem for nonlinear systems with gain bounded uncertainty. In other words, a state feedback controller such that the L_2 induced norm of the closed-loop system with the uncertainty is less than one can be

obtained by a smooth solution of Hamilton–Jacobi inequality. The approach developed in this note can be extended to output feedback case.

The following notations are adopted here. For vector $z \in R^n$, $\|z\|^2$ and $\|z\|_T$ denote $z^T z$ and $\{\int_0^T z^T(\tau)z(\tau)d\tau\}^{1/2}$, respectively. For a differentiable function $V: R^n \rightarrow R$, $\frac{\partial V}{\partial x}(x)$ is the row-vector of partial derivatives. $L_2(0, T)$ denotes a set of vector-valued function $z(t)$ satisfying $\|z(t)\|_T < \infty$.

II. PRELIMINARIES

Consider a nonlinear system with a gain bounded perturbation given by

$$\dot{x} = f(x) + \Delta f(x) + g_1(x)d + g_2(x)u \quad (1)$$

$$z = h_1(x) + k_{12}(x)u \quad (2)$$

where x is a state vector defined on a neighborhood \mathcal{X} of the origin in R^n , $u \in R^m$ denotes the control input, $d \in R^r$ the disturbance input, $z \in R^p$ the penalty variable, f, g_1, g_2, h_1 and k_{12} are known smooth mappings, and Δf is a smooth uncertain mapping. It is assumed that $f(0) = 0$ and $h_1(0) = 0$ without loss of generality.

We make the following assumption throughout this note.

Assumption 1: The uncertain mapping $\Delta f(x)$ is described by $\Delta f(x) = c(x)\delta(x)$ with known smooth mapping $c: R^n \rightarrow R^{n \times q_1}$ and unknown smooth mapping $\delta: R^n \rightarrow R^{q_1}$. Δf belongs to a bounded set defined by

$$\Omega := \{\Delta f(x) \mid \delta(0) = 0, \quad \|\delta(x)\|^2 \leq \|w(x)\|^2, \forall x \in \mathcal{X}\} \quad (3)$$

where $w: R^n \rightarrow R^{q_2}$ is a given weighting mapping.

Assumption 2: $k_{12}^T(x)[h_1(x) \ k_{12}(x)] = [0 \ I]$.

Assumption 2 is a nonlinear version of the standard assumption in [1] for simplicity.

For the system (1)–(2), consider a nonlinear state-feedback law

$$u = \alpha(x), \quad \alpha(0) = 0. \quad (4)$$

Definition 1: Let $\gamma > 0$ be given. The closed-loop system of (1) and (2) with (4) is said to have locally robust disturbance attenuation performance in $\mathcal{U} \subset \mathcal{X}$ if for any $\Delta f \in \Omega$, the free system with $d = 0$ is locally asymptotically stable with domain of attraction containing \mathcal{U} , and $\|z\|_T \leq \gamma\|d\|_T$ for every $T > 0$ and every $d \in \mathcal{D}$, where the set \mathcal{D} is defined by

$$\mathcal{D} := \{d \mid d \in L_2(0, T) \text{ s.t. } x(t) \text{ with } x(0) = 0 \text{ remains in } \mathcal{U}, \forall t \leq T\}. \quad (5)$$

The nonlinear robust H_∞ control problem is now defined as follows. Given the plant (1)–(2), find a state feedback controller (4) such that the closed-loop system has local robust disturbance attenuation performance. Without loss of generality, let $\gamma = 1$.

We collect some preliminary results in the next Lemma (see [2] and [4] for proof) which are useful to prove our main result.

Consider a smooth nonlinear system given by

$$\dot{x} = f(x) + g(x)d \quad (6)$$

$$z = h(x) \quad (7)$$

where the state x is defined on \mathcal{X} , $d \in R^r$ and $z \in R^p$ denote the input and the output, respectively. f, g , and h are smooth mappings satisfying $f(0) = 0$ and $h(0) = 0$.

Manuscript received January 21, 1994; revised June 2, 1994.

IEEE Log Number 9408793.

Lemma 1: Assume that the system (6)–(7) is zero-state observable [2]. The free system of (6) with $d = 0$ is asymptotically stable and $\|z\|_T \leq \|d\|_T$ for every $T > 0$, if system (6)–(7) is dissipative with respect to the supply rate [5]

$$w(d, z) = \frac{1}{2} \{ \|d\|^2 - \|z\|^2 \} \quad (8)$$

or equivalently, there exists a nonnegative definite smooth solution $V(x) \geq 0$ satisfying the Hamilton-Jacobi inequality

$$\begin{aligned} \frac{\partial V}{\partial x}(x)f(x) + \frac{1}{2} \frac{\partial V}{\partial x}(x)g(x)g^T(x) \frac{\partial^T V}{\partial x}(x) \\ + \frac{1}{2} h^T(x)h(x) \leq 0, \quad V(0) = 0. \end{aligned} \quad (9)$$

III. MAIN RESULT

The main result is to give a solution of the robust H_∞ control problem. We start with finding a sufficient condition for the nonlinear system having robust H_∞ performance.

Consider a nonlinear system with uncertainty described by

$$\dot{x} = f(x) + \Delta f(x) + g(x)d \quad (10)$$

$$z = h(x) \quad (11)$$

where the uncertain nonlinear mapping $\Delta f(x)$ satisfies Assumption 1.

For system (10)–(11), define an extended nonlinear system by

$$\begin{aligned} \dot{x} &= f(x) + [g(x)\lambda(x)e(x)]d' \\ h(x) & \end{aligned} \quad (12)$$

where $d' \in R^{r+q}$, $z' \in R^{r+q}$, and $\lambda(x) > 0$ is a given smooth scale function in $x \in \mathcal{X}$.

Theorem 1: Suppose that the system (10)–(11) is zero-state observable for every $\Delta f(x) \in \Omega$. If there exists a smooth scale function $\lambda(x) > 0$ such that the system (12)–(13) with respect to the supply rate $\frac{1}{2} \{ \|d'\|^2 - \|z'\|^2 \}$ is dissipative, then the nonlinear system (10)–(11) has locally robust disturbance attenuation performance in \mathcal{U} .

Proof: Suppose that system (12)–(13) with respect to supply rate $\frac{1}{2} \{ \|d'\|^2 - \|z'\|^2 \}$ is dissipative, then there exists a nonnegative definite smooth function $V(x) \geq 0$ ($V(0) = 0$) such that

$$V(x) \leq \int_0^t \frac{1}{2} \{ \|d'\|^2 - \|z'\|^2 \} d\tau + V(x_0). \quad (14)$$

So that

$$\frac{\partial V}{\partial x}(x) \{ f(x) + [g(x)\lambda(x)e(x)]d' \} \leq \frac{1}{2} \{ \|d'\|^2 - \|z'\|^2 \}. \quad (15)$$

From Theorem 2 in [2], there exists a $V(x) \geq 0$ ($V(0) = 0$) such that

$$\begin{aligned} \frac{\partial V}{\partial x}(x)f(x) + \frac{1}{2} \frac{\partial V}{\partial x}(x)g(x)g^T(x) \frac{\partial^T V}{\partial x}(x) \\ + \lambda^2(x)e(x)e^T(x) \frac{\partial^T V}{\partial x}(x) \\ + \frac{1}{2} \left\{ h^T(x)h(x) + \frac{1}{\lambda^2(x)} w^T(x)w(x) \right\} \leq 0. \end{aligned} \quad (16)$$

Adding and subtracting $\frac{\partial V}{\partial x}(x)\Delta f(x)$ in (16)

$$\begin{aligned} \frac{\partial V}{\partial x}(x) \{ f(x) + \Delta f(x) \} \\ + \frac{1}{2} \frac{\partial V}{\partial x}(x)g(x)g^T(x) \frac{\partial^T V}{\partial x}(x) + \frac{1}{2} h^T(x)h(x) \\ - \frac{\partial V}{\partial x}(x)v(x)\delta(x) \\ + \frac{\lambda^2(x)}{2} \frac{\partial V}{\partial x}(x)e(x)e^T(x) \frac{\partial^T V}{\partial x}(x) \\ + \frac{1}{2\lambda^2(x)} w^T(x)w(x) \leq 0. \end{aligned} \quad (17)$$

Rearranging some terms in (17), we have

$$\begin{aligned} \frac{\partial V}{\partial x}(x) \{ f(x) + \Delta f(x) \} \\ + \frac{1}{2} \frac{\partial V}{\partial x}(x)g(x)g^T(x) \frac{\partial^T V}{\partial x}(x) + \frac{1}{2} h^T(x)h(x) \\ + \frac{\lambda^2(x)}{2} \left\| e^T(x) \frac{\partial^T V}{\partial x}(x) - \frac{1}{\lambda^2(x)} \delta(x) \right\|^2 \\ + \frac{1}{2\lambda^2(x)} \{ \|w(x)\|^2 - \|\delta(x)\|^2 \} \leq 0. \end{aligned} \quad (18)$$

Since $\|\delta(x)\|^2 \leq \|w(x)\|^2$ for every $x \in \mathcal{X}$ and every $\Delta f(x) \in \Omega$, we obtain

$$\begin{aligned} \frac{\partial V}{\partial x}(x) \{ f(x) + \Delta f(x) \} \\ + \frac{1}{2} \frac{\partial V}{\partial x}(x)g(x)g^T(x) \frac{\partial^T V}{\partial x}(x) \\ + \frac{1}{2} h^T(x)h(x) \leq 0, \quad \Delta f \in \Omega. \end{aligned} \quad (19)$$

Therefore, by Lemma 1 the free system (10)–(11) with $d = 0$ is asymptotically stable and $\|z\|_T \leq \|d\|_T, \forall d \in D$ for every $\Delta f(x) \in \Omega$.

In consequence of Theorem 1, we have the following corollary.

Corollary 1. Suppose that the system (10)–(11) is zero-state observable for every $\Delta f \in \Omega$. The system has the locally robust disturbance attenuation performance in \mathcal{U} if there exists a smooth scale function $\lambda(x) > 0$ such that the Hamilton-Jacobi inequality

$$\begin{aligned} \frac{\partial V}{\partial x}(x)f(x) + \frac{1}{2} \frac{\partial V}{\partial x}(x)g(x)g^T(x) \\ + \lambda^2(x)e(x)e^T(x) \frac{\partial^T V}{\partial x}(x) \\ + \frac{1}{2} \left\{ h^T(x)h(x) + \frac{1}{\lambda^2(x)} w^T(x)w(x) \right\} \leq 0 \end{aligned} \quad (20)$$

has smooth solution $V(x) \geq 0$ ($V(0) = 0$).

Remark 1: It is interesting to compare the result in Corollary 1 with linear case given in [6] and [8]. Consider a linear system with parameter perturbation

$$\dot{x} = (A + E\Sigma(t))x + Bd \quad (21)$$

$$z = Cx \quad (22)$$

where unknown time-varying matrix $\Sigma(t)$ satisfies $\Sigma^T(t)\Sigma(t) \leq F^T F, \forall t$ for a given F . Since a smooth solution $V(x)$ of the Hamilton-Jacobi inequality can be given by $V(x) = x^T P x$, where P is the nonnegative definite solution of the Riccati inequality

$$A^T P + P A + P(BB^T + \lambda^2 E E^T)P + C^T C + \frac{1}{\lambda^2} F^T F < 0 \quad (23)$$

for a scale $\lambda > 0$, Corollary 1 implies that the linear system (21)–(22) has the robust H_∞ performance if the Riccati inequality has the nonnegative definite solution, which has been shown in [6].

Remark 2: Note that in nonlinear case the scaling parameter λ be chosen as a function of x , which may reduce conservativeness of the result.

We now consider the robust H_∞ control problem mentioned in Section II. Using the condition in Theorem 1, the problem can be solved by finding such a state feedback controller that makes the

closed-loop system dissipative with respect to the supply rate. It can be done by solving an Hamilton-Jacobi inequality.

Theorem 2 Assume that the system $\dot{x} = f(x) + \Delta f(x) + g_1(x)d$, $z = h_1(x)$ is zero-state observable for every $\Delta f(x) \in \Omega$. If there exists a scale smooth function $\lambda(x) > 0$ such that the Hamilton-Jacobi inequality

$$\begin{aligned} & \frac{\partial V}{\partial x}(x)f(x) + \frac{1}{2} \frac{\partial V}{\partial x}(x) \\ & \times \left\{ g_1(x)g_1^T(x) + \lambda^2(x)x(x)x^T(x) - g_2(x)g_2^T(x) \right\} \frac{\partial^T V}{\partial x}(x) \\ & + \frac{1}{2} \left\{ h_1^T(x)h_1(x) + \frac{1}{\lambda^2(x)}u^T(x)u(x) \right\} \leq 0 \end{aligned} \quad (24)$$

has a smooth solution $V(x) \geq 0$ ($V(0) = 0$), then a solution of the robust H_∞ control problem is given by

$$\alpha(x) = -g_2^T(x) \frac{\partial^T V}{\partial x}(x) \quad (25)$$

Proof Note that the closed loop system of the plant (1)-(2) with the state feedback controller $u = \alpha(x)$ is given by

$$\dot{x} = f(x) + \Delta f(x) + g_2(x)\alpha(x) + g_1(x)d \quad (26)$$

$$z = h_1(x) + k_{12}(x)\alpha(x) \quad (27)$$

Using the Hamilton-Jacobi inequality (24) and the assumptions in Section II, we obtain

$$\begin{aligned} & \frac{\partial V}{\partial x}(x)\{f(x) + \Delta f(x) + g_2(x)\alpha(x)\} \\ & + \frac{1}{2} \frac{\partial V}{\partial x}(x)g_1(x)g_1^T(x) \frac{\partial^T V}{\partial x}(x) \\ & + \frac{1}{2} \left\{ h_1^T(x) + \alpha^T(x)k_{12}^T(x) \right\} \left\{ h_1(x) + k_{12}(x)\alpha(x) \right\} \\ & \leq -\frac{1}{2} \left\| \lambda(x)x^T(x) \frac{\partial^T V}{\partial x}(x) - \frac{1}{\lambda(x)}\delta(x) \right. \\ & \quad \left. - 2\lambda^2(x) \frac{\partial^T V}{\partial x}(x) \right\|^2 - \|\delta(x)\|^2 \\ & + \frac{1}{2} g_2^T(x) \frac{\partial^T V}{\partial x}(x) + \alpha(x) \end{aligned} \quad (28)$$

Use of (25) for $\alpha(x)$ and assumption on the uncertain mapping $\delta(x)$ gives

$$\begin{aligned} & \frac{\partial V}{\partial x}(x)\{f(x) + \Delta f(x) + g_2(x)\alpha(x)\} \\ & + \frac{1}{2} \frac{\partial V}{\partial x}(x)g_1(x)g_1^T(x) \frac{\partial^T V}{\partial x}(x) \\ & + \frac{1}{2} \left\{ h_1^T(x) + \alpha^T(x)k_{12}^T(x) \right\} \left\{ h_1(x) + k_{12}(x)\alpha(x) \right\} \\ & \leq 0, \quad \forall \Delta f(x) \in \Omega \end{aligned} \quad (29)$$

By Theorem 2 in [2]

$$\begin{aligned} & \frac{\partial V}{\partial x}(x)\{f(x) + \Delta f(x) + g_2(x)\alpha(x)\} + \frac{\partial V}{\partial x}(x)g_1(x)d \\ & \leq \frac{1}{2}(\|d\|^2 - \|z\|^2), \quad \forall \Delta f(x) \in \Omega \end{aligned} \quad (30)$$

Hence, for every $T > 0$, $\|z\|_T \leq \|d\|_T$, $\forall d \in \mathcal{D}$ for every $\Delta f(x) \in \Omega$

To show the robust asymptotic stability of the free system

$$\dot{x} = f(x) + g_2(x)\alpha(x) + \Delta f(x) \quad (31)$$

we consider the solution $V(x) \geq 0$ as a Lyapunov function. From (29) and Assumption 2, we have $V \leq 0$, $\forall \Delta f(x) \in \Omega$ and $V = 0$ implies $h_1(x) = 0$ and $\alpha(x) = 0$. Therefore, the robust asymptotic stability follows from the Assumption that pair $\{f + \Delta f, h\}$ is zero state observable for every Δf .

Remark 3 As shown in Remark 1 in linear case the solution $V(x) \geq 0$ of (24) will be given by the solution of the Riccati inequality (see the result in [6]).

IV. CONCLUSION

In this note, a sufficient condition for that a nonlinear system with uncertainty has robust H_∞ performance is given based on the classical dissipativeness theory. Using this condition such a state feedback control law is derived based on the Hamilton-Jacobi inequality that the closed loop system has locally robust disturbance attenuation performance. It is also shown that the well known results for linear system are special cases of the presented results.

Optimal Nonparametric Identification from Arbitrary Corrupt Finite Time Series

Jie Chen, Carl N. Nett, and Michael K. H. Fan

Abstract—In this paper we formulate and solve a worst-case system identification problem for single-input, single-output, linear, shift-invariant, distributed parameter plants. The available *a priori* information in this problem consists of time-dependent upper and lower bounds on the plant impulse response and the additive output noise. The available *a posteriori* information consists of a corrupt finite output time series obtained in response to a known, nonzero, but otherwise arbitrary, input signal. We present a novel identification method for this problem. This method maps the available *a priori* and *a posteriori* information into an “uncertain model” of the plant, which is comprised of a nominal plant model, a bounded additive output noise, and a bounded additive model uncertainty. The upper bound on the model uncertainty is explicit and expressed in terms of both the ℓ_1 and H_∞ system norms. The identification method and the nominal model possess certain well-defined optimality properties and are computationally simple, requiring only the solution of a single linear programming problem.

I. INTRODUCTION

The primary goal of this paper is to develop a system identification method for identifying, from available *a priori* and *a posteriori* information, an “uncertain plant model” which can be used for robust control design. Typically, an uncertain model consists of a nominal design model, a noise specification, and a model error specification. Though the specific nature of the required noise and model error specifications is dictated by the specific robust control method to be applied, nearly all existing robust control design methods require that these specifications be stated as explicit, worst-case/deterministic bounds on the levels of noise and model error [7], [8]. For this reason a worst-case/deterministic identification approach is adopted in this paper. System identification methods that take a worst-case/deterministic, robust control oriented approach have recently received considerable interest; an extensive list of publications on these problems may be found in, e.g., [12] and [36] and the references therein.

The specific identification problem considered in this paper pertains to single-input, single-output, linear, shift-invariant, distributed parameter plants. The available *a priori* information in this problem consists of time-dependent upper and lower bounds on the plant impulse response and the additive output noise. The available *a posteriori* information consists of a corrupt finite output time series obtained in response to a known, nonzero, but otherwise arbitrary applied input. Our objective is to develop from the given information an uncertain model which has an additive model error structure and whose modeling uncertainty is measured in the ℓ_1 and H_∞ system norms. Our motivation for these choices of model error structures and system norms stems from the fact that they are consistent with the currently popular ℓ_1 and H_∞ design methods [7], [8]. Recently,

there has been a bulk of research work devoted to problems of this kind, under the name of identification in ℓ_1 and H_∞ . We refer the reader to some of the closely related problems and results in, e.g., [12], [15], [10], [27], [4], [21], [20], [33], [5], [16], [1], and [29] for a glimpse of the work in this area; discussions on these results are beyond the scope of this note.

Our main contribution in this paper consists of an identification algorithm and several model error bounds. The identification algorithm maps the given *a priori* and *a posteriori* information to an identified nominal model. The error bounds are explicit and are expressed in terms of both the ℓ_1 and H_∞ norms. Our algorithm possesses certain well-defined optimality properties and is generally referred to as an interpolatory algorithm in the information-based complexity (IBC) theory [31], [32]. It is a standard result in IBC that algorithms of the interpolatory class are worst-case strongly optimal to within a factor of two, in the sense that the worst-case error achievable in applying the algorithm to approximate the underlying plant is at most a factor of two of the smallest possible such error. Moreover, our algorithm also has the advantage that it can be constructed in an extremely simple manner: it requires only that a single linear programming problem be solved. Technically, our development shares some elements with the set membership method for parametric identification problems (see, e.g., [23]–[25] and the references therein).

The notation used throughout this paper is as follows. Let \mathbf{Z} denote the set of integers, $\mathbf{Z}_+ := \{k \in \mathbf{Z} : k \geq 0\}$, and $\mathbf{Z}_{+,n} := \{k \in \mathbf{Z}_+ : 0 \leq k \leq n-1\}$. Let \mathbf{R} denote the set of real numbers, and \mathbf{R}^n denote the space of n dimensional real vectors. Let $S_n(a, b) := \{x \in \mathbf{R}^n : a_k \leq x_k \leq b_k, k \in \mathbf{Z}_{+,n}\}$. Define the normed spaces $\ell_1 := \{f: \mathbf{Z}_+ \rightarrow \mathbf{R} \mid \|f\|_1 := \sum_{k=0}^{\infty} |f(k)| < \infty\}$, $\ell_2 := \{f: \mathbf{Z}_+ \rightarrow \mathbf{R} \mid \|f\|_2^2 := \sum_{k=0}^{\infty} |f(k)|^2 < \infty\}$, and $\ell_\infty := \{f: \mathbf{Z}_+ \rightarrow \mathbf{R} \mid \|f\|_\infty := \sup_{k \in \mathbf{Z}_+} |f(k)| < \infty\}$. Let $\mathbf{D} := \{z \in \mathbf{C} : |z| < 1\}$ and denote $H_\infty := \{f: \mathbf{D} \rightarrow \mathbf{C} \mid f \text{ analytic in } \mathbf{D} \text{ and } \|f\|_{H_\infty} := \sup_{z \in \mathbf{D}} |f(z)| < \infty\}$. Additionally, define the operator $T_n: \ell_\infty \rightarrow \mathbf{R}^n$ such that $(T_n f)(k) = f(k)$ for $k \in \mathbf{Z}_{+,n}$.

Finally, a preliminary version of this paper was presented previously in [3].

II. PROBLEM FORMULATION AND PRELIMINARY RESULTS

We consider the class of causal, single-input, single-output, linear, shift-invariant, stable distributed parameter systems. This class of systems can be identified with a normed linear space $\mathbf{X} \subset \ell_1$ which contains one-sided sequences and is endowed with a system induced norm $\|\cdot\|$. A system $h \in \mathbf{X}$ is represented by its impulse response $\{h(k)\}_{k=0}^{\infty}$, or alternatively, by the corresponding transform $\hat{h}(z)$, where¹

$$\hat{h}(z) := \sum h(k)z^k. \quad (2.1)$$

The system to be identified is assumed to belong to \mathbf{X} . Additionally, its impulse response $\{h(k)\}_{k=0}^{\infty}$ is assumed to satisfy $M_k^- \leq h(k) \leq M_k^+, \forall k \in \mathbf{Z}_+$, where $\{M_k^-\}_{k=0}^{\infty} \in \ell_1$ and $\{M_k^+\}_{k=0}^{\infty} \in \ell_1$ are two prespecified sequences which represent the available plant *a priori* information. We may write $h \in S_\infty(M^-, M^+) \subset \mathbf{X}$.

The experimental procedure considered consists of applying an arbitrary nonzero input $u \in \ell_\infty$ to the system $h \in \mathbf{X}$ to generate an

¹This transform corresponds to the standard z -transform evaluated at $1/z$.

output $h * u$. An additively corrupted version of $h * u$ is observed over a finite duration n . Let the corrupting noise be denoted by $v \in \ell_\infty$. Then, the experimental procedure can be precisely written as

$$E_n(h, v) := T_n((h * u) + v).$$

The *a priori* information on the output noise $v \in \ell_\infty$ consists of two prespecified sequences $\{\epsilon_k^-\}_{k=0}^\infty \in \ell_\infty$ and $\{\epsilon_k^+\}_{k=0}^\infty \in \ell_\infty$. The noise sequence $\{v(k)\}_{k=0}^\infty$ is assumed to satisfy $\epsilon_k^- \leq v(k) \leq \epsilon_k^+$, $\forall k \in \mathbb{Z}_+$ or, alternatively, $v \in S_\infty(\epsilon^-, \epsilon^+) \subset \ell_\infty$. The experiment operator $E_n(\cdot, \cdot) : \mathbf{X} \times \ell_\infty \rightarrow \mathbf{R}^n$ operates on the ordered pair (h, v) and yields an output data record $y \in \mathbf{R}^n$, $y(k) := (E_n(h, v))_k$ for all $k \in \mathbb{Z}_{+n}$. Let U be the lower triangular Toeplitz matrix formed by the input u

$$U := \begin{pmatrix} u(0) & 0 & 0 \\ u(1) & u(0) & 0 \\ & & \vdots \\ u(n-1) & u(n-2) & u(0) \end{pmatrix}$$

Then, the output data $y \in \mathbf{R}^n$ can be conveniently expressed as $y = UT_n h + T_n v$, where $h \in S_\infty(M^-, M^+)$, and $v \in S_\infty(\epsilon^-, \epsilon^+)$. The set of all possible such data is given by

$$\mathbf{Y} := \{y \in \mathbf{R}^n : y = UT_n h + T_n v \text{ for some } h \in S_\infty(M^-, M^+), v \in S_\infty(\epsilon^-, \epsilon^+)\}.$$

For each $y \in \mathbf{Y}$, we define the set of indistinguishable systems as

$$\mathbf{P}(y) := \{h \in S_\infty(M^-, M^+) : y = UT_n h + T_n v \text{ for some } v \in S_\infty(\epsilon^-, \epsilon^+)\}.$$

This set contains all plant models which are "unfalsified" and whose members cannot be rigorously distinguished by the available *a priori* and *a posteriori* information. Let $\mathbf{P}_n(y) := \{T_n h : h \in \mathbf{P}(y)\}$. Then, $\mathbf{P}_n(y)$ consists of the truncated series in $\mathbf{P}(y)$. One may readily observe that $\mathbf{P}_n(y)$ is a convex polytope in \mathbf{R}^n , as it is defined via a finite set of linear inequalities.

Given the above *a priori* and experimental information, our primary goal in this paper is to obtain an uncertain model through the development of an identification algorithm and the quantification of a corresponding identification error. An identification algorithm is a mapping² $A_n : \mathbf{R}^n \rightarrow \mathbf{X}$ which operates on the data record and generates a model $A_n(y) \in \mathbf{X}$. The identification error associated with an algorithm A_n is measured by the norm $\|\cdot\|$ and is used as a bound on the modeling uncertainty. Several notions concerning identification algorithms and errors are adapted below from the existing IBC and identification literature (cf. [31], [23], [24], [12]):

- local identification error: $e(A_n; y; \|\cdot\|) := \sup_{h \in \mathbf{P}(y)} \|h - A_n(y)\|$,
- global identification error: $e(A_n; \|\cdot\|) := \sup_{y \in \mathbf{Y}} e(A_n; y; \|\cdot\|)$,
- optimal local identification error: $e^*(y; \|\cdot\|) := \inf_{A_n \in \mathcal{A}_n(y) \in \mathbf{X}} e(A_n; y; \|\cdot\|)$,
- optimal global identification error: $e^*(\|\cdot\|) := \inf_{A_n \in \mathcal{A}_n(y) \in \mathbf{X}} e(A_n; \|\cdot\|)$.

An algorithm A_n^* is said to be locally optimal at y if $e(A_n^*; y; \|\cdot\|) = e^*(y; \|\cdot\|)$. If it is locally optimal at each $y \in \mathbf{Y}$, then it is said to be strongly optimal.

²In a broader sense, an identification algorithm acts on the input-output data pair (u, y) , as the input signal plays an important role in identification. It is not our aim, however, to discuss the role of input signals in this note. Hence, to simplify the notation, we omit the dependence of all the relevant notions (e.g., $\mathbf{P}(y)$, $A_n(y)$, etc.) on the input and the *a priori* information.

In the IBC framework, the optimal algorithm and error can be alternatively characterized as the center and radius of the set $\mathbf{P}(y)$. For a given data record $y \in \mathbf{Y}$, let the radius and diameter [31], [13] of $\mathbf{P}(y)$ be denoted by $r(\mathbf{P}(y); \|\cdot\|)$ and $d(\mathbf{P}(y); \|\cdot\|)$, respectively. Then, the following result is known [31].

Fact 2.1: For any data record y , $e^*(y; \|\cdot\|) = r(\mathbf{P}(y); \|\cdot\|)$ and $d(\mathbf{P}(y); \|\cdot\|)/2 \leq e^*(y; \|\cdot\|) \leq d(\mathbf{P}(y); \|\cdot\|)$. Furthermore, for any $p \in \mathbf{P}(y)$, $r(\mathbf{P}(y); \|\cdot\|) \leq \sup_{h \in \mathbf{P}(y)} \|h - p\| \leq d(\mathbf{P}(y); \|\cdot\|)$.

As in [31], we shall call $r(\mathbf{P}(y); \|\cdot\|)$ and $d(\mathbf{P}(y); \|\cdot\|)$ the local radius and diameter of information. Accordingly, the global radius and diameter of information are designated to the quantities $\sup_{y \in \mathbf{Y}} r(\mathbf{P}(y); \|\cdot\|)$ and $\sup_{y \in \mathbf{Y}} d(\mathbf{P}(y); \|\cdot\|)$. The center of $\mathbf{P}(y)$ is the element $p \in \mathbf{X}$ such that $r(\mathbf{P}(y); \|\cdot\|) = \sup_{h \in \mathbf{P}(y)} \|h - p\|$. If for some $A_n, p = A_n(y)$ for all $y \in \mathbf{Y}$, then A_n is called the central algorithm [31], [23]. Clearly, an algorithm is strongly optimal if and only if it is central. In general, it is difficult to find the center of $\mathbf{P}(y)$. If, however, $\mathbf{P}(y)$ is a symmetric set, then its center can be easily found. The set $\mathbf{P}(y)$ is said to be symmetric if there exists a $p \in \mathbf{X}$ such that for any $h \in \mathbf{P}(y)$, $p + h \in \mathbf{P}(y)$ implies $p - h \in \mathbf{P}(y)$. The element p possessing this property is called the point of symmetry in $\mathbf{P}(y)$. It was shown in [31] that a point of symmetry is a center, and hence it defines a central algorithm. We shall say that such a central algorithm is symmetrically central. It is useful to point out that a symmetrically central algorithm is central for all norms, as a point of symmetry is of a purely geometric nature.

In this paper, we are interested in a class of nearly optimal algorithms termed interpolatory algorithms [31]. An algorithm $A_n : \mathbf{R}^n \rightarrow \mathbf{X}$ is said to be interpolatory if $A_n(y) \in \mathbf{P}(y)$. An appealing property of interpolatory algorithms is that they yield an identification error that is tight to within a factor of two of the optimal error for all possible data records [31]. This is clear from Fact 2.1 and is summarized in the following.

Fact 2.2: Let A_n be an algorithm such that $A_n(y) \in \mathbf{P}(y)$. Then, $e^*(y; \|\cdot\|) \leq e(A_n; y; \|\cdot\|) \leq 2e^*(y; \|\cdot\|)$.

In the sense of Fact 2.2, we say that an interpolatory algorithm is strongly optimal to within a factor of two. It is clear that this property holds regardless of the norms. Note also from Fact 2.1 that the identification error for any interpolatory algorithm is bounded from above by $d(\mathbf{P}(y); \|\cdot\|)$ and from below by $d(\mathbf{P}(y); \|\cdot\|)/2$. This fact makes it possible to estimate the error by computing the diameter of information. The following characterization [31] may be used to compute the global diameter $\sup_{y \in \mathbf{Y}} d(\mathbf{P}_n(y); \|\cdot\|)$.

Fact 2.3: Let $M_k^- = -M_k^+$ and $\epsilon_k^- = -\epsilon_k^+$ for all $k \in \mathbb{Z}_{+n}$. Consider the normed space $(\mathbf{R}^n, \|\cdot\|)$. Then

$$\sup_{y \in \mathbf{Y}} d(\mathbf{P}_n(y); \|\cdot\|) = 2 \sup_{y \in \mathbf{P}_n(0)} \|\cdot\| \quad (2.2)$$

The key condition implicit in Fact 2.3 is that the hyperrectangle $S_n(M^-, M^+) \times S_n(\epsilon^-, \epsilon^+) \subset \mathbf{R}^{2n}$ is a balanced convex set [31]. An extension of this result will be given in the next section.

III. MAIN RESULTS

In this section, we shall first formulate and solve a problem concerning the consistency of the *a priori* and *a posteriori* information. This problem bears some similarity to the model validation problems studied in [30] and [28]. Significant differences also exist, however, between the two problems. Based on the solution of this problem, we construct an interpolatory algorithm and derive bounds for the corresponding identification error. Finally, we provide a brief discussion on central algorithms and optimal identification errors.

A. Consistency of Information

The problem of consistency between the *a priori* information and data record is concerned with the following question: Given the model set defined by $S_\infty(M^-, M^+)$, the noise set $S_\infty(\epsilon^-, \epsilon^+)$, and given also a data record $y \in \mathbf{R}^n$, will there exist an $h \in S_\infty(M^-, M^+)$ so that $y = T_n((h * u) + v)$? This problem can be equivalently posed as to determining whether the set $\mathbf{P}(y)$ is empty.

Definition 3.1: A data record $y \in \mathbf{R}^n$ is said to be consistent with the plant and noise *a priori* information if $\mathbf{P}(y) \neq \emptyset$.

It is important to note that the data and *a priori* information should be consistent for the identification problem to be meaningful, for if $\mathbf{P}(y)$ is empty, the identification error will become unbounded.

It can be readily recognized that $\mathbf{P}(y) \neq \emptyset$ if and only if $\mathbf{P}_n(y) \neq \emptyset$. This observation leads to the following simple necessary and sufficient condition that can be used to check the consistency between the data and *a priori* information.

Lemma 3.1: A data record $y \in \mathbf{R}^n$ is consistent with the *a priori* information if and only if the linear inequalities

$$M_k^- \leq h(k) \leq M_k^+, \quad k = 0, 1, \dots, n-1, \quad (3.1)$$

$$\epsilon_k^- \leq y(k) - \sum_{j=0}^k u(k-j)h(j) \leq \epsilon_k^+, \quad k = 0, 1, \dots, n-1 \quad (3.2)$$

admit a solution.

Consequently, the consistency problem amounts to solving a finite set of linear inequalities, which in turn may be solved efficiently using the linear programming method (see, e.g., [26]). It is easy to derive necessary or sufficient conditions by weakening (3.1)–(3.2). It is also possible to extend this result to solve a companion problem which is to compute a minimal noise envelope such that the data and *a priori* information are consistent. The reader is referred to [3] for a detailed discussion on these issues.

B. An Interpolatory Algorithm and Error Bounds

The interpolatory algorithm to be proposed below is motivated from the IBC theory [31] and requires only solving the data consistency problem. More specifically, it follows from Fact 2.2 and Lemma 3.1 that any solution of (3.1) and (3.2) serves as an identified model that yields a local identification error to within a factor of two of the optimal local error. Hence, the following result is clear.

Theorem 3.1: Let $\{h(k)\}_{k=0}^{n-1}$ be a solution to (3.1)–(3.2). Construct A_n so that

$$[A_n(y)]_k = \begin{cases} h(k) & 0 \leq k \leq n-1 \\ \frac{M_k^+ + M_k^-}{2} & k \geq n. \end{cases} \quad (3.3)$$

Then, for any data record $y \in \mathbf{Y}$, $\epsilon^*(y; \|\cdot\|) \leq \epsilon(A_n; y; \|\cdot\|) \leq 2\epsilon^*(y; \|\cdot\|)$.

As a result of this construction, the algorithm A_n is clearly interpolatory, and it can be readily computed by solving a single linear program. As pointed out in the preceding section, this algorithm is strongly optimal to within a factor of two for all norms.

Having constructed the above interpolatory algorithm, in the remainder of this section we shall derive explicit bounds for the local and global identification errors. Denote

$$\delta M_k := M_k^+ - M_k^-, \quad \delta \epsilon_k := \epsilon_k^+ - \epsilon_k^-. \quad (3.4)$$

We shall first present the following preliminary lemmas.

Lemma 3.2: Let $c := [c_0 \ c_1 \ \dots \ c_{n-1}]^T \in \mathbf{R}^n$ be the center of $\mathbf{P}_n(y)$, and let δM_k be defined by (3.4). Then, the algorithm A_n^* , such that

$$[A_n^*(y)]_k = \begin{cases} c_k & 0 \leq k \leq n-1 \\ \frac{M_k^+ + M_k^-}{2} & k \geq n \end{cases}$$

is central. Furthermore

$$\epsilon^*(y; \|\cdot\|_1) = \frac{1}{2} \sum_{k=n}^{\infty} \delta M_k + r(\mathbf{P}_n(y), \|\cdot\|_1). \quad (3.5)$$

Proof: By definition, we have

$$\begin{aligned} r(\mathbf{P}(y), \|\cdot\|_1) &= \inf_{h \in \mathbf{X}} \sup_{p \in \mathbf{P}(y)} \sum_{k=0}^{\infty} |h(k) - p(k)| \\ &= \inf_{h \in \mathbf{R}^n} \sup_{p \in \mathbf{P}_n(y)} \sum_{k=0}^{n-1} |h(k) - p(k)| \\ &\quad + \inf_{h \in \mathbf{X}/\mathbf{R}^n} \sup_{p \in \mathbf{P}(y)/\mathbf{P}_n(y)} \sum_{k=n}^{\infty} |h(k) - p(k)|. \end{aligned}$$

It is easy to see that $\mathbf{P}(y)/\mathbf{P}_n(y)$ is a symmetric set, and its point of symmetry is h^* , where $h^*(k) = (1/2)(M_k^+ + M_k^-)$ for all $k \geq n$. Hence, it follows that

$$\inf_{h \in \mathbf{X}/\mathbf{R}^n} \sup_{p \in \mathbf{P}(y)/\mathbf{P}_n(y)} \sum_{k=n}^{\infty} |h(k) - p(k)| \leq \frac{1}{2} \sum_{k=n}^{\infty} (M_k^+ - M_k^-).$$

The proof is now completed by using the definition of radius and Fact 2.1. \square

Lemma 3.3: Let $A_n(y)$ be given by (3.3). Then

$$\epsilon(A_n; y; \|\cdot\|_1) = \frac{1}{2} \sum_{k=n}^{\infty} \delta M_k + \max_{h \in \mathbf{P}_n(y)} \|T_n h - T_n A_n(y)\|_1. \quad (3.6)$$

Proof: Similar to that of Lemma 3.2. \square

It follows from Lemmas 3.2 and 3.3 that the problem of finding the central algorithm reduces to that of finding the center of $\mathbf{P}_n(y)$, and the problem of finding an interpolatory algorithm simply reduces to that of finding an element of $\mathbf{P}_n(y)$. The latter observation is precisely the underlying idea for the algorithm (3.3), whose construction for $k \in \mathbf{Z}_{+n}$ amounts to finding an element of $\mathbf{P}_n(y)$, and for $k \geq n$ the center of $\mathbf{P}(y)/\mathbf{P}_n(y)$ is selected. It is important to note from these results that the condition $\{\delta M_k\}_{k=0}^{\infty} \in \ell_1$ is necessary so that the identification error is finite. This is clear because the series $\sum_{k=0}^{\infty} \delta M_k$ and $\sum_{k=n}^{\infty} \delta M_k$ have the same convergence behavior (see, e.g., [17]). This condition is always satisfied because $\{M_k\}_{k=0}^{\infty} \in \ell_1$ and $\{M_k^+\}_{k=0}^{\infty} \in \ell_1$.

In what follows we shall develop bounds for the diameter of $\mathbf{P}_n(y)$. According to Lemma 3.3, these quantities can then be used to calculate bounds for the identification error. With no loss of generality, we assume that $u(0) \neq 0$. It follows readily that U is invertible and that U^{-1} is also a lower triangular Toeplitz matrix. We shall write

$$U^{-1} = \begin{bmatrix} a_0 & 0 & \cdots & 0 \\ a_1 & a_0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ a_{n-1} & a_{n-2} & \cdots & a_0 \end{bmatrix}.$$

Theorem 3.2: Suppose that $A_n(y)$ is given by (3.3). Let $\tilde{h} \in \mathbf{X}$

be defined as $\hat{h}(k) := (M_k^+ + M_k^-)/2$, and $\bar{v} \in \ell_\infty$ be defined as $\bar{v}(k) := (\epsilon_k^+ + \epsilon_k^-)/2$, for all $k \in \mathbb{Z}_+$. Furthermore, denote $\bar{y} := y - UT_n \bar{h} - T_n \bar{v}$

$$h_u(k) := \min \left\{ \sum_{j=0}^k (a_{k-j} \bar{y}(j) + |a_{k-j}| \delta \epsilon_j), \delta M_k \right\}, \quad (3.7)$$

$$h_l(k) := \max \left\{ \sum_{j=0}^k (a_{k-j} \bar{y}(j) - |a_{k-j}| \delta \epsilon_j), -\delta M_k \right\}. \quad (3.8)$$

Then

$$\begin{aligned} \epsilon(A_n; y; \|\cdot\|_{H_\infty}) &\leq \epsilon(A_n; y; \|\cdot\|_1) \\ &\leq \frac{1}{2} \sum_{k=n}^{\infty} \delta M_k + \sum_{k=0}^{n-1} (h_u(k) - h_l(k)). \end{aligned} \quad (3.9)$$

Proof We show that the bound holds for $\epsilon(A_n; y; \|\cdot\|_1)$, as the inequality between $\epsilon(A_n; y; \|\cdot\|_{H_\infty})$ and $\epsilon(A_n; y; \|\cdot\|_1)$ follows from the well-known fact $\|\cdot\|_{H_\infty} \leq \|\cdot\|_1$ [6]. Toward this end, it suffices to prove that $d(\mathbf{P}_n(y), \|\cdot\|_1) \leq \sum_{k=0}^{n-1} (h_u(k) - h_l(k))$ or $\mathbf{P}_n(y) \subset \mathbf{S}_n(h_l + \bar{h}, h_u + \bar{h})$. Note that for any $h \in \mathbf{P}_n(y)$, we have $M_k^- \leq h(k) \leq M_k^+$, and $h(k) = \sum_{j=0}^k a_{k-j} y(j) + \sum_{j=0}^k a_{k-j} v(j)$, where $k \in \mathbb{Z}_+$, and $v \in \mathbf{S}_\infty(\epsilon^-, \epsilon^+)$. The latter equality is equivalent to $\bar{h}(k) - \hat{h}(k) = \sum_{j=0}^k a_{k-j} y(j) + \sum_{j=0}^k a_{k-j} (v(j) - \bar{v}(j))$. Hence, it follows that $-\delta M_k \leq h(k) - \hat{h}(k) \leq \delta M_k$, and that

$$\begin{aligned} \sum_{j=0}^k a_{k-j} \bar{y}(j) - \sum_{j=0}^k |a_{k-j}| \delta \epsilon_j &\leq h(k) - \hat{h}(k) \\ &\leq \sum_{j=0}^k a_{k-j} y(j) + \sum_{j=0}^k |a_{k-j}| \delta \epsilon_j. \end{aligned}$$

This implies that $h - \hat{h} \in \mathbf{S}_n(h_l, h_u)$, and hence that $h \in \mathbf{S}_n(h_l + \bar{h}, h_u + \bar{h})$ and $\mathbf{P}_n(y) \subset \mathbf{S}_n(h_l + \bar{h}, h_u + \bar{h})$. As a result, $d(\mathbf{P}_n(y), \|\cdot\|_1) \leq d(\mathbf{S}_n(h_l + \bar{h}, h_u + \bar{h}), \|\cdot\|_1)$. However

$$\begin{aligned} d(\mathbf{S}_n(h_l + \bar{h}, h_u + \bar{h}), \|\cdot\|_1) &= d(\mathbf{S}_n(h_l, h_u), \|\cdot\|_1) \\ &= \sum_{k=0}^{n-1} (h_u(k) - h_l(k)). \end{aligned}$$

This completes the proof. \square

In addition to the above bound for the local error, we shall also derive below bounds for the global identification error and establish a convergence condition of the proposed interpolatory algorithm. Here an algorithm A_n is said to be convergent [12] if it satisfies the property

$$\lim_{n \rightarrow \infty} \epsilon(A_n; \|\cdot\|) = 0$$

where $\delta \epsilon := \max_k \delta \epsilon_k$. Note that the condition $\{\delta M_k\}_{k=0}^\infty \in \ell_1$ is necessary for any algorithm to be convergent. We shall first need the following extension of Fact 2.3.

Lemma 3.4: Let \bar{h} and \bar{v} be defined as in Theorem 3.2. Then

$$\sup_{y \in \mathbf{Y}} d(\mathbf{P}_n(y), \|\cdot\|) = 2 \sup_{T_n \bar{h} \in \mathbf{P}_n(T_n \bar{h} + T_n \bar{v})} \|T_n \bar{h} - T_n \hat{h}\|. \quad (3.10)$$

Proof: For any $h \in \mathbf{S}_\infty(M^-, M^+)$ and $v \in \mathbf{S}_\infty(\epsilon^-, \epsilon^+)$, we define $\bar{h} := h - \hat{h}$ and $\bar{v} := v - \bar{v}$. Then, $h \in \mathbf{S}_\infty(M^-, M^+)$ if and only if $\bar{h} \in \mathbf{S}_\infty(-\delta M/2, \delta M/2)$, and $v \in \mathbf{S}_\infty(\epsilon^-, \epsilon^+)$ if and only if $\bar{v} \in \mathbf{S}_\infty(-\delta \epsilon/2, \delta \epsilon/2)$. Similarly, for any $y \in \mathbf{Y}$, let \bar{y} be defined

as in Theorem 3.2, i.e., $\bar{y} := y - UT_n \bar{h} - T_n \bar{v}$. Define further

$$\begin{aligned} \bar{\mathbf{Y}} &:= \{\bar{y} \in \mathbf{R}^n : \bar{y} = UT_n \bar{h} + T_n \bar{v} \text{ for some} \\ &\quad \bar{h} \in \mathbf{S}_\infty(-\delta M/2, \delta M/2), \bar{v} \in \mathbf{S}_\infty(-\delta \epsilon/2, \delta \epsilon/2)\}. \end{aligned}$$

Correspondingly, define the sets

$$\begin{aligned} \bar{\mathbf{P}}(\bar{y}) &:= \{\bar{h} \in \mathbf{S}_\infty(-\delta M/2, \delta M/2) : \bar{y} = UT_n \bar{h} + T_n \bar{v} \\ &\quad \text{for some } \bar{v} \in \mathbf{S}_\infty(-\delta \epsilon/2, \delta \epsilon/2)\} \end{aligned}$$

and $\bar{\mathbf{P}}_n(\bar{y}) := \{T_n \bar{h} : \bar{h} \in \bar{\mathbf{P}}(\bar{y})\}$. It follows that $\bar{y} \in \bar{\mathbf{Y}}$ if and only if $y \in \mathbf{Y}$ and that $T_n \bar{h} \in \bar{\mathbf{P}}_n(\bar{y})$ if and only if $T_n h \in \mathbf{P}_n(y)$. As a result, we have

$$\sup_{y \in \mathbf{Y}} d(\mathbf{P}_n(y), \|\cdot\|) = \sup_{\bar{y} \in \bar{\mathbf{Y}}} d(\bar{\mathbf{P}}_n(\bar{y}), \|\cdot\|).$$

Since $\mathbf{S}_n(-\delta M/2, \delta M/2) \times \mathbf{S}_n(-\delta \epsilon/2, \delta \epsilon/2)$ is a balanced convex set, we may invoke Fact 2.3. This gives

$$\begin{aligned} \sup_{y \in \mathbf{Y}} d(\mathbf{P}_n(y), \|\cdot\|) &= 2 \sup_{T_n \bar{h} \in \bar{\mathbf{P}}_n(\bar{y})} \|T_n \bar{h}\| \\ &= 2 \sup_{T_n \bar{h} \in \bar{\mathbf{P}}_n(T_n \bar{h} + T_n \bar{v})} \|T_n \bar{h} - T_n \bar{h}\| \end{aligned}$$

which establishes (3.10) \square

Theorem 3.3 Let $A_n(y)$ be given by (3.3), and let δM_k and $\delta \epsilon_k$ be defined by (3.4). Then

$$\begin{aligned} \frac{1}{2} \sum_{k=n}^{\infty} \delta M_k + \frac{1}{2} \max_{0 \leq k \leq n-1} \tau_k &\leq \epsilon(A_n; \|\cdot\|_1) \\ &\leq \frac{1}{2} \sum_{k=n}^{\infty} \delta M_k + \sum_{k=0}^{n-1} \tau_k \end{aligned} \quad (3.11)$$

where

$$\tau_k := \min \left\{ \sum_{j=0}^k |a_{k-j}| \delta \epsilon_j, \delta M_k \right\}.$$

Furthermore, A_n will be convergent in ℓ_1 if $\{\delta M_k\}_{k=0}^\infty$ is a monotonically decreasing sequence

Proof From Lemma 3.3, we have

$$\begin{aligned} \frac{1}{2} \sum_{k=n}^{\infty} \delta M_k + \frac{1}{2} \sup_{y \in \mathbf{Y}} d(\mathbf{P}_n(y), \|\cdot\|_1) \\ \leq \epsilon(A_n; \|\cdot\|_1) \leq \frac{1}{2} \sum_{k=n}^{\infty} \delta M_k + \sup_{y \in \mathbf{Y}} d(\mathbf{P}_n(y), \|\cdot\|_1). \end{aligned}$$

It follows from Lemma 3.4 that

$$\begin{aligned} \sup_{y \in \mathbf{Y}} d(\mathbf{P}_n(y), \|\cdot\|_1) &= 2 \max \left\{ \|T_n^{-1} T_n(v - \bar{v})\|_1 : T_n^{-1} T_n(v - \bar{v}) \right. \\ &\quad \left. \in \mathbf{S}_n\left(-\frac{\delta M}{2}, \frac{\delta M}{2}\right), v \in \mathbf{S}_\infty(\epsilon^-, \epsilon^+)\right\} \\ &= 2 \max \left\{ \|T_n^{-1} T_n v\|_1 : \left| \sum_{j=0}^k a_{k-j} v(j) \right| \right. \\ &\quad \left. \leq \frac{\delta M_k}{2}, v \in \mathbf{S}_\infty\left(-\frac{\delta \epsilon}{2}, \frac{\delta \epsilon}{2}\right) \right\} \\ &\leq \sum_{k=0}^{n-1} \min \left\{ \sum_{j=0}^k |a_{k-j}| \delta \epsilon_j, \delta M_k \right\}. \end{aligned}$$

This gives the upper bound in (3.11). The lower bound is established by observing that

$$\begin{aligned} \max \left\{ \|U^{r-1} T_n v\|_1 : \left| \sum_{j=0}^k a_{k-j} v(j) \right| \leq \frac{\delta M_k}{2}, \right. \\ \left. v \in S_\infty \left(-\frac{\delta \epsilon}{2}, \frac{\delta \epsilon}{2} \right) \right\} \\ \geq \frac{1}{2} \max_{0 \leq k \leq n-1} \min \left\{ \sum_{j=0}^k |a_{k-j}| \delta \epsilon_j, \delta M_k \right\}. \end{aligned}$$

To establish the convergence result, define l to be the largest integer $k \in \mathbf{Z}_+$ such that $\delta M_k \geq \delta \epsilon \sum_{j=0}^k |a_j|$. Then, for any $k > l$, $\delta M_k < \delta \epsilon \sum_{j=0}^k |a_j|$. Let $l^* := \min\{l, n\}$. Then, it follows that $l^* \rightarrow \infty$ as $\delta \epsilon \rightarrow 0$ and $n \rightarrow \infty$. Consider now weakening the upper bound in (3.11). We have

$$\begin{aligned} \epsilon(A_n; \|\cdot\|_1) &\leq \frac{1}{2} \sum_{k=n}^{\infty} \delta M_k + \sum_{k=0}^{l^*-1} \min \left\{ \delta \epsilon \sum_{j=0}^k |a_j|, \delta M_k \right\} \\ &< \sum_{k=l^*}^{\infty} \delta M_k + l^* \delta M_{l^*}. \end{aligned}$$

Since $\{\delta M_k\}_{k=0}^{\infty}$ is a monotonically decreasing sequence, it follows from [17, Theorem 3.3.1, p. 61] that $l^* \delta M_{l^*} \rightarrow 0$ as $l^* \rightarrow \infty$. Also, $\sum_{k=l^*}^{\infty} \delta M_k \rightarrow 0$ when $l^* \rightarrow \infty$, because $\{\delta M_k\}_{k=0}^{\infty} \in \ell_1$. Therefore, the last upper bound goes to zero as $\delta \epsilon \rightarrow 0$ and $n \rightarrow \infty$. This completes the proof. \square

Additionally, the upper bound in (3.11) clearly bounds the global identification error $\epsilon(A_n; \|\cdot\|_{H_\infty})$. Hence the convergence condition in Theorem 3.3 is also sufficient for the interpolatory algorithm to be convergent in H_∞ . A similar lower bound will show that the condition $\{\delta M_k\}_{k=0}^{\infty} \in \ell_1$ is necessary for the identification error to be finite in H_∞ . To see this, we first give a condition under which the H_∞ and ℓ_1 norms of a transfer function coincide. The proof for this result is simple and is thus omitted.

Lemma 3.5 Suppose that $h \in \mathbf{X}$ satisfies i) $h(k) \geq 0, \forall k \in \mathbf{Z}_+$, ii) $h(k) \leq 0, \forall k \in \mathbf{Z}_+$, or iii) $h(k)h(k+1) \leq 0, \forall k \in \mathbf{Z}_+$. Then, $\|h(z)\|_{H_\infty} = \|h\|_1$.

The following result gives a lower bound for the identification error in the H_∞ case.

Corollary 3.1 Let $A_n(y)$ be given by (3.3), and let δM_k and $\delta \epsilon_k$ be defined by (3.4). Then

$$\epsilon(A_n; \|\cdot\|_{H_\infty}) \geq \frac{1}{2} \max \left\{ \sum_{k=n}^{\infty} \delta M_k, \max_{0 \leq k \leq n-1} \gamma_k \right\}. \quad (3.12)$$

Proof: Since $\mathbf{P}(y)/\mathbf{P}_n(y)$ is a symmetric set, it follows from [32, p. 11] that

$$\begin{aligned} r(\mathbf{P}(y)/\mathbf{P}_n(y); \|\cdot\|_{H_\infty}) &= \frac{1}{2} d(\mathbf{P}(y)/\mathbf{P}_n(y); \|\cdot\|_{H_\infty}) \\ &\leq \frac{1}{2} d(\mathbf{P}(y)/\mathbf{P}_n(y); \|\cdot\|_1) \\ &= \frac{1}{2} \sum_{k=n}^{\infty} \delta M_k. \end{aligned}$$

However

$$\begin{aligned} d(\mathbf{P}(y)/\mathbf{P}_n(y); \|\cdot\|_{H_\infty}) &= \sup_{h \in \mathbf{P}(y)/\mathbf{P}_n(y)} \|\hat{h}(z) - \hat{p}(z)\|_{H_\infty} \\ &\geq \left\| \sum_{k=n}^{\infty} \delta M_k z^k \right\|_{H_\infty}. \end{aligned}$$

From Lemma 3.5, we have $\|\sum_{k=n}^{\infty} \delta M_k z^k\|_{H_\infty} = \sum_{k=n}^{\infty} \delta M_k$. Therefore, $r(\mathbf{P}(y)/\mathbf{P}_n(y); \|\cdot\|_{H_\infty}) = (1/2) \sum_{k=n}^{\infty} \delta M_k$. This proves the fact that $\epsilon(A_n; \|\cdot\|_{H_\infty}) \geq (1/2) \sum_{k=n}^{\infty} \delta M_k$. Additionally, note that $d(\mathbf{P}(y); \|\cdot\|_{H_\infty}) \geq d(\mathbf{P}(y); \|\cdot\|_2) \geq d(\mathbf{P}_n(y); \|\cdot\|_2)$. It follows analogously as in the proof of Theorem 3.3 that

$$\begin{aligned} \sup_{y \in \mathbf{Y}} d(\mathbf{P}_n(y); \|\cdot\|_2) \\ = 2 \max \left\{ \|U^{r-1} T_n v\|_2 : \left| \sum_{j=0}^k a_{k-j} v(j) \right| \leq \frac{\delta M_k}{2}, \right. \\ \left. v \in S_\infty \left(-\frac{\delta \epsilon}{2}, \frac{\delta \epsilon}{2} \right) \right\} \\ \geq \max_{0 \leq k \leq n-1} \min \left\{ \sum_{j=0}^k |a_{k-j}| \delta \epsilon_j, \delta M_k \right\}. \end{aligned}$$

This establishes that $\epsilon(A_n; \|\cdot\|_{H_\infty}) \geq (1/2) \gamma_k$ for all $k \in \mathbf{Z}_+, n$. The proof is now completed. \square

C. The Central Algorithm and Optimal Error

We now turn to the central algorithm and optimal identification error. Our purpose in this section is to demonstrate, by considering the case of ℓ_1 norm, that the problem of solving the central algorithm and optimal error may, in general, be computationally infeasible, so is the problem of computing exactly the identification error and the diameter of information. This should give certain justification to our pursuit of an interpolatory algorithm and error bounds.

From Lemma 3.2, it is clear that finding the central algorithm in the ℓ_1 case requires computing the center of $\mathbf{P}_n(y)$ and that the optimal identification error corresponds to the radius of the same set. Since $\mathbf{P}_n(y)$ is a convex polytope, it can be expressed in terms of its vertices [35]. Let the vertices of $\mathbf{P}_n(y)$ be denoted by the collection $\{h_1, \dots, h_m\}$, where $h_i \in \mathbf{P}_n(y)$ for $1 \leq i \leq m$. Then

$$\mathbf{P}_n(y) = \left\{ \sum_{i=1}^m \lambda_i h_i : h_i \in \mathbf{P}_n(y), \lambda_i \geq 0, \sum_{i=1}^m \lambda_i = 1 \right\}. \quad (3.13)$$

The following result gives a characterization of $r(\mathbf{P}_n(y); \|\cdot\|_1)$ in terms of the vertices of $\mathbf{P}_n(y)$. The proof is simple and thus is omitted.

Proposition 3.1 Let $\mathbf{P}_n(y)$ be described by (3.13). Then

$$r(\mathbf{P}_n(y); \|\cdot\|_1) = \begin{aligned} &\text{minimize } \delta \\ &\text{subject to } \|h - h_k\|_1 \leq \delta, k=1, 2, \dots, m \end{aligned} \quad (3.14)$$

It is not difficult to see that the minimization problem in (3.14) amounts to a linear program, which, however, requires explicit use of the vertices of $\mathbf{P}_n(y)$. The problem of finding the vertices of a convex polytope has been well studied; see [22], [25], and [34] and the references therein. An important result in [22] states that the number of vertices of a polytope increases exponentially with its dimension. According to this result, the task of generating all the vertices of $\mathbf{P}_n(y)$ and hence the problem of computing the central algorithm and optimal error via the linear program (3.14) becomes computationally

intractable. Alternatively, the complexity in computing the radius $r(\mathbf{P}_n(y), \|\cdot\|_1)$ may also be observed by noting that its computation involves maximizing a convex function over a convex polytope. A recent result [2] in combinatorial theory establishes rigorously that the problem of this class is computationally intractable, in the sense that its computational complexity grows exponentially with the dimension of the polytope. It is clear that the problems of computing exactly the identification error and the diameter of information both belong to this class, and the exact computation of these quantities is also computationally intractable.

IV. IDENTIFICATION WITH IMPULSE AND STEP INPUTS

The general framework developed in the preceding sections will now be examined in the more specific context where the following two important signals will be taken as experimental inputs. The first input is the unit impulse signal, denoted by u_I

$$u_I(k) := \begin{cases} 1 & k = 0 \\ 0 & k \geq 1 \end{cases}$$

The second input is the unit step signal, denoted by u_s

$$u_s(k) := 1, \quad k \in \mathbf{Z}_+$$

The identification problem will first be considered with the general *a priori* information, and then that corresponding to the class of exponentially stable systems.

A. Identification with General *a priori* Information

In using the unit impulse signal as an experimental input, the ℓ_1 identification problem for a class of exponentially stable systems has been studied in detail in [15]. Both the central algorithm and global optimal error were given for the ℓ_1 case in these references. Our development in this section constitutes a generalization to [15], and more importantly, we show that the central algorithm and optimal error are actually the same in both the ℓ_1 and H_∞ cases when the impulse signal is used.

Consider first the set $\mathbf{P}(y)$ corresponding to u_I . Notice trivially that I is an identity matrix. As a result, the set $\mathbf{P}_n(y)$ becomes a hyperrectangle in \mathbf{R}^n

$$\begin{aligned} \mathbf{P}_n(y) &= \{T_n h : \max\{y(k) - \epsilon_k^+, M_k^-\} \leq h(k) \\ &\leq \min\{y(k) - \epsilon_k^-, M_k^+\}, \quad k \in \mathbf{Z}_{+n}\}. \end{aligned}$$

Clearly, the set $\mathbf{P}_n(y)$, and therefore $\mathbf{P}(y)$, are symmetric. For any $k \in \mathbf{Z}_{+n}$, let $h_n(k) = \min\{y(k) - \epsilon_k^-, M_k^+\}$, and $h_I(k) = \max\{y(k) - \epsilon_k^+, M_k^-\}$. Then, the point of symmetry of $\mathbf{P}(y)$ is at $c \in \mathbf{P}(y)$, where $c(k) := (1/2)(h_n(k) + h_I(k))$ for $k \in \mathbf{Z}_{+n}$, and $c(k) := (M_k^+ + M_k^-)/2$ for $k \geq n$. This gives a symmetrically central algorithm.

Theorem 4.1: Let $u = u_I$. Also, let $A_n^*(y)$ be given by

$$[A_n^*(y)]_k := \begin{cases} \frac{1}{2}(h_n(k) + h_I(k)) & k \leq n-1 \\ \frac{M_k^+ + M_k^-}{2} & k \geq n. \end{cases} \quad (4.1)$$

Then, A_n^* is symmetrically central and hence strongly optimal for any norm.

Note that the strong optimality of this algorithm was only established in the ℓ_1 case in [15]. Our derivation shows that it is strongly optimal for any norm. Additionally, our following result gives explicit

expressions of the optimal identification errors in both the ℓ_1 and H_∞ cases.

Theorem 4.2: Let $u = u_I$. Then:

i) for any data record y

$$\begin{aligned} \epsilon^*(y; \|\cdot\|_{H_\infty}) &= \epsilon^*(y; \|\cdot\|_1) \\ &= \frac{1}{2} \sum_{k=n}^{\infty} \delta M_k + \frac{1}{2} \sum_{k=0}^{n-1} (h_n(k) - h_I(k)). \end{aligned} \quad (4.2)$$

ii) Furthermore

$$\begin{aligned} \epsilon^*(\|\cdot\|_{H_\infty}) &= \epsilon^*(\|\cdot\|_1) \\ &= \frac{1}{2} \sum_{k=n}^{\infty} \delta M_k + \frac{1}{2} \sum_{k=0}^{n-1} \min\{\delta \epsilon_k, \delta M_k\}. \end{aligned} \quad (4.3)$$

Proof: We first establish (4.2)-(4.3) for the ℓ_1 case. In this regard, the proof for (4.2) follows from the fact that $A_n^*(y)$ is the point of symmetry of $\mathbf{P}(y)$. It can be readily verified that (4.2) gives the radius of $\mathbf{P}(y)$. Indeed, the radius $r(\mathbf{P}(y), \|\cdot\|_1) = \max_{h \in \mathbf{P}(y)} \|h - A_n^*(y)\|_1$ is achieved at h^* , where $h^*(k) := h_n(k)$ for $k \in \mathbf{Z}_{+n}$ and $h^*(k) := M_k^+$ for $k \geq n$. Since $\mathbf{P}(y)$ is a symmetric set, we have $r(\mathbf{P}(y), \|\cdot\|_1) = (1/2)d(\mathbf{P}(y), \|\cdot\|_1)$ for any y (see, e.g., [32, p. 11]). The proof for (4.3) follows from this observation and using Lemma 3.4. To show that $\epsilon^*(y; \|\cdot\|_{H_\infty}) = \epsilon^*(y; \|\cdot\|_1)$, one simply notes that $h^*(k) - [A_n^*(y)]_k \geq 0$ for all $k \in \mathbf{Z}_+$. The result then follows by applying Lemma 3.5. \square

B. Identification of Exponentially Stable Systems

We now consider a class of exponentially stable systems. The plant *a priori* information corresponding to this class of systems consists of two constants $0 \leq M < \infty$ and $\rho > 1$, so that $-M_k^- = M_k^+ = M/\rho^k$ for all $k \in \mathbf{Z}_+$ [15]. Following [15], we shall also assume a uniform noise bound $\epsilon \geq 0$ for all measurement instants: $-\epsilon_k^- = \epsilon_k^+ = \epsilon$ for all $k \in \mathbf{Z}_+$. As a result, we have $\delta M_k = 2M/\rho^k$, and $\delta \epsilon_k = 2\epsilon$. A direct application of Theorem 4.2 then yields the following simplified expression of the optimal global error in the impulse input case. The result for ℓ_1 case is precisely the one given in [15].

Corollary 4.1 Let $u = u_I$. Denote $n^* = (1/\ln \rho) \ln(M/\epsilon)$, and $n_I = \min\{n, \lceil n^* \rceil\}$. Then

$$\epsilon^*(\|\cdot\|_{H_\infty}) = \epsilon^*(\|\cdot\|_1) = n_I \epsilon + \frac{M}{\rho^{n_I-1}(\rho-1)}. \quad (4.4)$$

In the step input case, we give an explicit expression of the global diameter of information for both the ℓ_1 and H_∞ identification problems, hence providing an estimate tight to within a factor of two of the global optimal error. We summarize this result in the following theorem.

Theorem 4.3. Let $u = u_s$. Let also

$$n_s := \begin{cases} 0 & M \leq \epsilon \\ \min\{n, \lceil n^* \rceil\} & \text{otherwise} \end{cases} \quad (4.5)$$

where $n^* := (1/\ln \rho) \ln(M/2\epsilon)$. Then

$$\begin{aligned} \sup_{y \in \mathbf{Y}} d(\mathbf{P}(y), \|\cdot\|_{H_\infty}) &= \sup_{y \in \mathbf{Y}} d(\mathbf{P}(y), \|\cdot\|_1) \\ &= 2 \begin{cases} n_s \epsilon + \frac{M}{\rho^{n_s-1}(\rho-1)} & n_s \leq 1 \\ (2n_s - 1)\epsilon + \frac{M}{\rho^{n_s-1}(\rho-1)} & n_s > 1. \end{cases} \end{aligned} \quad (4.6)$$

Proof: Again, we first prove the result for the ℓ_1 case. In this regard, we notice that for $u = u_s$,

$$U^{n-1} = \begin{bmatrix} 1 & 0 & \cdots & 0 \\ -1 & 1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & \cdots & -1 & 1 \end{bmatrix}.$$

Therefore, $h \in \mathbf{P}(0)$ if and only if $|h(k)| \leq M/\rho^k$ for all $k \in \mathbf{Z}_+$, and $h(0) = v(0)$, $h(k) = v(k) - v(k-1)$ for $k \in \mathbf{Z}_{+n}$, where $|v(k)| \leq \epsilon$. It follows from Fact 2.3 that

$$\begin{aligned} & \frac{1}{2} \sup_{y \in Y} d(\mathbf{P}(y), \|\cdot\|_1) \\ &= \max \left\{ \sum_{k=0}^{n-1} |v(k) - v(k-1)| : |v(k)| \leq \epsilon, \right. \\ & \quad \left. |v(k) - v(k-1)| \leq \frac{M}{\rho^k} \right\} + \sum_{k=n}^{\infty} \frac{M}{\rho^k} \\ &\leq \min\{\epsilon, M\} + \sum_{k=1}^{n-1} \min\left\{2\epsilon, \frac{M}{\rho^k}\right\} + \sum_{k=n}^{\infty} \frac{M}{\rho^k}. \end{aligned}$$

If $n_s = 0$ (i.e., $M \leq \epsilon$) or $n_s = 1$ ($M > \epsilon$, $2\epsilon \leq M/\rho$), then we have

$$\begin{aligned} & \frac{1}{2} \sup_{y \in Y} d(\mathbf{P}(y), \|\cdot\|_1) \leq n_s \epsilon + \sum_{k=n_s}^{\infty} \frac{M}{\rho^k} \\ &= n_s \epsilon + \frac{M}{\rho^{n_s-1}(\rho-1)}. \end{aligned}$$

It is easy to see that the equality can actually be attained by the sequence $\{v(k)\}_{k=0}^{n-1}$

$$v(k) := \begin{cases} v(0) & k=0 \\ v(k-1) + (-1)^k M/\rho^k & 1 \leq k \leq n-1 \end{cases} \quad (4.7)$$

where $v(0) = M$ for $n_s = 0$, and $v(0) = \epsilon$ for $n_s = 1$. Hence (4.6) holds for the case $n_s = 0$ and $n_s = 1$. Consider now the case $n_s > 1$. It follows that

$$\begin{aligned} & \frac{1}{2} \sup_{y \in Y} d(\mathbf{P}(y), \|\cdot\|_1) \leq \epsilon + 2(n_s - 1)\epsilon + \sum_{k=n_s}^{\infty} \frac{M}{\rho^k} \\ &= (2n_s - 1)\epsilon + \frac{M}{\rho^{n_s-1}(\rho-1)}. \end{aligned}$$

Again, equality can be attained by the sequence $\{v(k)\}_{k=0}^{n-1}$, constructed as

$$v(k) := \begin{cases} (-1)^k \epsilon & k \leq n_s \\ v(k-1) + (-1)^k M/\rho^k & n_s \leq k \leq n-1 \end{cases} \quad (4.8)$$

Hence (4.6) also holds for the case $n_s > 1$. This completes the proof for the ℓ_1 case. To show that the global diameters are identical in both the ℓ_1 and H_∞ cases, we note that the sequences constructed in (4.7) and (4.8) lead to $h(k)h(k+1) \leq 0$, where $h(k) = v(k) - v(k-1)$ for all $k \in \mathbf{Z}_{+n}$. The result then follows from Lemma 3.5. \square

V. CONCLUSION

In this paper we have formulated and solved a worst-case/deterministic system identification problem. Our main effort has been concentrated on developing an interpolatory algorithm and bounds for the identification error. An important reason in our pursuit of the interpolatory algorithm and error bounds has been that the optimal algorithm and error is generally very difficult to compute. In contrast, the interpolatory algorithm, albeit suboptimal, can be computed easily by solving a linear program.

The proposed algorithm is "tuned" [12] to the plant and noise *a priori* information. It is possible, as in [15], to construct an algorithm tuned to only the plant *a priori* information. Note that in the present formulation the past input has been assumed to be zero. Nevertheless, this assumption can be relaxed, and the present results can be extended to the more general setting, as evidenced by an extension in [11], which appears to be directly built on the present approach and techniques. Future extensions building on this work may also be pursued by considering mixed parametric and nonparametric identification problems [19], [18], [9]. Finally, we note the recent work in this area on input design and sample complexity in e.g., [5], [29], [16], and [1].

ACKNOWLEDGMENT

The authors would like to thank Profs. M. Milanese and J. P. Norton for calling [25] and [34] to their attention, respectively, and Profs. J. R. Partington and G. Gu for pointing out an error in an earlier draft of this paper.

Input Saturation and Global Stabilization of Nonlinear Systems via State and Output Feedback

Wei Lin

Abstract—For multi-input multi-output nonlinear systems whose free dynamics are Lyapunov stable, we show how the problem of global stabilization via dynamic output feedback can be solved by using the technique of input saturation. The power of this technique is also illustrated by solving the problem of global stabilization via bounded state feedback for affine nonlinear systems with stable unforced dynamics. Analogous results are established for discrete-time nonlinear systems.

I. INTRODUCTION

Consider multi-input multi-output (MIMO) nonlinear systems described by differential equations of the form

$$\dot{x} = Ax + \sum_{i=1}^m g_i(x)u_i \quad (1.1)$$

$$y = Cx \quad (1.2)$$

where $x \in \mathbb{R}^n$ is the state, $u_i \in \mathbb{R}$, $1 \leq i \leq m$, are the control inputs and $y \in \mathbb{R}^s$ is the system output, $A \in \mathbb{R}^{n \times n}$ and $C \in \mathbb{R}^{s \times n}$ are constant matrices, and $g_i: \mathbb{R}^n \rightarrow \mathbb{R}^n$, $1 \leq i \leq m$, are smooth functions. In this paper, we assume that the nonlinear systems under consideration, which include bilinear systems as a particular case, satisfy the following hypothesis:

H1) There exists a positive definite matrix P such that

$$A^T P + P A \leq 0.$$

In other words, the unforced dynamic system of (1.1) is assumed to be Lyapunov stable.

The purpose of this paper is to study the following two problems of global stabilization for a nonlinear system (1.1)–(1.2) with Hypothesis H1).

Problem 1: When is there a smooth state feedback or a bounded state feedback control law which renders the equilibrium $x = 0$ of system (1.1) globally asymptotically stable?

In the case where the state x is not available for measurement but only the output y is measurable, the following problem becomes more realistic and rather important.

Problem 2: When does there exist a dynamic compensator

$$\begin{aligned} \dot{\xi} &= \eta(\xi, y), \quad \eta(0, 0) = 0 \\ u &= \theta(\xi), \quad \theta(0) = 0 \end{aligned} \quad (1.3)$$

such that the closed-loop system (1.1)–(1.3) is globally asymptotically stable at the equilibrium $(x, \xi) = (0, 0)$?

In the case of single-input single-output (SISO) bilinear systems (i.e., $g(x) = Bx + N$), these two problems have been investigated by Gauthier–Kupka in [7], which improves the nonlinear separation principle initially developed by Vidyasagar [17] in the bilinear case. More specifically, Gauthier and Kupka [7] develop sufficient conditions for global stabilization of SISO bilinear systems via smooth state feedback by using the Jurdjevic–Quinn technique [8]. Based on the Jurdjevic–Quinn type feedback control law, they then present a "small stabilizing control law." This, in turn, leads to a separation principle for a class of SISO bilinear systems whose free dynamics are dissipative. The result of [7] is nice, and the proof is clever but somewhat unsatisfactory because it is only applicable to a SISO system. In addition, it requires that for $W \triangleq \{x: x^T(A^T P + P A)x = 0\} \cap \{x: x^T P(Bx + N) = 0\}$

$$\begin{aligned} \dim \operatorname{span} \{Ax, \operatorname{ad}_{Ax}^0(Bx + N), \dots, \operatorname{ad}_{Ax}^k(Bx + N), \dots\} \\ = n \quad \forall x \in W - \{0\} \end{aligned} \quad (1.4)$$

i.e., the ad-condition is satisfied on $W - \{0\}$.

Note that requirement (1.4) is too strong even for a linear system. More explicitly, it is easy to see that for the linear system [12]

$$\Sigma_L: \dot{x} = Ax + bu = \begin{bmatrix} 0 & 0 & 0 \\ 0 & -1 & 2 \\ 0 & 0 & -1 \end{bmatrix} x + \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} u$$

$$\dim \text{span}\{Ax, b, Ab, A^2b\}$$

$$= \dim \text{span}\left\{ \begin{bmatrix} 0 \\ -x_2 + 2x_3 \\ -x_3 \end{bmatrix}, \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} \right\} \leq 2.$$

Thus, ad-condition (1.4) can never be satisfied. If, however, we use Corollary A.2, which is a slight generalization of Theorem 1 given in [12], a straightforward calculation shows that for $V(x) = x_1^2 + x_2^2 + x_3^2$

$$\Omega_{\Sigma} = \{x \in \mathbb{R}^3 : x_2 = x_3 = 0\}$$

and

$$S_{\Sigma} = \{x \in \mathbb{R}^3 : x_1 = 0\}.$$

Hence, $\Omega_{\Sigma} \cap S_{\Sigma} = \{0\}$. Thus Σ_L is stabilizable by $u = -L_b V(x) = -2x_1$.

In this paper, we address Problems 1 and 2 for MIMO nonlinear control systems (1.1)–(1.2), with the property H1). In particular, a solution to these problems is proposed. The approach employed in the paper is based on Lyapunov analysis, LaSalle's invariance principle, and the center manifold theory [5], in the spirit of [7]. Our solution to Problem 2 depends heavily on the technique of input saturation, which has recently obtained a strong renewed interest in the linear control literature [13], [15]–[16]. The power of this technique is first illustrated by solving the problem of global stabilization via bounded state feedback for affine nonlinear control systems. The result incorporates and generalizes a number of well-known stabilization theorems [1], [6], [8]–[9], [12], and [14] proposed in the nonlinear control literature for global asymptotic stabilization of certain classes of affine systems. Since the material is somehow independent of the theme of this paper, we put it in Appendix A. Appendix B includes a useful boundedness criterion for perturbed systems. Section II deals with Problems 1 and 2 for MIMO continuous-time nonlinear systems of the form (1.1)–(1.2) and we show how the ad-condition can be removed. Discrete-time counterparts of systems (1.1)–(1.2) are treated in Section III. Section IV includes the concluding remarks of this paper.

The preliminary version of this work was presented at the 33rd IEEE Conference on Decision and Control [10].

II. SOLUTIONS OF GLOBAL STABILIZATION PROBLEMS

In this section, we present a solution to Problems 1 and 2 stated in the previous section. To describe our main results in this paper, we need to recall some notations related to nonlinear systems of the form (1.1).

For smooth vector fields Ax and $g_i(x)$, $1 \leq i \leq m$, on \mathbb{R}^n , $[Ax, g_i(x)]$ denotes their Lie bracket and we define inductively

$$\begin{aligned} ad_{Ax}^0 g_i(x) &= g_i(x), \dots, ad_{Ax}^{k+1} g_i(x) \\ &= [Ax, ad_{Ax}^k g_i(x)], \quad k = 0, 1, \dots \end{aligned}$$

for $i = 1, \dots, m$. If $V: \mathbb{R}^n \rightarrow \mathbb{R}$ is a C^r ($r \geq 1$) smooth function, the Lie derivative of V with respect to the vector field Ax is defined by $L_{Ax} V(x) = \frac{\partial V}{\partial x} Ax$. In a similar manner, higher order Lie derivatives can be defined inductively as follows

$$\begin{aligned} L_{Ax}^0 V(x) &= V(x), \dots, L_{Ax}^{k+1} V(x) \\ &= L_{Ax} (L_{Ax}^k V(x)) \quad 1 \leq k \leq r-1. \end{aligned}$$

With the vector fields $Ax, g_1(x), \dots, g_m(x)$ we associate the distribution

$$D = \text{span}\{ad_{Ax}^k g_i(x) : 0 \leq k \leq n-1, 1 \leq i \leq m\}. \quad (2.1)$$

Let Ω and S denote the sets associated with $V(x) \triangleq \frac{1}{2} x^T P x$, $P > 0$

$$\left. \begin{aligned} \Omega &\triangleq \{x \in \mathbb{R}^n : L_{Ax}^k V(x) = 0 = x^T P A^k x, \\ &\quad 1 \leq k \leq r\} \\ S &\triangleq \{x \in \mathbb{R}^n : L_{Ax}^k L_{\tau}(x^T P x) = 0 \\ &\quad \forall \tau \in D, 0 \leq k \leq r-1\} \end{aligned} \right\}. \quad (2.2)$$

With these notations in mind, we can easily deduce from Appendix A sufficient conditions for the solution of global stabilization via smooth state feedback or bounded state feedback for continuous-time multi-input nonlinear systems of form (1.1).

Theorem 1: Suppose a continuous-time multi-input nonlinear system (1.1) satisfies Hypothesis H1). If $\Omega \cap S = \{0\}$, then

- i) the equilibrium $x = 0$ of system (1.1) is globally asymptotically stabilized by the bounded state feedback control law

$$\begin{aligned} u_i^*(x) &= -\text{sgn}(x^T P g_i(x)) \\ &\quad \times \min(|x^T P g_i(x)|, \alpha), \quad 1 \leq i \leq m \end{aligned} \quad (2.3)$$

where α is an arbitrarily positive real number.

As an immediate consequence of (2.3),

- ii) system (1.1) is globally asymptotically stabilizable via the smooth state feedback control law

$$u = -[g_1(x), \dots, g_m(x)]^T P x \triangleq -g^T(x) P x. \quad (2.4)$$

Proof: Let $V(x) = \frac{1}{2} x^T P x$ with $P > 0$. Conclusion i) follows from Theorem A.1 proposed in the appendix; ii) is a consequence of Corollary A.2.

In the case where the state x of system (1.1) is not available for measurement, the feedback control schemes proposed in Theorem 1 cannot be applied directly, thus it is necessary and important to develop sufficient conditions for Problem 2 to be solvable. In the remainder of this section, we assume that the pair (A, C') of the input-output nonlinear system (1.1)–(2.2) is observable. Then, it can be shown that a dynamic compensator of the form (1.3), which consists of a "Luenberger-type" nonlinear observer and a bounded state feedback control strategy, solves Problem 2 for MIMO nonlinear systems (1.1)–(1.2). \square

Theorem 2: Consider continuous-time MIMO nonlinear systems of the form (1.1)–(1.2) satisfying Hypothesis H1). Suppose the pair (A, C') is observable and $\Omega \cap S = \{0\}$. Assume that the functions $g_i(x)$, $1 \leq i \leq m$, are global Lipschitz $\forall x \in \mathbb{R}^n$. Then for any sufficiently small $\alpha > 0$, a dynamic compensator

$$\left. \begin{aligned} \dot{\xi} &= A\xi + \sum_{i=1}^m g_i(\xi) u_i + K(y - C\xi) \\ u_i &= u_i^*(\xi), \quad 1 \leq i \leq m \end{aligned} \right\} \quad (2.5)$$

is such that the closed-loop system formed by (1.1), (1.2), and (2.5) is globally asymptotically stable at the equilibrium $(x, \xi) = (0, 0)$, where $u_i^*(\cdot)$ is given by (2.3) and the gain matrix K is designed in such a way that $A - KC$ is Hurwitz.

Proof: Let e denote the error signal

$$e(t) = \xi(t) - x(t).$$

Then, the closed-loop system can be represented as

$$\dot{e} = (A - KC)e + \sum_{i=1}^m (g_i(\xi) - g_i(x))u_i^\alpha(\xi) \quad (2.6)$$

$$\dot{\xi} = A\xi + \sum_{i=1}^m g_i(\xi)u_i^\alpha(\xi) - KCe. \quad (2.7)$$

Since $A - KC$ is Hurwitz, there exists a unique positive definite matrix R satisfying the Lyapunov equation

$$(A - KC)^T R + R(A - KC) = -I.$$

Thus a straightforward calculation proves that

$$\begin{aligned} \frac{d}{dt}(e^T Re) &= -e^T e + 2e^T R \sum_{i=1}^m (g_i(\xi) - g_i(x))u_i^\alpha(\xi) \\ &\leq -e^T e \left(1 - 2\alpha \|R\| \sum_{i=1}^m \beta_i\right) \end{aligned}$$

because $|u_i^\alpha(\xi)| \leq \alpha$ and $\|g_i(x) - g_i(\xi)\| \leq \beta_i \|x - \xi\|$ for $\alpha > 0$ and $\beta_i > 0$, $i = 1, \dots, m$. Choosing $\alpha \leq \frac{1}{4\|R\| \sum_{i=1}^m \beta_i}$, yields

$$\frac{d}{dt}(e^T Re) \leq -\frac{1}{2}e^T e \leq -\frac{1}{2\lambda_{\min}(R)}e^T Re.$$

This, in turn, implies

$$\begin{aligned} \lambda_{\min}(R)\|e\|^2 &\leq e^T Re \\ &\leq \exp\left(-\frac{t}{2\lambda_{\min}(R)}\right)\exp(e(0)^T Re(0)). \end{aligned}$$

Hence

$$\|e(t)\| \leq M \exp(-\beta t) \quad \text{for } M > 0 \text{ and } \beta > 0. \quad (2.8)$$

Let $d(t) = -KCe(t)$ in (2.7). Recall that by Theorem 1 system (2.7) with $d(t) = 0$ is globally asymptotically stable at $\xi = 0$. In particular, for $V(\xi) \triangleq \xi^T P\xi$ and $f(\xi) \triangleq A\xi + \sum_{i=1}^m g_i(\xi)u_i^\alpha(\xi)$

$$L_f V(\xi) = f^T(\xi)P\xi + \xi^T P f(\xi) \leq 0.$$

Moreover, it is easy to check that in this case

$$V(\xi) = \xi^T P\xi \geq \lambda_{\min}(P)\|\xi\|^2, \quad \left\|\frac{\partial V}{\partial \xi}\right\| \leq 2\|P\|\|\xi\|$$

and

$$\int_0^\infty \|d(t)\| dt \leq \int_0^\infty M\|KC\|\exp(-\beta t) dt < +\infty.$$

With this in mind, we apply Theorem B.1 given in Appendix B to system (2.7) and then conclude that $\|\xi(t)\| \leq N \forall t \geq 0$, for some $N > 0$.

So far, we have shown that every trajectory $(e(t), \xi(t))$ of the closed-loop system (2.6)–(2.7) is bounded $\forall t \geq 0$ and $(e(0), \xi(0)) \in \mathbb{R}^n \times \mathbb{R}^n$. To show $(e, \xi) = (0, 0)$ is a global asymptotically stable equilibrium of (2.6), we let $(e(t), \xi(t))$ be a trajectory of system (2.6)–(2.7) with the initial value $(e(0), \xi(0))$. Let r^0 denote its ω -limit set. Clearly, r^0 is nonempty, compact, and invariant because $(e(t), \xi(t))$ is bounded $\forall t \geq 0$. In addition, it follows from (2.8) that $\lim_{t \rightarrow \infty} e(t) = 0$. Therefore, any point in r^0 must be a pair of the form $(0, \bar{\xi}(t))$. Let $(0, \bar{\xi}) \in r^0$ and

$(0, \bar{\xi}(t))$ be the corresponding trajectory. Obviously, this trajectory is characterized by the following differential equation

$$\dot{\bar{\xi}}(t) = A\bar{\xi}(t) + \sum_{i=1}^m g_i(\bar{\xi}(t))u_i^\alpha(\bar{\xi}(t)) \quad (2.9)$$

which has been proved to be globally asymptotically stable at $\xi = 0$. In other words, the global asymptotic behavior of the closed-loop system (2.6)–(2.7) at $(e, \xi) = (0, 0)$ is completely determined by the flow on the invariant manifold governed by system (2.9) [5]. Since the latter is globally asymptotically stable, so is the closed-loop system (2.6)–(2.7).

As an immediate consequence, we have the following global separation principle for MIMO bilinear systems.

Corollary 1: Consider a continuous-time MIMO bilinear system

$$\begin{cases} \dot{x} = Ax + \sum_{i=1}^m (B_i x + N_i) u_i \\ y = Cx \end{cases} \quad (2.10)$$

Suppose Assumption H1) holds. Suppose the pair (A, C) is observable and $\Omega \cap S = \{0\}$. Then a dynamic compensator of the form (2.5) with $g_i(\xi) = B_i \xi + N_i$, $1 \leq i \leq m$, renders the closed-loop system (2.5)–(2.10) globally asymptotically stable.

III. THE DISCRETE-TIME CASE

The goal of this section is to show how discrete counterparts of the stabilization results established in Section II can be carried out for a class of MIMO discrete-time nonlinear systems of the form

$$x(k+1) = Ax(k) + \sum_{i=1}^m g_i(x(k))u_i(k) \quad (3.1)$$

$$y(k) = Cx(k) \quad (3.2)$$

whose free dynamic system $x(k+1) = Ax(k)$ is Lyapunov stable, so that there is a positive definite matrix P satisfying

$$H2) \quad A^T P A - P \leq 0.$$

Unlike the case of linear systems, the generalization from continuous time to discrete time in the nonlinear context is infamous for its bifurcation into two cases—the routine extension and the technically impossible with relatively few exceptions. This is primarily caused by a nonlinear nature. In [3], we have pointed out that one cannot transport the stabilization results via smooth state feedback for continuous-time affine systems ([1], [6], [8]–[9], [12], [14]) to the discrete-time case. The reason why this is impossible has been explained in [2]–[4] from a passive system point of view. In what follows, on the basis of our previous work [3], we construct a bounded state feedback control law by the use of a modified saturation design technique. This, in turn, leads to a global separation principle for discrete-time nonlinear systems (3.1)–(3.2).

To begin with, we introduce the sets Ω_d and S_d which correspond to the sets defined in (2.2)

$$\begin{cases} \Omega_d = \{x \in \mathbb{R}^n \mid (A^t x)^T (A^T P A - P) A^t x = 0, \\ \quad t = 0, 1, \dots\} \\ S_d = \{x \in \mathbb{R}^n \mid (A^{t+1} x)^T P g_i(A^t x) = 0, \\ \quad 1 \leq i \leq m, t = 0, 1, \dots\} \end{cases} \quad (3.3)$$

In addition, set

$$g(x) = [g_1(x), \dots, g_m(x)]. \quad (3.4)$$

We are now in the position to state and prove our main result in this section. To keep the exposition simple and highlight the central idea behind our design approach, we first study the single-input case.

Theorem 3: Consider a single-input discrete-time nonlinear system (3.1) with the property H2). Suppose $\Omega_d \cap S_d = \{0\}$. Then

- i) the equilibrium $x = 0$ of system (3.1) is globally asymptotically stabilized by the bounded state feedback control law

$$u_\alpha(x) = -\frac{\min(|g^T(x)PAx|, \alpha) \operatorname{sgn}(g^T(x)PAx)}{1 + \frac{1}{2}g^T(x)Pg(x)}, \quad (3.5)$$

for any $\alpha > 0$.

- ii) As a consequence of i), the equilibrium $x = 0$ of (3.1) is globally asymptotically stabilized by the smooth state feedback control law

$$u(x) = -\frac{g^T(x)PAx}{1 + \frac{1}{2}g^T(x)Pg(x)}. \quad (3.6)$$

Proof: Consider a proper Lyapunov function $V(x) = \frac{1}{2}x^T Px$. Then the difference of $V(x)$ along the trajectory of the closed-loop system (3.1)–(3.5) is

$$\begin{aligned} \Delta V(x(k)) &= V(x(k+1)) - V(x(k)) \\ &= \frac{1}{2}x^T(k) \left((A^T P A - P) \right) x(k) \\ &\quad + u_\alpha^T(k) g^T(x(k)) P A x(k) \\ &\quad + \frac{1}{2} u_\alpha^T(k) g^T(x(k)) P g(x(k)) u_\alpha(k). \end{aligned} \quad (3.7)$$

By Assumption H2), it is clear that

$$\begin{aligned} \Delta V(x) &\leq u_\alpha^T g^T(x) P A x \\ &\quad + u_\alpha^T \left(1 + \frac{1}{2} g^T(x) P g(x) \right) u_\alpha - u_\alpha^T u_\alpha. \end{aligned} \quad (3.8)$$

Substituting the feedback control law (3.5) into (3.8) yields

$$\begin{aligned} \Delta V(x) &\leq -u_\alpha^2 - \frac{\min(|g^T(x)PAx|, \alpha) \operatorname{sgn}(g^T(x)PAx)}{1 + \frac{1}{2}g^T(x)Pg(x)} \\ &\quad \times g^T(x)PAx + \frac{[\min(|g^T(x)PAx|, \alpha)]^2}{1 + \frac{1}{2}g^T(x)Pg(x)}. \end{aligned}$$

Note that $|x| = x \operatorname{sgn} x$. With this in mind, we deduce from the inequality above that

$$\begin{aligned} \Delta V(x) &\leq -u_\alpha^2 - \frac{\min(|g^T(x)PAx|, \alpha)}{1 + \frac{1}{2}g^T(x)Pg(x)} \\ &\quad \times \left(|g^T(x)PAx| - \min(|g^T(x)PAx|, \alpha) \right) \leq 0. \end{aligned} \quad (3.9)$$

This proves that the closed-loop system (3.1)–(3.5) is globally stable at $x = 0$. To show global asymptotic stability, we need to distinguish two cases. First, suppose $\min(|g^T(x)PAx|, \alpha) = \alpha$. Then it follows from (3.9) that

$$\Delta V(x) \leq -u_\alpha^2 = -\frac{\alpha^2}{(1 + \frac{1}{2}g^T(x)Pg(x))^2} < 0$$

which implies that the origin of the closed-loop system is globally asymptotically stable. In the case of $\min(|g^T(x)PAx|, \alpha) = |g^T(x)PAx|$, by LaSalle's theorem, all trajectories of the closed-loop system approach to the largest invariant set I contained in the zero locus of $\Delta V(x)$. From (3.7) and (3.9), we see that $\Delta V(x) = 0$ implies for all $k = 0, 1, \dots$

$$u_\alpha(k) = 0, \quad x^T(k) (A^T P A - P) x(k) = 0$$

and

$$g^T(x(k)) P A x(k) = 0.$$

This, in turn, results in $\forall x(0) = x$

$$(A^k x)^T (A^T P A - P) A^k x = 0 \quad \text{and} \quad g^T(A^k x) P A^{k+1} x = 0.$$

In view of the assumption $\Omega \cap S = \{0\}$, we conclude that $I = \{x \in \mathbb{R}^n : \Delta V(x) = 0\} = \{0\}$. This completes the proof of Theorem 3 i). Let $\alpha = +\infty$, conclusion ii) follows from i) immediately.

Similar to the continuous-time case, we can establish a global separation principle for a SISO discrete-time nonlinear system of the form (3.1)–(3.2), by using the bounded state feedback control strategy proposed in Theorem 3.

Theorem 4: Consider a discrete-time SISO nonlinear system (3.1)–(3.2) which satisfies Hypothesis H2). Suppose the pair (A, C) is observable and $\Omega_d \cap S_d = \{0\}$. Suppose the function $g(x)$ is global Lipschitz on \mathbb{R}^n . Then for any sufficiently small $\alpha > 0$, a Luenberger-observer-like based output feedback control law

$$\left. \begin{aligned} \xi(k+1) &= A\xi(k) + g(\xi(k))u_\alpha(k) + K(g(k) - C\xi(k)) \\ u_\alpha(k) &= -\frac{\min(|g^T(\xi(k))PA\xi(k)|, \alpha)}{1 + \frac{1}{2}g^T(\xi(k))Pg(\xi(k))} \\ &\quad \times \operatorname{sgn}(g^T(\xi(k))PA\xi(k)) \end{aligned} \right\} \quad (3.10)$$

renders the equilibrium $(x, \xi) = (0, 0)$ of the closed-loop system (3.1)–(3.2)–(3.10) globally asymptotically stable, where K is a constant matrix such that $A - KC$ is Hurwitz.

Proof: Let $\epsilon(k) = \xi(k) - x(k)$. Then the closed-loop system (3.1)–(3.2)–(3.10) can be expressed as

$$\left. \begin{aligned} \epsilon(k+1) &= (A - KC)\epsilon(k) + (g(\xi(k)) - g(x(k)))u_\alpha(k) \\ \xi(k+1) &= A\xi(k) + g(\xi(k))u_\alpha(k) - KC\epsilon(k) \end{aligned} \right\} \quad (3.11)$$

By assumption, there is a positive definite matrix R such that

$$(A - KC)^T R (A - KC) - R = -I$$

because $A - KC$ is Hurwitz. Let $W(\epsilon(k)) = \frac{1}{2}\epsilon^T(k)R\epsilon(k)$. Then

$$\begin{aligned} \Delta W(\epsilon(k)) &= W(\epsilon(k+1)) - W(\epsilon(k)) \\ &= -\frac{1}{2}\|\epsilon(k)\|^2 + \epsilon^T(k)(A - KC)^T \\ &\quad \times R(g(\xi(k)) - g(x(k)))u_\alpha(k) \\ &\quad + \frac{1}{2}u_\alpha^T(k)(g(\xi(k)) - g(x(k)))^T \\ &\quad \times R(g(\xi(k)) - g(x(k)))u_\alpha(k). \end{aligned}$$

From Lipschitzness of $g(\cdot)$ and $|u_\alpha(k)| \leq \alpha$, we deduce that

$$\begin{aligned} \Delta W(\epsilon(k)) &\leq -\frac{1}{2}\|\epsilon(k)\|^2 \\ &\quad \times (1 - 2\alpha N \|(A - KC)R\| - \alpha^2 N^2 \|R\|) \end{aligned}$$

where N is the Lipschitz constant associated with $g(\cdot)$. Obviously, it is possible to choose $\alpha > 0$ sufficient small so that for some $\theta, 0 < \theta < 1$

$$\begin{aligned} \Delta W(\epsilon(k)) &= \frac{1}{2}(\epsilon^T(k+1)R\epsilon(k+1) - \epsilon^T(k)R\epsilon(k)) \\ &\leq -\frac{\theta}{2}\epsilon^T(k)R\epsilon(k) \leq 0. \end{aligned}$$

This, in turn, implies

$$\begin{aligned} \epsilon^T(k)R\epsilon(k) &\leq (1 - \theta)\epsilon^T(k-1)R\epsilon(k-1) \\ &\leq \dots \leq (1 - \theta)^k \epsilon^T(0)R\epsilon(0). \end{aligned}$$

Thus

$$\|\epsilon(k)\| \leq M a^k \quad \text{for } k = 0, 1, \dots, M > 0 \text{ and } 0 < a < 1. \quad (3.12)$$

On the other hand, recall that by Theorem 3 [or inequality (3.9)], the following relationship

$$\|A\xi(k) + g(\xi(k))u_\alpha(k)\|_P^2 \leq \|\xi(k)\|_P^2, \quad k = 0, 1, \dots \quad (3.13)$$

is satisfied. Without loss of generality, Let $P = I$ in (3.13). Then, we deduce from (3.11) and (3.13) that

$$\begin{aligned} \|\xi(k+1)\| &\leq \|A\xi(k) + g(\xi(k))u_n(k)\| + \|K^*C\xi(k)\| \\ &\leq \|\xi(k)\| + M\alpha^k \|K^*C\| \leq \dots \\ &\leq \|\xi(0)\| + \frac{M\|K^*C\|}{1-\alpha}. \end{aligned} \quad (3.14)$$

From (3.12) and (3.14), we conclude that all trajectories of the closed-loop system (3.11) are bounded. Since $\lim_{k \rightarrow \infty} \epsilon(k) = 0$, the same arguments as the ones used in the proof of Theorem 2 show that every bounded trajectory of system (3.11) eventually converges to the invariant manifold characterized by the difference equation

$$\xi(k+1) = A\xi(k) + g(\xi(k))u_n(k)$$

which is globally asymptotically stable. Thus the proof is complete.

Finally, we turn our attention to the multi-input case. In this case, the input saturation technique developed in Theorem 3 cannot be applied directly to the multi-input discrete-time systems, because there exists a couple matrix $[I + \frac{1}{2}g^T(x)Pg(x)]^{-1}$ which appeared in the smooth state feedback control law. This is in sharp contrast to the case of continuous-time affine nonlinear systems (see Theorem 1). Nevertheless, using a modified state feedback control law, we can prove that it is possible to extend Theorems 3 and 4 to discrete-time MIMO nonlinear systems of the form (3.1)–(3.2).

Theorem 5: A multi-input discrete-time nonlinear system (3.1), which satisfies Hypothesis H2) and the assumption, $\Omega_s \cap S_s = \{0\}$, is always globally asymptotically stabilizable via smooth state feedback. In particular, a possible choice is

$$u = -\left[I + \frac{1}{2}g^T(x)Pg(x)\right]^{-1} g^T(x)PAx. \quad (3.15)$$

Moreover, system (3.1) can also be globally asymptotically stabilized by the bounded state feedback control law

$$\begin{aligned} u_n(x) &= -\alpha \left[I + \frac{1}{2}g^T(x)Pg(x)\right]^{-1} \\ &\quad \times \frac{g^T(x)PAx}{1 + \|g^T(x)PAx\|^2}, \text{ for any } 0 < \alpha < 1. \end{aligned} \quad (3.16)$$

Theorem 6: Under Assumptions H2) and $S \cap \Omega = \{0\}$, a discrete-time MIMO nonlinear system (3.1)–(3.2) can be globally asymptotically stabilized by the dynamic compensator

$$\begin{cases} \xi(k+1) = A\xi(k) + g(\xi(k))u(k) + K(y(k) - C\xi(k)) \\ u(k) = u_n(\xi(k)) \end{cases} \quad (3.17)$$

with any sufficient small $\alpha > 0$, provided that the pair (A, C) is observable and $g_i(x)$ is global Lipschitz for $1 \leq i \leq m$, where $u_n(\cdot)$ is given by (3.16) and K is such that $A - KC'$ is Hurwitz.

The proofs of Theorems 5 and 6 are strongly reminiscent of the proofs of Theorems 3 and 4 and therefore are left to the reader as an exercise.

Remark 1: As discussed in the last section, we note that discrete-time nonlinear systems (3.1)–(3.2) include bilinear systems as a particular case, a class of systems which has attracted considerable attention in the last two decades. Therefore, it is easy to see that all the global stabilization results developed in this section can be directly applied to discrete-time bilinear systems. Indeed, simply replacing $g_i(x)$ by $B_i x + N_i$ in Theorems 3–6 yields desired results for bilinear systems. It must be noted that Theorem 6 has provided a solution to the open problem raised in [11], namely the problem of global asymptotic stabilization via dynamic output feedback for MIMO bilinear systems.

IV. CONCLUSION

In this paper, we have presented smooth and bounded state feedback control schemes which globally asymptotically stabilize a class of continuous-time affine nonlinear systems whose free dynamics are Lyapunov stable. Based on an arbitrarily small bounded state feedback control law thus developed, we have been able to prove that a class of MIMO nonlinear systems which are "controllable" and "observable" is globally asymptotically stabilizable by a nonlinear Luenberger-observer-like based output feedback control law. The crucial point behind the development of a nonlinear enhancement of global separation principle is to use the technique of input saturation, which has attracted considerable attention in the literature recently in [13], [15], and [16]. The stabilization results established in continuous-time nonlinear systems have also been extended to their discrete-time counterparts. It must be pointed out that such generalizations are neither routine nor trivial. This certainly raises the value of Section III.

APPENDIX A

GLOBAL STABILIZATION OF AFFINE SYSTEMS BY BOUNDED STATE FEEDBACK

Consider an affine nonlinear control system

$$\Sigma: \dot{x} = f(x) + \sum_{i=1}^m g_i(x)u_i, \quad (A.1)$$

where $x \in \mathbb{R}^n$ is the state and $u_i \in \mathbb{R}$, $1 \leq i \leq m$, are control inputs, $f: \mathbb{R}^n \rightarrow \mathbb{R}^n$, and $g_i: \mathbb{R}^n \rightarrow \mathbb{R}^n$, $1 \leq i \leq m$, are smooth mappings, with $f(0) = 0$. Suppose there exists a C^1 ($\nu \geq 1$) proper and positive definite function $V: \mathbb{R}^n \rightarrow \mathbb{R}$ such that

$$H) \quad L_f V(x) \leq 0 \quad \forall x \in \mathbb{R}^n$$

i.e., the unforced dynamics of (A.1) are Lyapunov stable. Then the following global stabilization result via bounded state feedback can be established.

Theorem A.1. An affine nonlinear control system (A.1) with property H) is always globally asymptotically stabilizable via arbitrarily small bounded state feedback provided that $\Omega_s \cap S_s = \{0\}$, where Ω_s and S_s denote the sets

$$\begin{aligned} \Omega_s &\triangleq \{x \in \mathbb{R}^n : L_k^i V(x) = 0, \quad 1 \leq k \leq r\} \\ S_s &\triangleq \{x \in \mathbb{R}^n : L_\tau^k V(x) = 0, \quad \forall \tau \in D, \quad 0 \leq k \leq r-1\} \end{aligned} \quad (A.2)$$

the distribution D is defined by

$$D = \text{span}\{ad_i^k g_i : 0 \leq k \leq n-1, 1 \leq i \leq m\}. \quad (A.3)$$

In particular, a typical bounded state feedback control law is given by

$$u_i^*(x) \triangleq -\text{sgn}(L_{g_i} V(x)) \min(|L_{g_i} V(x)|, \alpha), \quad 1 \leq i \leq m \quad (A.4)$$

where α is an arbitrarily positive real number.

Proof. Substituting the bounded state feedback control law (A.4) into system (A.1) yields the closed-loop system

$$\dot{x} = f(x) - \sum_{i=1}^m g_i(x) \text{sgn}(L_{g_i} V(x)) \min(|L_{g_i} V(x)|, \alpha). \quad (A.5)$$

Clearly, the equilibrium $x = 0$ of the closed-loop system is Lyapunov stable. As a matter of fact, a routine calculation proves that

$$\begin{aligned} \dot{V}(x) &= L_f V(x) - \sum_{i=1}^m L_{g_i} V(x) \text{sgn}(L_{g_i} V(x)) \\ &\quad \times \min(|L_{g_i} V(x)|, \alpha). \end{aligned}$$

Observe that $x \operatorname{sgn}(x) \equiv |x|$. With this in mind, it follows from Assumption H) that

$$\dot{V}(x) = L_f V(x) - \sum_{i=1}^m |L_{g_i} V(x)| \min(|L_{g_i} V(x)|, \alpha) \leq 0 \quad (\text{A.6})$$

Thus the claim follows.

To show that the equilibrium $x = 0$ of (A.5) is globally asymptotically stable, we let $\dot{V}(x) = 0$. This yields

$$L_f V(x) = 0 \quad \text{and} \quad L_{g_i} V(x) = 0, \quad 1 \leq i \leq m. \quad (\text{A.7})$$

Hence $u_i^*(x) = 0$ for $1 \leq i \leq m$. Let $x(t, x_0)$ be the trajectory of the free dynamics $\dot{x} = f(x) \forall t \geq 0$ starting from $x(0) = x_0$. Let r^0 denote its ω -limit set. Since $L_f V(x) \leq 0$, r^0 is nonempty, compact and invariant. Therefore for any initial $\bar{x} \in r^0$, the corresponding trajectory $x(t, \bar{x})$ of $\dot{x} = f(x)$ stays in r^0 forever. Note that $V(x(t))$ is positive definite and nonincreasing along every trajectory of the free dynamics. Thus $\lim_{t \rightarrow \infty} V(x(t)) = \beta \geq 0$. By continuity of V , $V(\bar{x}) = \beta$ for every $\bar{x} = \lim_{j \rightarrow \infty} x(t_j, x_0)$ in r^0 . In other words, $V(x)$ is constant over r^0 . In particular, $\forall t \geq 0$

$$L_f^k V(x(t, \bar{x})) = 0 \quad \forall \bar{x} \in r^0, \quad 1 \leq k \leq r. \quad (\text{A.8})$$

On the other hand, since $L_{g_i} V(x)$ vanishes $\forall x \in \{x: \dot{V}(x) = 0\}$, so does $L_{g_i} V(\bar{x}) \forall \bar{x} \in r^0$. Thus $L_{g_i} V(x(t, \bar{x})) = 0 \forall t \geq 0, 1 \leq i \leq m$. This, together with (A.7), implies that for $\tau = [f, g_i]$

$$\begin{aligned} L_\tau V(x(t, \bar{x})) &= L_f L_{g_i} V(x(t, \bar{x})) - L_{g_i} L_f V(x(t, \bar{x})) \\ &= 0, \quad 1 \leq i \leq m. \end{aligned}$$

By induction, it is straightforward to prove that

$$L_f^k L_\tau V(x(t, \bar{x})) = 0 \quad \forall \bar{x} \in D_\Sigma \text{ and } 0 \leq k \leq r-1. \quad (\text{A.9})$$

According to the arguments above, we conclude from (A.8)–(A.9) and LaSalle's Invariant Principle that all trajectories of the closed-loop system (A.6) eventually approach the largest invariant set I of $\{x \in \mathbb{R}^n: \dot{V} = 0\}$, which is contained in $S_\Sigma \cap \Omega_\Sigma$. By assumption, $\Omega_\Sigma \cap S_\Sigma = \{0\}$. This implies $I = \{x \in \mathbb{R}^n: \dot{V} = 0\} = \{0\}$, thus completing the proof of global asymptotic stability.

Let $\alpha = +\infty$. We deduce immediately from Theorem A.1 the following result which is a slight extension of Theorem 1 proposed in [12].

Corollary A.2: An affine nonlinear system (A.1) whose free dynamics are Lyapunov stable can always be globally asymptotically stabilizable by smooth state feedback if $\Omega_\Sigma \cap S_\Sigma = \{0\}$. In particular, a smooth state feedback control law is given by

$$u = -(L_{g_m} V(x))^T = -[L_{g_1} V(x), \dots, L_{g_m} V(x)]^T. \quad (\text{A.10})$$

APPENDIX B

A BOUNDEDNESS CRITERION FOR PERTURBED SYSTEMS

Theorem B.1: Consider a perturbed system described by differential equations of the form

$$\Sigma_p: \dot{x} = f(x) + d(t). \quad (\text{B.1})$$

Suppose there exists a C^1 function $V: \mathbb{R}^n \rightarrow \mathbb{R}$, with $V(0) = 0$, such that

$$\text{A1) } V(x) \geq a_1 \|x\|^2, \quad \left\| \frac{\partial V}{\partial x} \right\| \leq a_2 \|x\| \text{ and } L_f V(x) \leq 0.$$

Assume that the disturbance $d: \mathbb{R} \rightarrow \mathbb{R}^n$ is piecewise continuous and satisfies

$$\text{A2) } \int_0^\infty \|d(t)\| dt \leq a_3 < +\infty$$

where $a_i, 1 \leq i \leq 3$, are positive real constants. Then all the trajectories of system (B.1) are bounded.

Proof: By Assumption A1)

$$\dot{V} = L_f V(x) + \frac{\partial V}{\partial x} d(t) \leq \frac{\partial V}{\partial x} d(t).$$

Hence

$$\begin{aligned} V(x(t)) &\leq V(x_0) + \int_0^t \frac{\partial V}{\partial x} d(\tau) d\tau \\ &\leq V(x_0) + \int_0^t \left\| \frac{\partial V}{\partial x} \right\| \|d(\tau)\| d\tau. \end{aligned}$$

Using Assumption A1) again, we have

$$a_1 \|x(t)\|^2 \leq V(x_0) + a_2 \int_0^t \|x(\tau)\| \|d(\tau)\| d\tau. \quad (\text{B.2})$$

Thus

$$\begin{aligned} a_1 \|x(t)\| &\leq a_1 \|x(t)\|^2 + a_1 \\ &\leq a_1 + V(x_0) + a_2 \int_0^t \|x(\tau)\| \|d(\tau)\| d\tau. \end{aligned}$$

This, in turn, implies

$$\|x(t)\| \leq \alpha_1 + \alpha_2 \int_0^t \|x(\tau)\| \|d(\tau)\| d\tau$$

for some $\alpha_i \geq 0, i = 1, 2$. From the Bellman–Gronwall inequality, we obtain the estimate

$$\|x(t)\| \leq \alpha_1 e^{\alpha_2 \int_0^t \|d(\tau)\| d\tau} \quad \forall t \geq 0. \quad (\text{B.3})$$

Because of A2), Theorem B.1 follows from (B.4).

Remark. A similar argument shows that Theorem B.1 remains true if A1) is replaced by the following assumption

$$\text{A) } V(x) \geq a_1 \|x\|^{q+1}, \quad \left\| \frac{\partial V}{\partial x} \right\| \leq a_2 \|x\|^q$$

and

$$L_f V(x) \leq 0, \text{ for any positive integer } q.$$

Optimal Control for Systems with Deterministic Production Cycles

Jian-Qiang Hu and Dong Xiang

Abstract—In this paper we consider a failure prone production system with deterministic production cycles. The objective is to find the optimal production rate to minimize long-run average cost. We first show that the optimal control policy belongs to a type of switching curve policy which has a special structural property and can be characterized by a single parameter. We then establish a relationship between the surplus process of the system under the optimal control policy and the workload process of a $D/G/1$ queue, based on which the existing results in queueing theory which can be applied to obtain the steady-state probability distribution of the surplus process under the optimal control policy.

1. INTRODUCTION

Consider a production system which has a single machine and produces a single part-type. The system meets a constant demand rate d and backlog is allowed. The machine has two states: up and down, which are denoted by one and zero, respectively. The produced parts are represented by a fluid flow. When the machine is up, it can produce at any rate between zero and a maximum value r . Denote the production surplus at time t by X_t ; a positive value of X_t represents inventory while a negative value represents backlog. Let $\alpha_t \in \{0, 1\}$ be the state of the machine at time t and u_t be the controlled production rate of the machine at time t under a control policy π . X_t can then be characterized by the following differential

equation

$$\frac{dX_t}{dt} = u_t - d \quad (1)$$

where $0 \leq u_t \leq \alpha_t r$. For each control policy π , we use J_π to denote its long-run average expected cost

$$J_\pi = \lim_{T \rightarrow \infty} \frac{1}{T} E \int_0^T (C^+ X_t^+ + C^- X_t^-) dt \quad (2)$$

where $X_t^+ = \max(X_t, 0)$, $X_t^- = \max(-X_t, 0)$ and C^+ , C^- are two nonnegative constants. The goal is to find a control policy π^* to minimize J_{π^*} .

A few variations of the above problem (e.g., systems with multiple machines and/or multiple part types) have been studied by many researchers (see [1], [2] and references therein). The key assumption used in almost all previous work, with a few exceptions [3]–[9], is that the machine state process $\{\alpha_t\}$ is a Markov process, i.e., the machine up and down times are exponentially distributed. Under such an assumption, the system can be modeled as a system with jump Markov disturbances based on Rishel's formulation ([3]), and it can be shown [10] that the optimal control is a hedging point policy. The Markov assumption, however, is not very realistic in many applications. So far, only limited work has been done for general systems.

In this paper we consider the one machine and one part-type system in which the machine has deterministic up time and general down time. A production system with deterministic up time, which is similar to ours, is also studied by Meyer *et al.* [11]. The system we consider here can be ideally used to model production systems in which production is only interrupted after (approximately) a fixed amount of time since it starts. For example, consider a production system in which preventive maintenance is performed after the system is in operation for a fixed amount of time. If the system rarely fails due to its scheduled preventive maintenance, then its up time is approximately deterministic. Another example is an inventory system which replenishes its inventory continuously (with no interruption) but only receives demands (orders) periodically. In such a system each period corresponds to one up time and an order (a random variable) received at the end of each period corresponds to total demands accumulated during one down time. It is also worth pointing out that the periodic review system with limited capacity studied in inventory theory ([12]) is very similar to our system and their relationship is investigated in a recent paper by Fu and Hu [14]. As we shall see, the well-known hedging point policy is no longer optimal for our system. Our analysis shows, however, that its optimal control policy belongs to a class of so-called switching curve policies whose switching curves have a very simple structure and can be characterized by a single parameter. Furthermore, we show that the surplus process of the system operated under a switching curve policy is related to the workload process of a $D/G/1$ queue, a result similar to the one established in [15] for the one machine and one part-type system under a hedging point policy (also see [16]–[19] for similar results on the relationship of fluid models to the workload process of queueing systems). This enables us to use the existing results in queueing theory to obtain the steady-state distribution function of the surplus process for the class of parameterized switching curve policies to which the optimal control belongs.

If $\{X_t; t \geq 0\}$ has steady-state probability distribution function $F(x)$ under a control policy π , then the average expected cost J_π

IEEE Log Number 9408787.

can be computed as the expected cost with respect to $F(x)$, i.e.,

$$J_\pi = \int_{-\infty}^{\infty} (C^+ x^+ + C^- x^-) dF(x). \quad (3)$$

Therefore, with the steady-state probability we obtained we can finally convert the original optimal control problem into an optimization problem with a single parameter, which is much simpler and easier to solve.

The rest of this paper is organized as follows. In Section II, we first establish a structural property for the optimal control. Then, we discuss the switching curve policies and show that the optimal switching curve can be characterized by a single parameter. In Section III, we show how the surplus process of the system under a switching curve policy is related to the workload process of a $D/G/1$ queue. This relationship is used in Section IV to obtain the steady-state probability distribution of the surplus process for the system under the class of switching curve policies to which the optimal switching curve policy belongs. A simple example with exponential machine down times is provided in Section V.

II. THE OPTIMAL CONTROL POLICY

In this section, we first establish a structural property for the optimal control based on sample path analysis. Then we discuss a class of so-called switching curve policies. Using the structural property established, we can show that when restricting ourselves to the switching curve policies, the switching curve for the optimal control belongs to a class of switching curves which can be characterized by a single parameter.

Intuitively, the structural property of the optimal control we are about to establish can be interpreted as follows: to minimize the surplus cost, one needs to maintain a nonnegative surplus at the end of each machine up period to anticipate future capacity shortages brought by machine failures while keeping the surplus level close to zero as much as possible. Most of our derivations are quite straightforward. We hope that the accompanying figures greatly aid in the understanding of the derivations.

Suppose π^* is the optimal control policy. Given the machine state process $\{\alpha_t\}$, let $\{u_t^*\}$ be the optimal control process generated under the optimal control policy π^* , and $\{X_t^*\}$ be the corresponding surplus process determined by (1) with u_t being replaced by u_t^* .

Lemma 1: There exists an optimal control $\{u_t^*\}$ that satisfies the following condition

$$u_t^* \begin{cases} = r & \text{if } X_t^* < 0, \alpha_t = 1; \\ \geq d & \text{if } X_t^* = 0, \alpha_t = 1. \end{cases} \quad (4)$$

Condition (4) can be explained as follows: When the surplus is negative the production rate should be set at the maximum rate r so that the surplus can be brought back to zero level as quickly as possible; when the surplus is at zero level we should keep it at a nonnegative level as long as we can. In other words, we should always prevent the surplus from being negative. Based on Lemma 1, we shall henceforth assume the optimal control we consider satisfies (4).

Proof: If $\{u_t^*\}$ does not satisfy (4), we can construct another optimal control based on $\{u_t^*\}$ which satisfies (4). Suppose $\alpha_{t_0} = 1$. Let us first consider the case $X_{t_0}^* < 0$. We denote the first hitting time to 0 from $X_{t_0}^*$ by

$$t_0^b = \inf\{t: X_t^* = 0, t > t_0\}.$$

By definition, we have $X_t^* < 0$ for $t \in [t_0, t_0^b)$. We construct

$$u_t = \begin{cases} r\alpha_t, & \text{if } t \in [t_0, t_0^b) \text{ and } X_t < 0; \\ d\alpha_t, & \text{if } t \in [t_0, t_0^b) \text{ and } X_t = 0; \\ u_t^*, & \text{otherwise} \end{cases} \quad (5)$$

Fig. 1. Comparison between X_t^* and X_t during $[t_0, t_0^b]$ for the case $X_{t_0}^* < 0$.

where $\{X_t\}$ is the surplus process associated with $\{u_t\}$. Under the control $\{u_t\}$, the machine produces at the maximum rate r (if possible) until the surplus level reaches zero and then remains at zero (if possible) until t_0^b . Therefore, we have $u_{t_0} = r$ (in fact, $\{u_t\}$ satisfies (4) at least during the time interval $[t_0, t_0^b]$) and

$$X_t \begin{cases} \geq X_t^*, & \text{if } t \in [t_0, t_0^b]; \\ = X_t^*, & \text{otherwise} \end{cases}$$

(see Fig. 1), from which we immediately obtain

$$\begin{aligned} & \int_0^T (C^+ X_t^+ + C^- X_t^-) dt \\ & \leq \int_0^T (C^+ (X_t^*)^+ + C^- (X_t^*)^-) dt \quad \text{for any } T \geq 0. \end{aligned} \quad (6)$$

That is to say $\{u_t\}$ is also an optimal control process.

For the case $X_{t_0}^* = 0$, we define

$$t_0^b = \inf\{t: X_t^* > 0, t > t_0\}.$$

If $t_0^b = t_0$, we then have $dX_t^*/dt \geq 0$, which implies $u_t^* \geq d$. If $t_0^b > t_0$, we have $X_t^* \leq 0$ for $t \in (t_0, t_0^b)$, in which case we construct $\{u_t\}$ based on (5) with t_0^b being replaced by t_0^b . The rest of the proof remains the same. \square

Lemma 2: There always exists an optimal control $\{u_t^*\}$ such that it only takes three values 0, d , and r , and its value increases with respect to the age of the machine up time when the surplus level becomes nonnegative.

Proof: Denote the (deterministic) machine up time by D . We consider a time interval $[t_1, t_2]$ during which the machine is up, where t_1 is the epoch at which the machine up period is initiated and $t_2 = t_1 + D$ (i.e., t_2 is the time epoch at which the machine up period ends). Unless otherwise stated, in what follows we shall focus on the interval $[t_1, t_2]$. Since $\{u_t^*\}$ satisfies (4), it is not difficult for us to verify that

- i) If $X_{t_1}^* < 0$, then $X_{t_2}^* \geq X_{t_1}^*$;
- ii) If $X_t^* \geq 0$ for some $t \in [t_1, t_2]$, then $X^*(\tau) \geq 0$ for all $\tau \in [t, t_2]$.

Therefore, we have the following three cases:

- 1) $X_{t_1}^* < 0$ and $X_{t_2}^* < 0$. In this case $X_t^* < 0$ for all $t \in [t_1, t_2]$, which implies $u_t^* = r$ for all $t \in [t_1, t_2]$.
- 2) $X_{t_1}^* < 0$ and $X_{t_2}^* \geq 0$. Let t_1^b be the first hitting time to zero from $X_{t_1}^*$. It immediately follows that $u_t^* = r$ for $t \in [t_1, t_1^b)$ since $X_t^* < 0$ for $t \in [t_1, t_1^b)$. Also it is clear that $X_t^* \geq 0$ for $t \in [t_1^b, t_2]$. We now construct another control $\{u_t\}$ based on $\{u_t^*\}$ as follows

$$u_t = \begin{cases} d, & \text{if } t \in [t_1^b, t_2 - X_{t_2}^*/(r-d)); \\ r, & \text{if } t \in [t_2 - X_{t_2}^*/(r-d), t_2]; \\ u_t^*, & \text{otherwise.} \end{cases}$$

We can easily verify that the surplus process $\{X_t\}$ associated with the control $\{u_t\}$ satisfies

$$X_t \begin{cases} \leq X_t^*, & \text{if } t \in [t_2 - X_{t_2}^*/(r-d), t_2]; \\ = X_t^*, & \text{otherwise} \end{cases}$$

Fig. 2. Comparison between X_t^* and X_t during $[t_1, t_2]$ for Case 2.Fig. 3. Comparison between X_t^* and X_t during $[t_1, t_2]$ for Case 3.1.Fig. 4. Comparison between X_t^* and X_t during $[t_1, t_2]$ for Case 3.2.

(see Fig. 2), which immediately leads to (6). Hence, $\{u_t\}$ is also an optimal control.

- 3) $X_{t_1}^* \geq 0$ and $X_{t_2}^* \geq 0$. In this case we have $X_t \geq 0$ for all $t \in [t_1, t_2]$. There are two subcases to consider:

- 3.1). $X_{t_2}^*/(r-d) + X_{t_1}^*/d \geq D$. We construct the following control $\{u_t\}$ based on $\{u_t^*\}$

$$u_t = \begin{cases} 0, & \text{if } t \in [t_1, t_1 + t_m]; \\ r, & \text{if } t \in [t_1 + t_m, t_2]; \\ u_t^*, & \text{otherwise} \end{cases}$$

where $t_m = (X_{t_1}^* + (r-d)D - X_{t_2}^*)/r$. Similar to Case 2 we can then show that the surplus process $\{X_t\}$ associated with the control $\{u_t\}$ satisfies

$$X_t \begin{cases} \leq X_t^*, & \text{if } t \in [t_1, t_2]; \\ = X_t^*, & \text{otherwise} \end{cases}$$

(see Fig. 3), from which (6) follows immediately. Therefore, $\{u_t\}$ is also an optimal control.

- 3.2). $X_{t_2}^*/(r-d) + X_{t_1}^*/d < D$. If we construct the following control $\{u_t\}$

$$u_t = \begin{cases} 0, & \text{if } t \in [t_1, t_1 + X_{t_1}^*/d]; \\ d, & \text{if } t \in [t_1 + X_{t_1}^*/d, t_2 - X_{t_2}^*/(r-d)]; \\ r, & \text{if } t \in [t_2 - X_{t_2}^*/(r-d), t_2]; \\ u_t^*, & \text{otherwise} \end{cases}$$

then the same result as that of Case 3.1 can be obtained (see Fig. 4). \square

We now consider a class of so-called switching curve policies.

Definition 1: A switching curve policy π is defined by

$$u_t = \pi(x_t, a_t) = \begin{cases} r\alpha_t & \text{if } x_t < S(a_t); \\ (d + S'(a)|_{a=a_t})\alpha_t & \text{if } x_t = S(a_t); \\ 0 & \text{if } x_t > S(a_t) \end{cases}$$

where $S: [0, D] \rightarrow \mathbb{R}$ is piecewise differentiable and its derivative $S'(a)$ (whenever it exists) satisfies $-d \leq S'(a) \leq r-d$. We call $S(\cdot)$ the switching curve.

The following result follows immediately from the proof of Lemma 2.

Lemma 3: The optimal switching curve is given by

$$S(a) = \begin{cases} 0 & \text{if } 0 \leq a \leq D - z/(r-d), \\ z - (D-a)(r-d) & \text{if } D - z/(r-d) < a \leq D. \end{cases} \quad (7)$$

In (7) z is the inventory level at which the surplus needs to be maintained at the end of the machine up period to hedge against future capacity shortages brought by machine failures. Therefore, it plays a similar role as the hedging point in a hedging point policy. There is a significant difference, however, between the hedging point policy and the control policy defined by (7). Under the hedging point policy, the machine produces at its maximum rate until the surplus reaches the hedging level (i.e., the surplus is brought to the hedging level as fast as it could be). Under (7) one only has to make sure that the surplus is brought to the level z at the end of each machine up period and before that the surplus level should be kept as close as to zero (therefore minimizing the surplus cost). Obviously, this is because the machine up time is now deterministic, and we know exactly when the machine will fail so that the machine only needs to produce parts at its maximum rate toward the end of each machine up period to guarantee that the surplus level will eventually reach the level z before the machine fails.

In the remainder of this paper, we restrict ourselves to the switching curve policies. We shall show how to obtain the steady-state probability distribution of the surplus process for the system operated under the switching curve policy (7).

III. QUEUEING EQUIVALENCE

In this section we study the surplus process of the system under a switching curve policy. We shall show that the surplus levels at instances when the machine is up and down are "equivalent" to the system and waiting times of jobs of a $D/G/1$ queue, a result which is similar to the one established in Hu and Xiang [15] for the one machine and one part-type system under the hedging point policy. This queueing equivalent result enables us to use the existing results for single-server queues to obtain the steady-state probability distribution for the surpluses at these instances, based on which we can then derive the steady-state probability distribution of the surplus process for the system under the switching curve policy (7) using the level crossing technique.

Denote $S(D)$ by z . For the sake of convenience, we assume $X_0 = z$ and $a_0 = D$ (i.e., $\alpha_{0-} = 1$ and $\alpha_{0+} = 0$). Denote by $t_{d,n}$ the length of the n th down time and by $t_{u,n}$ the length of the n th up time. Therefore, $t_{d,n}$'s are i.i.d. random variables, say, with probability distribution function $G(x)$ and density function $g(x)$, and $t_{u,n}$'s are equal to D . Let $T_{d,n}$ be the epoch at which the n th machine down time starts and $T_{u,n}$ be the epoch at which the n th machine up time starts, i.e.,

$$T_{d,n} = \sum_{i=1}^{n-1} (t_{d,i} + t_{u,i}) \quad \text{and} \quad T_{u,n} = T_{d,n} + t_{d,n}. \quad (8)$$

For simplicity, we denote

$$X_{d,n} \triangleq X_{T_{d,n}} \quad \text{and} \quad X_{u,n} \triangleq X_{T_{u,n}}.$$

Let $Y_{d,n} = z - X_{d,n}$ and $Y_{u,n} = z - X_{u,n}$. Then applying the same method used in [15], we can show that $Y_{d,n}$ and $Y_{u,n}$ correspond to the waiting time and the system time of job n in a $GI/G/1$

queue with service times $\{t_{d,n}d: n = 1, 2, \dots\}$ and interarrival times $\{t_{u,n}(r-d): n = 1, 2, \dots\}$. Since $t_{u,n}(r-d)$ is equal to a constant $D(r-d)$, the $GI/G/1$ queue is in fact a $D/G/1$ queue. Therefore, we can apply various methods developed for single server queues in the literature to obtain the steady-state probability distribution functions of $Y_{d,n}$ and $Y_{u,n}$ (hence $X_{d,n}$ and $X_{u,n}$) (e.g., see [20]). In the following sections, we shall simply assume that the steady-state probability distributions of $X_{d,n}$ and $X_{u,n}$ are available.

IV. DISTRIBUTION FUNCTION

In this section, we consider the switching curve policy (7). We use the level crossing technique to derive the steady-state distribution function of the surplus process under (7). We should point out, however, that the technique can also be used to obtain the steady-state distribution function of the surplus process under a general switching curve policy though the derivation becomes a bit more involved.

Denote the steady-state distribution function of $X_{u,n}$ by $F_{X_{u,n}}(x)$, and its density function by $f_{X_{u,n}}(x)$. Define

$D_t(x)$ = the number of x downcrossings of the process $\{X_t\}$ during $[0, t]$;

$U_t(x)$ = the number of x -upcrossings of the process $\{X_t\}$ during $[0, t]$.

Notice that the accumulated time that the process $\{X_t\}$ takes value between $[x, x + \delta x]$ during $[0, t]$ is equal to

$$\frac{U_t(x)\delta x}{t-d} + \frac{D_t(x)\delta x}{d}.$$

Therefore, the steady-state probability density function of $\{X_t\}$ is given by

$$f_X(x) = \lim_{t \rightarrow \infty} \frac{1}{t} \left(U_t(x) + \frac{D_t(x)}{d} \right) \quad \text{for } x \leq z \text{ and } x \neq 0. \quad (9)$$

(The interested reader is referred to [16] for a rigorous derivation of (13).) Note that

$$\lim_{t \rightarrow \infty} \frac{U_t(x)}{t} = \lim_{t \rightarrow \infty} \frac{D_t(x)}{t}$$

it then follows from (13) that

$$\begin{aligned} f_X(x) &= \frac{r}{d(r-d)} \lim_{t \rightarrow \infty} \frac{U_t(x)}{t} \\ &= \frac{r}{d(r-d)} \lim_{n \rightarrow \infty} \frac{U_{t_{u,n+1}}(x)}{T_{u,n+1}} \quad \text{for } x \leq z \text{ and } x \neq 0. \end{aligned} \quad (10)$$

(Recall $T_{u,n+1}$ is the epoch at which the $(n+1)$ th machine up time initiated.) To calculate $\lim_{n \rightarrow \infty} U_{t_{u,n+1}}(x)/T_{u,n+1}$, we consider an down and up cycle $[T_{u,n}, T_{u,n+1}]$. First, it is obvious that the process $\{X_t\}$ can have at most one x -upcrossing during $[T_{u,n}, T_{u,n+1}]$ (in fact during $[T_{u,n}, T_{d,n+1}]$). Define

$$c(x) = \begin{cases} D - \frac{x}{r-d}, & \text{if } x > 0, \\ 0, & \text{if } x \leq 0. \end{cases}$$

(See Fig. 5.) Then $\{X_t\}$ has one x -upcrossing during $[T_{u,n}, T_{d,n+1}]$ if and only if $x - (r-d)D < X_{u,n} \leq x + dc(x)$. Therefore

$$U_{t_{u,n+1}}(x) = \sum_{i=1}^n \mathbf{1}(x - (r-d)D < X_{u,i} \leq x + dc(x)).$$

It follows that

$$f_X(x) = \frac{r}{d(r-d)} \lim_{n \rightarrow \infty} \frac{n}{T_{u,n+1}} \frac{1}{n}$$

Fig. 5. Definition of $c(x)$.

$$\begin{aligned} & \times \sum_{i=1}^n \mathbf{1}(x - (r-d)D < X_{u,i} \leq x + dc(x)) \\ & = b[F_{X_{u,n}}(x + dc(x)) - F_{X_{u,n}}(x - (r-d)D)] \\ & \quad \text{for } x \leq z \text{ and } x \neq 0 \end{aligned} \quad (11)$$

where $b = r/((D+R)d(r-d))$ and R is the average machine down time. Taking the normalization factor into consideration, we have

$$F_X(0) = 1 - \int_{-\infty}^z f_X(x) dx. \quad (12)$$

Let J be the run-long average expected cost associated with the switching curve policy [7], then

$$J = \int_{-\infty}^z (C^+ x^+ + C^- x^-) f_X(x) dx.$$

Therefore, the optimal switching curve (i.e., the optimal value of z) can be obtained by solving the following optimization problem: $\min J$.

V. AN EXAMPLE

In this section, we study a simple example in which the machine down time is exponentially distributed with mean R and rate $\mu (= 1/R)$. We will use the results obtained in the previous section to calculate $f_X(x)$ and J . Since now the down time is exponentially distributed, the corresponding $D/G/1$ queue becomes a $D/M/1$ with the mean interarrival time $(r-d)D$ and the mean service time Rd . Hence we have ([20])

$$F_{X_{u,n}}(x) = e^{-(1-\sigma)(-x)\mu/d} \quad \text{for } x \leq z$$

where σ is the unique solution to the following equation in the range $0 \leq \sigma < 1$

$$\sigma = e^{-(1-d)D(1-\sigma)\mu/d}.$$

Based on [15] we obtain

$$\begin{aligned} f_X(x) &= b(e^{-(1-\sigma)\mu(-x+(r-d)D)/d} \\ & \quad - e^{-(1-\sigma)\mu(-x+(r-d)D)/d}) \\ & \quad \text{for } x \leq z \text{ and } x \neq 0. \end{aligned} \quad (13)$$

When $z < d(r-d)D/r$, (13) gives

$$\begin{aligned} f_X(x) &= \\ & \begin{cases} b(1 - e^{-(1-\sigma)\mu(-x+(r-d)D)/d}) & \text{if } 0 < x \leq z, \\ b e^{-(1-\sigma)\mu(-x)/d} (1 - e^{-(1-\sigma)\mu(r-d)D/d}) & \text{if } x < 0 \end{cases} \end{aligned}$$

and

$$J_s = \frac{C^+ b \omega^2}{2} - C^+ b e^{-\mu(1-\sigma)(1-d)D/r} \left[\frac{d}{\mu(1-\sigma)} - \frac{d^2}{\mu^2(1-\sigma)^2} + \frac{d^2}{\mu^2(1-\sigma)^2} e^{-\mu(1-\sigma)/r} \right] + \frac{C^+ b d^2}{\mu^2(1-\sigma)^2} e^{-\mu(1-\sigma)/r} (1 - e^{-\mu(1-\sigma)(1-d)D/r})$$

When $\omega \geq d(1-d)D/r$, (13) gives

$$f_s(x) = \begin{cases} b(1 - e^{-(1-\sigma)\mu(x + (1-d)D/r)}) & \text{if } x - d(1-d)D/r < x < \omega, \\ b(e^{-(1-\sigma)\mu(x - (1-d)D/r)} - e^{-(1-\sigma)\mu(\omega - (1-d)D/r)}) & \text{if } 0 < x \leq -d(1-d)D/r, \\ b e^{-(1-\sigma)\mu(x)/r} (1 - e^{-(1-\sigma)\mu(\omega - (1-d)D/r)}) & \text{if } x < 0 \end{cases}$$

and

$$J = \frac{bC^+ d}{\mu(1-\sigma)} \times \left(\frac{1-d}{r} (D(1-\sigma)\mu + 1) - e^{-\mu(1-\sigma)(1-d)D/r} \right) + \frac{bC^+ d^2}{\mu^2(1-\sigma)^2} (1 - e^{-\mu(1-\sigma)/r}) e^{-(1-\sigma)\mu(\omega - (1-d)D/r)} + \frac{bC^+ d^2}{\mu^2(1-\sigma)^2} e^{-\mu(1-\sigma)/r} (1 - e^{-(1-\sigma)\mu(\omega - (1-d)D/r)}) - \frac{bC^+ d^2(1-d)^2 D}{2r^2} \left(\frac{2}{(1-\sigma)\mu} + D \right) + \frac{bC^+ d^2(1-d)^2}{\mu^2(1-\sigma)^2 r^2} \left(e^{-(1-\sigma)\mu(\omega - (1-d)D/r)} - 1 \right)$$

Book Reviews

In this section, the IEEE Control Systems Society publishes reviews of books in the control field and related areas. Readers are invited to send comments on these reviews for possible publication in the Technical Notes and Correspondence section of this TRANSACTIONS. The CSS does not necessarily endorse the opinions of the reviewers.

If you have used an interesting book for a course or as a personal reference, we encourage you to share your insights with our readers by writing a review for possible publication in the TRANSACTIONS. All material published in the TRANSACTIONS is reviewed prior to publication. Submit a completed review or a proposal for a review to:

Analysis and Control of Nonlinear Infinite Dimensional Systems
— V. Barbu. (San Diego, CA: Academic Press, 1993). Reviewed by
H. O. Fattorini.

I. DIFFERENTIAL EQUATIONS IN LINEAR SPACES

Let Ω be a domain with boundary Γ in m -dimensional Euclidean space \mathbb{R}^m . An initial or initial-boundary value problem such as

$$u_t(t, x) = \Delta u(t, x), \quad u(0, x) = u_0(x) \quad (x \in \Omega) \quad (1)$$

$$u(x, t) = 0 \quad (x \in \Gamma) \quad (2)$$

($x = (x_1, x_2, \dots, x_m)$, Δ the Laplacian in the space variables) can be studied in the form of an "ordinary differential" evolution equation

$$u'(t) = Au(t), \quad u(0) = u_0 \quad (3)$$

in a suitable function space E ; $u(t)$ takes values in E and $A = \Delta$, the boundary conditions included in the definition of the domain $D(A)$ of A or of the space E . For instance, we may take $E = L^2(\Omega)$, $D(A)$ consisting of all $u \in L^2(\Omega)$ such that $\Delta u \in L^2(\Omega)$ (in the sense of distributions) and $u = 0$ on Γ . Alternately, we may set $E = C_0(\bar{\Omega})$ (the space of all continuous functions on the closure $\bar{\Omega}$ that vanish at the boundary Γ); in this case, the boundary condition (2) is included in the definition of the space rather than that of $D(A)$.

The formal similarity of (3) with a linear, constant coefficient system of ordinary differential equations gives insight into the original problem (1)–(2); for instance, we may expect to be able to write the solution in the form $u(t) = S(t) = \exp(tA)u_0$, which is true if the exponential is correctly interpreted. This approach to evolution problems for partial differential equations was initiated by Hille [9] and Yosida [20] under the semigroup theory point of view of studying the exponential operator equation $S(s+t) = S(s)S(t)$, $S(0) = I$; their main result, the Hille–Yosida theorem, characterizes the infinitesimal generator $A = \lim_{h \rightarrow 0} h^{-1}(S(h) - I)$ of $S(t)$ in terms of the resolvent operator $(\lambda I - A)^{-1}$. Equivalently, it characterizes the operators A (not necessarily bounded or everywhere defined) such that the initial value problem (3) is well posed; this means solutions exist for a dense set of initial data and depend

continuously on these initial data. (The Hille–Yosida theorem was given full generality by R. S. Phillips, I. Miyadera, and W. Feller). Among the many subsequent highlights of the linear theory, we mention the introduction of dissipative operators in Hilbert space [19] (corresponding to an important particular case of the Hille–Yosida Theorem) and their Banach space extension in [16].

Semigroup theory was extended to nonlinear operators by Komura in [11] in Hilbert spaces, soon after by Kato [10] in certain "smooth" Banach spaces, and finally by Crandall and Liggett [5] in arbitrary Banach spaces (see [17] for more information). A class of equations (2) lying between the linear and the fully nonlinear is that of semilinear and quasilinear equations; these can be treated by a combination of linear semigroup methods combined with results on integral equations and fixed point theory. See [8] and [18] for more information on these equations and on linear semigroup theory.

The author of the present book has contributed many important results on nonlinear semigroup theory as well as the first textbook in this area [1] (the Romanian version appeared in 1974). Part of this work can be considered as an update of [1]. It includes a short review of linear semigroup theory, the key results of nonlinear semigroup theory, and numerous applications to partial differential equations.

II. INFINITE DIMENSIONAL OPTIMAL CONTROL THEORY

Finite dimensional control theory deals with systems described by ordinary differential equations; infinite dimensional control theory studies systems described by partial differential equations (and also by functional differential equations). Control theory of partial differential equations began to be practiced by engineers in the fifties, and was raised to a higher mathematical level in the Soviet Union by Butkovskii and others during the sixties [3]. Using a more abstract approach, [15] brought to bear on control theory the extensive theory of boundary value problems developed in the previous decade by Magenes and the author. At about the same time, [6], [7] a different approach to evolution control problems was initiated, based on the Banach space version (3) of the equations. Since then, mathematical optimal control theory of partial differential equations has developed along these two lines, sometimes combining both approaches. There are problems (such as those described by elliptic equations or elliptic variational inequalities) where the evolution approach (3) is not germane; however, many other tools of functional analysis apply.

IEEE Log Number 9408268.

For several years the emphasis was on obtaining versions of Pontryagin's maximum principle for optimal control problems of all types. Recently, much work has been done on the dynamic programming approach to control of partial differential equations which extends the finite dimensional theory in [2]. Potentially the most promising approach (it provides closed-loop feedback solutions), it was partly heuristic even in finite dimensions. New developments in nonlinear analysis such as viscosity solutions of nonsmooth nonlinear partial differential equations have plugged many of the mathematical gaps and put the theory on a firmer footing, although much remains to be done.

The present book comprises both control of steady state and evolution systems. Among the first are optimal control of elliptic equations and variational inequalities, including the Signorini problem, the obstacle problem and free boundary problems. Treatment of evolution problems includes both results of maximum principle type and the dynamic programming approach.

We mention in passing that the 'engineering' control theory of partial differential equations has gone its own way although often intersecting with the mathematical theory, it usually approaches problems by discretization and application of finite dimensional theory, sometimes leaving aside rigorous proofs. On this it must be said, however that mathematics lags behind the applications in this area as in others. There are works such as [4] that straddle both fields: they adopt in some ways the engineering point of view but provide mathematical rigor as well.

III. CONCLUSIONS

Infinite dimensional optimal control theory within acceptable mathematical standards requires a considerable overhead. Without counting measure theory, a great deal of partial differential equations and functional analysis must be absorbed before one can face even the simplest problems. The same can be said of the abstract theory of evolution equations. This book provides a clear example filled with exploration into the two subjects written by a main protagonist in the latest developments. The work can be used as both a textbook in infinite dimensional control theory or in a modern course in partial differential equations presenting much of the recent research into such subjects as the dynamic programming approach. We believe its main audience will consist of mathematicians but there are in many advanced graduate students in engineering that could profit from it. It is a welcome contribution in a field not very well represented. There are other works on the market mostly in such other subjects

as stabilization by feedback [4], [13], the linear-quadratic problem [14], or controllability [12]. This book is a welcome and timely addition to the literature.
